Trauma to the thorax or upper abdomen can restrict chest expansion because of pain. Trauma to the chest also can cause structural and mechanical changes that impair the ability of the chest to expand normally. **Flail chest** results from the fracture of several consecutive ribs in more than one place, or the fracture of the sternum and several consecutive ribs. These multiple fractures result in instability of a portion of the chest wall, causing paradoxical movement of the chest with breathing. During the negative intrathoracic pressure of inspiration, the unstable portion of the chest wall moves inward and during expiration it moves outward, impairing movement of gas in and out of the lungs (Figure 35-3). Flail chest is usually associated with significant underlying lung contusion. The clinical manifestations of flail chest are pain, dyspnea, unequal chest expansion, hypoventilation, and hypoxemia. Treatment is internal fixation by controlled mechanical ventilation until the chest wall has stabilized.

Chest wall restriction results in decreased tidal volume. An increase in respiratory rate can temporarily compensate and

restore minute ventilation, but many individuals will eventually progress to hypercapnic respiratory failure. Diagnosis of chest restriction is made by pulmonary function testing (reduction in forced vital capacity [FVC]), arterial blood gas measurement (hypercapnia), and radiographs. Treatment is aimed at any reversible underlying cause, but is otherwise supportive. In severe cases, mechanical ventilation may be indicated.

Pleural Abnormalities

Pneumothorax

Pneumothorax is the presence of air or gas in the pleural space caused by a rupture in the visceral pleura (which surrounds the lungs) or the parietal pleura and chest wall (see Chapter 34). As air separates the visceral and parietal pleurae, it destroys the negative pressure of the pleural space. This disrupts the state of equilibrium that normally exists between elastic recoil forces of the lung and chest wall. No longer held in check by the recoil forces of the chest wall, the lung fulfills its tendency to recoil by collapsing toward the hilum.

Primary (spontaneous) pneumothorax, which occurs unexpectedly in healthy individuals (usually men) between ages 20 and 40 years, is most often caused by the spontaneous rupture of blebs (blister-like formations) on the visceral pleura, although there may be underlying pleural disease with emphysema-like changes.[16] Approximately 10% of affected individuals have a significant family history of primary pneumothorax that has been linked to mutations in the folliculin gene (Birt-Hogg-Dubé-syndrome), which influences cell–cell adhesion.[17] Bleb rupture can occur during sleep, rest, or exercise. The ruptured bleb or blebs are usually located in the apexes of the lungs. **Secondary (traumatic) pneumothorax** can be caused by chest trauma, such as a rib fracture, stab or bullet wounds, or a surgical procedure that tears the pleura; rupture of a bleb or bulla (larger vesicle) as occurs in COPD; or mechanical ventilation, particularly if it includes positive end-expiratory pressure (PEEP).[18] **Iatrogenic pneumothorax** is most commonly caused by transthoracic needle aspiration.[19]

Spontaneous and traumatic pneumothorax can present as either open or tension. In **open pneumothorax (communicating pneumothorax),** air pressure in the pleural space equals barometric pressure because air that is drawn into the pleural space during inspiration (through the damaged chest wall and parietal pleura or through the lungs and damaged visceral pleura) is forced back out during expiration. In **tension pneumothorax,** however, the site of pleural rupture acts as a one-way valve, permitting air to enter on inspiration, but preventing its escape by closing during expiration. As more and more air enters the pleural space, air pressure in the pneumothorax begins to exceed barometric pressure. The pathophysiologic effects of tension pneumothorax are life threatening. Air pressure in the pleural space pushes against the already recoiled lung, causing compression atelectasis, and against the mediastinum, compressing and displacing the heart and great vessels (Figure 35-4).

Clinical manifestations of spontaneous or secondary pneumothorax begin with sudden pleural pain, tachypnea, and possibly mild dyspnea. Manifestations depend on the size of the pneumothorax. Physical examination may reveal absent or

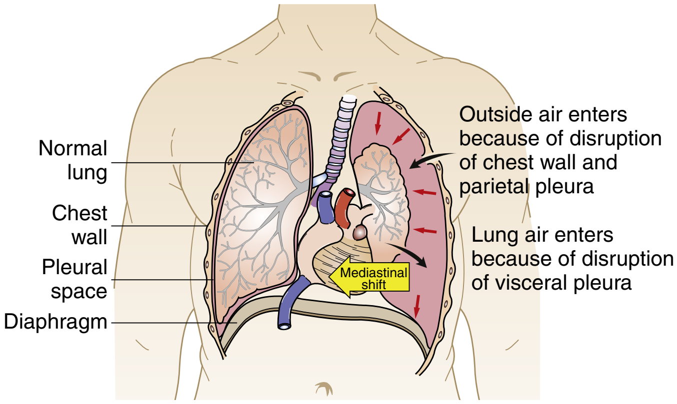

FIGURE 35-4 Tension Pneumothorax. Air in the pleural space causes the lung to collapse around the hilus and may shift trachea and mediastinal contents (heart and great vessels) toward the other lung.

decreased breath sounds and hyperresonance to percussion on the affected side. Diagnosis of pneumothorax is made with chest radiographs, ultrasound, and CT. Tension pneumothorax may be complicated by severe hypoxemia, tracheal deviation away from the affected lung, and hypotension (low blood pressure). Deterioration occurs rapidly and immediate treatment is required. Pneumothorax is treated with insertion of a chest tube that is attached to a water-seal drainage system with suction. After the pneumothorax is evacuated and the pleural rupture is healed, the chest tube is removed. For individuals with persistent air leaks, other interventions may be needed including surgery, pleurodesis (instillation of a caustic substance, such as talc, into the pleural space), or thoracoscopic surgical techniques.[20]

Pleural Effusion

Pleural effusion is the presence of fluid in the pleural space. The source of the fluid is usually blood vessels or lymphatic vessels lying beneath either pleura, but occasionally an abscess or other lesion may drain into the pleural space. Because the pleura is a relatively permeable membrane, fluids that accumulate in the lung can cross into the pleural space. Pleural effusions that enter the pleural space from the intact blood vessels can be transudative or exudative. In **transudative effusion,** the fluid, or transudate, is watery and diffuses out of the capillaries as a result of disorders that increase intravascular hydrostatic pressure or decrease capillary oncotic pressure. Examples are congestive heart failure, in which venous and left atrial pressures are increased, and liver or kidney disorders that cause hypoproteinemia. Hypoproteinemia decreases capillary oncotic pressure, which promotes diffusion of water out of the capillaries. (This mechanism is discussed in Chapter 3).

Exudative effusion is less watery and contains high concentrations of white blood cells and plasma proteins. Exudative effusion occurs in response to inflammation, infection, or malignancy and involves inflammatory processes that increase capillary permeability (see Chapter 7). When stimulated by biochemical mediators of inflammation, junctions in the capillary endothelium separate slightly, enabling leukocytes and plasma proteins to migrate out into affected tissues. Other

TABLE 35-2 MECHANISMS OF PLEURAL EFFUSION

TYPE OF FLUID/EFFUSION	SOURCE OF ACCUMULATION*	PRIMARY OR ASSOCIATED DISORDER
Transudate (hydrothorax)	Watery fluid that diffuses out of capillaries beneath the pleurae (i.e., capillaries in lung or chest wall)	Cardiovascular disease that causes high blood pressure; liver or kidney disease that disrupts plasma protein production, causing hypoproteinemia (decreased oncotic pressure in the blood vessels)
Exudate	Fluid rich in proteins (leukocytes, plasma proteins of all kinds; see Chapter 7) that migrates out of the capillaries	Infection, inflammation, or malignancy of the pleurae that stimulates mast cells to release biochemical mediators that increase capillary permeability
Empyema (pus)	Detritus of infection (microorganisms, leukocytes, cellular debris) dumped into the pleural space by blocked lymphatic vessels	Pulmonary infections, such as pneumonia; lung abscesses; infected wounds
Hemothorax (blood)	Hemorrhage into the pleural space	Traumatic injury, surgery, rupture, or malignancy that damages blood vessels
Chylothorax (chyle)	Chyle (milky fluid containing lymph and fat droplets) that is dumped by lymphatic vessels into the pleural space instead of passing from the gastrointestinal tract to the thoracic duct	Traumatic injury, infection, or disorder that disrupts lymphatic transport

*NOTE: The principles of diffusion are discussed in Chapter 1; mechanisms that increase capillary permeability and cause exudation of cells and proteins are discussed in Chapter 7.

types of pleural effusion are characterized by the presence of pus **(empyema),** blood **(hemothorax),** or chyle **(chylothorax).** Mechanisms of pleural effusion are summarized in Table 35-2.

Small pleural effusions may not affect lung function and remain undetected. Most will be removed by the lymphatic system once the underlying condition is resolved. Dyspnea, compression atelectasis with impaired ventilation, and pleural pain are common. Mediastinal shift and cardiovascular manifestations occur in a large, rapidly developing effusion. Physical examination reveals decreased breath sounds and dullness to percussion on the affected side. A pleural friction rub can be heard over areas of inflamed pleura.

Diagnosis is confirmed by chest x-ray and thoracentesis (needle aspiration), which can determine the type of effusion and provide symptomatic relief. If the effusion is large, drainage usually requires the placement of a chest tube and surgical interventions may be needed to prevent recurrence of the effusion.[20]

Empyema

Empyema (infected pleural effusion) is the presence of pus in the pleural space. It is thought to develop when the pulmonary lymphatics become blocked, leading to an outpouring of contaminated lymphatic fluid into the pleural space. Empyema occurs most commonly in older adults and children and usually develops as a complication of pneumonia, surgery, trauma, or bronchial obstruction from a tumor.[21] Commonly documented infectious microorganisms include *Staphylococcus aureus, Escherichia coli,* anaerobic bacteria, and *Klebsiella pneumoniae.*

Individuals with empyema present clinically with cyanosis, fever, tachycardia (rapid heart rate), cough, and pleural pain. Breath sounds are decreased directly over the empyema. Diagnosis is made by chest radiographs, thoracentesis, and sputum culture. Treatment for empyema includes the administration of appropriate antimicrobials and drainage of the pleural space with a chest tube. In severe cases, ultrasound-guided pleural drainage, instillation of fibrinolytic agents, or deoxyribonuclease (DNase) injected into the pleural space may be needed to achieve adequate drainage.[22]

PULMONARY DISORDERS

Restrictive Lung Disorders

Restrictive lung disorders are characterized by decreased compliance of lung tissue. This means that it takes more effort to expand the lungs during inspiration, which increases the work of breathing. Individuals with lung restriction complain of dyspnea and have an increased respiratory rate and decreased tidal volume. Pulmonary function testing reveals a decrease in FVC. Restrictive lung diseases can cause ventilation and perfusion mismatch and affect the alveolocapillary membrane, which reduces the diffusion of oxygen from the alveoli into the blood and results in hypoxemia. Some of the most common restrictive lung diseases in adults are aspiration, atelectasis, bronchiectasis, bronchiolitis, pulmonary fibrosis, inhalational disorders, pneumoconiosis, allergic alveolitis, pulmonary edema, and acute respiratory distress syndrome.

Aspiration

Aspiration is the passage of fluid and solid particles into the lung. It tends to occur in individuals whose normal swallowing mechanism and cough reflex are impaired by a decreased level of consciousness or central nervous system abnormalities. Predisposing factors include altered level of consciousness caused by substance abuse, sedation, or anesthesia; seizure disorders; cerebrovascular accident; and neuromuscular disorders that cause dysphagia. There is a risk of aspiration and development of pneumonia in individuals who require enteral feeding (through a nasogastric feeding tube).[23] The right lung, particularly the right lower lobe, is more susceptible to aspiration than the left lung because the branching angle of the right

mainstem bronchus is straighter than the branching angle of the left mainstem bronchus.

Aspiration of large food particles or gastric fluid with pH of less than 2.5 has serious consequences. Solid food particles can obstruct a bronchus, resulting in bronchial inflammation and collapse of airways distal to the obstruction. If the aspirated solid is not identified and removed by bronchoscopy, a chronic, local inflammation develops that may lead to recurrent infection and bronchiectasis (permanent dilation of the bronchus). Once the pathologic process has progressed to bronchiectasis, surgical resection of the affected area is usually required.

Aspiration of oral or pharyngeal secretions can lead to aspiration pneumonia, especially if the oral cavity is colonized with bacteria (e.g., individuals with poor dentition). Intubation of the trachea also can cause aspiration and bacterial pneumonia. Aspiration of acidic gastric fluid may cause severe pneumonitis. Bronchial damage includes inflammation, loss of ciliary function, and bronchospasm. In the alveoli, acidic fluid damages the alveolocapillary membrane. This allows plasma and blood cells to move from capillaries into the alveoli, resulting in hemorrhagic pneumonitis. The lung becomes stiff and noncompliant as surfactant production is disrupted, leading to further edema and collapse. Hypoventilation may develop as this process progresses, and systematic complications, such as hypotension, may occur.

Clinical manifestations of aspiration include the sudden onset of choking and intractable cough with or without vomiting, fever, dyspnea, and wheezing. Some individuals have no symptoms acutely; instead they have recurrent lung infections, chronic cough, or persistent wheezing over months and even years.

Preventive measures for individuals at risk are more effective than treatment of known aspiration. The most important preventive measures include use of a semirecumbent position, surveillance of enteral feeding, use of promotility agents, and avoidance of excessive sedation. Individuals being administered general anesthetics should not receive food or fluid for several hours before or after surgery. Antacids are sometimes given to individuals at risk for aspiration to keep gastric pH greater than 2.5. Individuals who have difficulty swallowing are fed with extreme caution and positioned to minimize the likelihood of aspiration. Nasogastric tubes, which often are used to remove stomach contents and reduce the risk for aspiration, also can cause aspiration, if fluid and particulate matter are regurgitated as the tube is being placed. For those who suffer from swallowing difficulties, speech-language pathologists can often improve swallowing abilities that may prevent recurrence.

Treatment of aspiration, pneumonia, or pneumonitis includes supplemental oxygen and may require mechanical ventilation with positive end-expiratory pressure (PEEP). Fluids are restricted to decrease blood volume and minimize pulmonary edema. Corticosteroids may be administered during the first 72 hours after aspiration. Bacterial pneumonia may develop as a complication of aspiration pneumonitis and must be treated with broad-spectrum antibiotics.[24]

Atelectasis

Atelectasis is the collapse of lung tissue. There are three types of atelectasis: compression, absorption, and surfactant impairment:

1. **Compression atelectasis** is caused by the external pressure exerted on lung tissue, such as occurs with tumors, or by fluid or air in the pleural space. Atelectasis at the base of the lungs can be caused by abdominal distention pressing on a portion of the lung, causing the alveoli to collapse.
2. **Absorption atelectasis** results from gradual absorption of air from obstructed or hypoventilated alveoli or from inhalation of concentrated oxygen or anesthetic agents.
3. **Surfactant impairment** results from decreased production or inactivation of surfactant, which is necessary to reduce surface tension in the alveoli and thus prevent lung collapse during expiration. Surfactant impairment can occur because of premature birth, acute respiratory distress syndrome, anesthesia, or mechanical ventilation.

Atelectasis tends to occur after surgery and with use of general anesthesia.[25] In addition, individuals are often in pain, breathe shallowly, are reluctant to change position, and produce viscous secretions that tend to pool in dependent portions of the lung after surgical procedures, especially those involving the thorax or upper abdomen.[26]

Clinical manifestations of atelectasis are similar to those of pulmonary infection: dyspnea, cough, fever, and leukocytosis. Prevention and treatment of postoperative atelectasis usually include deep breathing exercises (often with the aid of an incentive spirometer), frequent position changes, and early ambulation. Deep breathing is beneficial because it (1) promotes the ciliary clearance of secretions, (2) stabilizes the alveoli by redistributing surfactant, and (3) permits collateral ventilation of the alveoli through pores of Kohn in the alveolar septa. The pores of Kohn, which open only during deep breathing, allow air to pass from well-ventilated alveoli to obstructed alveoli, minimizing their tendency to collapse and facilitating expectoration of the bronchial obstruction (Figure 35-5).

Bronchiectasis

Bronchiectasis is persistent abnormal dilation of the bronchi. It usually occurs in conjunction with other respiratory conditions that are associated with chronic bronchial inflammation, such as obstruction of an airway with mucous plugs, atelectasis, aspiration of a foreign body, infection, cystic fibrosis, tuberculosis, congenital weakness of the bronchial wall, or impaired defense mechanisms. Bronchiectasis is also associated with a number of systemic disorders such as rheumatologic disease, inflammatory bowel disease, and immunodeficiency syndromes (e.g., acquired immunodeficiency syndrome [AIDS]).[27] Chronic inflammation of the bronchi leads to destruction of elastic and muscular components of their walls, bronchial lumen obstruction, traction from adjacent fibrosis, and permanent dilation. Bronchial dilation (Figure 35-6) may be *cylindrical* **(cylindrical bronchiectasis),** with symmetrically dilated airways, as can be seen after pneumonia and is reversible; *saccular* **(saccular bronchiectasis),** in which the bronchi become large and balloon-like; or *varicose* **(varicose bronchiectasis),** in which constrictions and dilations

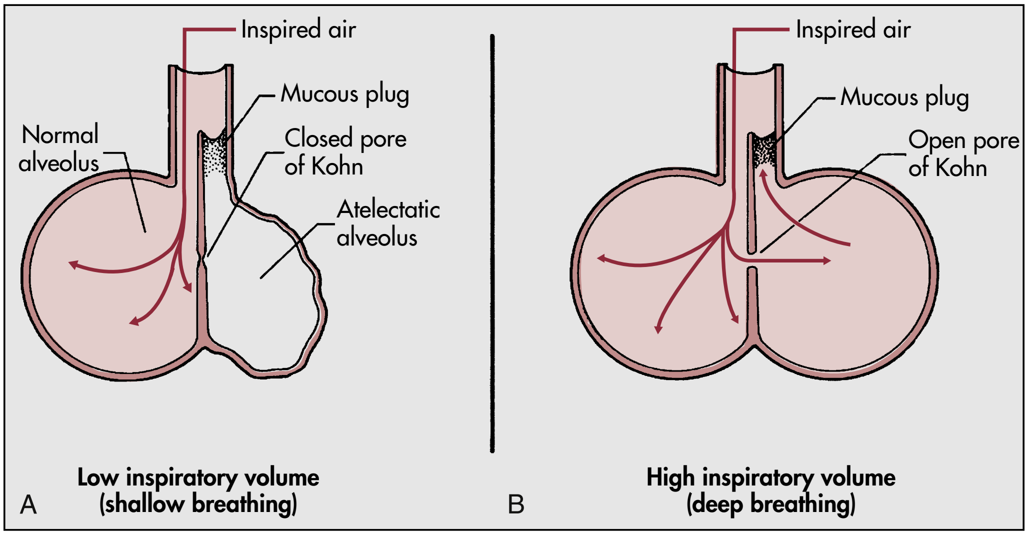

FIGURE 35-5 Pores of Kohn. **A,** Absorption atelectasis caused by lack of collateral ventilation through pores of Kohn. **B,** Restoration of collateral ventilation during deep breathing.

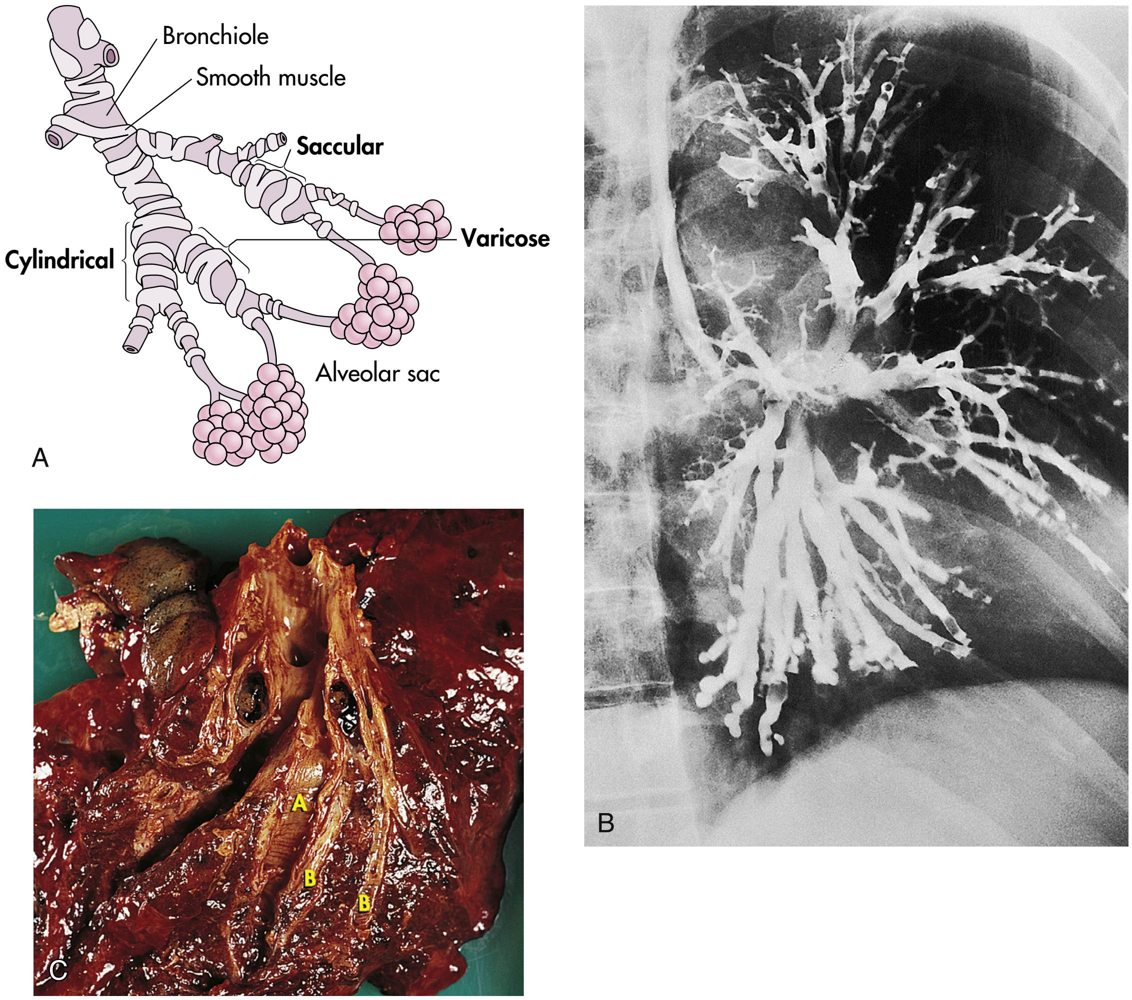

FIGURE 35-6 Bronchiectasis. **A,** Types of bronchiectasis. **B,** Left posterior oblique projection of a left bronchogram showing cylindrical bronchiectasis affecting the entire lower lobe except for the superior segment. Few side branches fill. The basal airways are crowded together, indicating volume loss of the lower lobe, a common feature in bronchiectasis. **C,** Cylindrical bronchiectasis. The dilated bronchi *(A)* and bronchioles *(B)* can be dissected almost to the pleural surface. (**B** from Hansell: *Imaging of diseases of the chest,* ed 5, St Louis, 2009, Mosby; **C** from Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

deform the bronchi, creating a bulbous appearance. In both varicose and saccular bronchiectases, the smaller bronchial divisions are plugged with secretions or obliterated by fibrosis. Large anastomoses (connections) develop between the bronchial and pulmonary blood vessels, increasing blood flow through the bronchial circulation. These anastomoses are thought to cause the hemoptysis experienced by individuals with bronchiectasis. Airway damage leads to bronchospasm and copious production of purulent mucus. Ventilation-perfusion abnormalities develop and result in hypoxemia. In severe cases, minute ventilation is also compromised and $Paco_2$ may become elevated.

The primary symptom of bronchiectasis is chronic productive cough, which may date back to a childhood illness or infection. The disease is commonly associated with recurrent lower respiratory tract infections and expectoration of voluminous amounts of foul-smelling purulent sputum (measured in cups). If the individual is not receiving antibiotics, the sputum has a foul odor. Clubbing of the fingers from chronic hypoxemia is common. Hemoptysis can occur from mucosal inflammation and necrosis and, in some instances, can be massive. Pulmonary function studies show decreases in FVC and expiratory flow rates. Diagnosis is usually confirmed by the use of high-resolution CT. Bronchiectasis is treated with sputum culture antibiotics, bronchodilators, anti-inflammatory drugs, chest physiotherapy, and supplemental oxygen. In selected individuals with localized areas of involvement, surgery may be indicated to remove the affected portion of the lung.[28]

Bronchiolitis

Bronchiolitis is diffuse inflammation of the small airways or bronchioles. It is most common in children (see Chapter 36). In adults it usually occurs with chronic bronchitis, but can occur in otherwise healthy individuals in association with an upper or lower airway viral infection (e.g., respiratory syncytial virus [RSV]), or with inhalation of toxic gases. Atelectasis or emphysematous destruction of the alveoli may develop distal to the inflammatory lesion. Bronchiolitis is usually diffuse. The resulting decrease in the ventilation-perfusion ratio results in hypoxemia. A decrease in minute ventilation with resulting carbon dioxide retention also may occur as lung restriction worsens.

Clinical manifestations include a rapid ventilatory rate; marked use of accessory muscles; low-grade fever; dry, nonproductive cough; and hyperinflated chest. If bronchiolitis is caused by an inhalation injury, pulmonary edema occurs rapidly. Respiratory distress can develop within 24 to 72 hours with severe hypoxia. Infiltrates can be seen on chest radiographs.[29] A decrease in the ventilation-perfusion ratio results in hypoxemia. Diagnosis is made by spirometry and bronchoscopy with biopsy. Bronchiolitis is treated with appropriate antibiotics, steroids, and chest physical therapy (humidified air, coughing and deep breathing, postural drainage).

Bronchiolitis obliterans is a late-stage fibrotic process that occludes the airways and causes permanent scarring of the lungs. This process can occur in all causes of bronchiolitis, but is most common after lung transplantation and is associated with acute rejection and infection. Bronchiolitis obliterans can be further complicated by the development of pneumonia (called **bronchiolitis obliterans organizing pneumonia** [**BOOP**]) in which the alveoli and bronchioles become filled with plugs of connective tissue.[30] This complication of lung transplant has a high morbidity. Diagnosis is made by spirometry and bronchoscopy with biopsy. Treatment includes corticosteroids and other immunomodulatory agents.[31]

Pulmonary Fibrosis

Pulmonary fibrosis is an excessive amount of fibrous or connective tissue in the lung. When no specific cause for the development of fibrosis is known, it is called *idiopathic pulmonary fibrosis.* Although fibrosis can complicate healing after active pulmonary diseases, such as ARDS or tuberculosis, specific causes most often include inhalation of harmful substances, such as toxic gases, inorganic dusts, or organic dusts, and underlying autoimmune systemic disorders, such as rheumatologic disease. The fibrotic process results from chronic inflammation, alveolar epithelialization, and myofibroblast proliferation. Fibrosis causes a marked loss of lung compliance. The lung becomes stiff and difficult to ventilate, and the diffusing capacity of the alveolocapillary membrane may decrease, causing hypoxemia. Diffuse pulmonary fibrosis has a poor prognosis.

Idiopathic Pulmonary Fibrosis. **Idiopathic pulmonary fibrosis (IPF)** is the most common idiopathic interstitial lung disorder. It is more common in men than in women and most cases occur after age 60. The median survival is only 2 to 4 years after diagnosis. IPF is thought to result from multiple injuries at different sites of the lung followed by aberrant repair.[32] Chronic inflammation and fibroproliferation of the interstitial lung tissue occur around the alveoli with disruption of the alveolocapillary basement membrane. This causes decreased oxygen diffusion across the alveolocapillary membrane and hypoxemia. As the disease progresses decreased lung compliance leads to increased work of breathing, decreased tidal volume, and resultant hypoventilation with hypercapnia. Acute exacerbations of IPF can occur with rapid decompensation and a death rate as high as 50%.[33] The primary symptom of IPF is increasing dyspnea on exertion; examination reveals diffuse inspiratory crackles and diagnosis is confirmed by pulmonary function testing (decreased FVC), high-resolution CT, and lung biopsy. Treatment with corticosteroids alone causes remission in approximately 50% of individuals. Combined treatment with cytotoxic drugs has a higher success rate, but also higher toxicity. Newer therapies include antifibrotic drugs (such as *N*-acetylcysteine and pirfenidone), interferon, and anticoagulation. Selected individuals may benefit from lung transplantation.[34]

Exposure to Toxic Gases. Inhalation of gaseous irritants can cause significant respiratory dysfunction. Commonly encountered toxic gases include ammonia, hydrogen chloride, sulfur dioxide, chlorine, phosgene, and nitrogen dioxide. Inhalation injuries in burns can include toxic gases from household or industrial combustants, heat, and smoke particles. Inhaled toxic particles cause damage to the airway epithelium, cilia, and alveoli. There is increased mucus secretion, promotion of inflammation, and mucosal and pulmonary edema. Surfactant and other protective buffers and antioxidants are inactivated.[35] The cellular effects of toxic gases are described in

Chapter 2. Acute toxic inhalation is frequently complicated by the development of ARDS and pneumonia. Initial symptoms include burning of the eyes, nose, and throat; coughing; chest tightness; and dyspnea. Hypoxemia is common. Treatment includes supplemental oxygen, mechanical ventilation with PEEP, and support of the cardiovascular system. Corticosteroids sometimes are used, although their effectiveness has not been well documented. Most individuals respond quickly to therapy. Some, however, may improve initially and then deteriorate as a result of bronchiectasis or bronchiolitis.

Prolonged exposure to high concentrations of supplemental oxygen can result in a relatively rare iatrogenic condition known as **oxygen toxicity.** The basic underlying mechanism of injury is a severe inflammatory response mediated primarily by oxygen free radicals. The result is damage to alveolocapillary membranes, disruption of surfactant production, interstitial and alveolar edema, and decrease in compliance.[36] Treatment involves ventilatory support and reduction of inspired oxygen concentration to less than 60%, as soon as tolerated.

Pneumoconiosis. **Pneumoconiosis** represents any change in the lung caused by inhalation of inorganic dust particles, which usually occurs in the workplace. As in all cases of environmentally acquired lung disease, the individual's history of exposure is important in determining the diagnosis. Pneumoconiosis often occurs after years of exposure to the offending dust with progressive fibrosis of lung tissue.

The dusts of silica, asbestos, and coal are the most common causes of pneumoconiosis. Others include talc, fiberglass, clays, mica, slate, cement, cadmium, beryllium, tungsten, cobalt, aluminum, and iron. Deposition of these materials in the lungs cause the release of proinflammatory cytokines (e.g., interleukin-1-beta). This leads to chronic inflammation with scarring of the alveolocapillary membrane, resulting in pulmonary fibrosis and progressive pulmonary deterioration. Clinical manifestations with advancement of disease may include cough, sputum production, dyspnea, decreased lung volumes, and hypoxemia. In most cases, diagnosis is made by performing chest x-ray or CT and by obtaining careful occupational history.[37] Treatment is usually palliative and focuses on preventing further exposure and improving working conditions, along with pulmonary rehabilitation and management of associated hypoxemia and bronchospasm.

Silicosis is a type of pneumoconiosis resulting from the inhalation of free silica (silicon dioxide) and silica-containing compounds as occurs in mining and industries involved with the extraction and processing of ores; preparation and use of sand; and manufacture of pipe, building, and roofing materials. Silica exposure activates innate and adaptive immune mechanisms, and triggers inflammation with subsequent fibrosis.[38] Acute inflammation contributes to bronchospasm and wheezing. Release of proteolytic enzymes and toxic oxygen free radicals increases the risk for lung cancer. Exposed individuals may remain asymptomatic long after the nodules are visible on chest radiography. When clinical manifestations do appear, they include cough and dyspnea. There is no curative treatment for the disease, although corticosteroids may produce some improvement in the early, more acute stages.

Coal worker pneumoconiosis (**coal miner lung, black lung**) is caused by coal dust deposits in the lung. Although coal dust itself is relatively well tolerated by the lung, it is frequently inhaled as a mixture of coal, silica, and quartz, which is strongly inflammatory. Its mild form is asymptomatic, except for possible chronic bronchitis. Its advanced form manifests as severe pulmonary fibrosis. Individuals usually are seen with a productive cough and wheezing. Symptoms are more severe with advanced disease and mimic those of chronic bronchitis and emphysema.[39] Diagnosis is made by obtaining a history of exposure and observing chest radiographs for characteristic signs. There is no specific treatment for coal worker pneumoconiosis. Individuals with the mild form of the disease usually have a favorable prognosis. Those with more complicated forms often develop marked cardiopulmonary dysfunction.

Asbestos exposure affects not only factory workers but also individuals who live in areas of asbestos emission. Asbestos exposure can result in a type of pulmonary fibrosis called **asbestosis,** but can also cause lung cancer, mesothelioma (cancer of the pleura), or pleural plaques, especially in those also exposed to cigarette smoke.[40]

Asbestosis is caused by inhalation of hydrous silicates of various metals in fibrous form. Asbestos fibers cause inflammation and alveolitis. Activated macrophages release toxic oxygen free radicals and cause cellular apoptosis, leading to both fibrosis and malignancy. The most prominent clinical manifestations of asbestosis with fibrosis are dyspnea on exertion, a nonproductive cough, diffuse inspiratory crackles on examination, hypoxemia, and decreased lung volume. Progressive disease may take years and leads to respiratory failure and cardiac complications. Diagnosis is made by chest x-ray, pulmonary function testing, and CT. Therapy is supportive.

Hypersensitivity Pneumonitis. **Hypersensitivity pneumonitis** (**extrinsic allergic alveolitis**) is an allergic, inflammatory disease of the lungs caused by inhalation of organic particles or fumes. Many allergens (antigens) can cause this disorder, including grains, silage, bird droppings or feathers, wood dust (particularly redwood and maple), cork dust, animal pelts, coffee beans, fish meal, mushroom compost, grain molds, mists from standing water, and fumes from paints and resins. A type III immune response (see Chapter 9) is initiated by alveolar macrophages and results in immunoglobulin G (IgG) antibody production. Continued exposure results in a type IV cellular immune activation. The inflammatory response causes pneumonitis.[41] Granuloma formation is common. Lung capacity and alveolocapillary diffusion are reduced. A genetic predisposition may increase the risk for this disease.

Allergic alveolitis can be acute, subacute, or chronic. The acute form causes a fever, cough, dyspnea, and chills a few hours after exposure that resolve without treatment in 1 to 3 days. With continued exposure, the disease becomes chronic and pulmonary fibrosis develops. (The mechanisms of hypersensitivity reactions are discussed in Chapter 9.) Chronic allergic alveolitis causes weight loss, fever, fatigue, and gradually progressive respiratory failure. Diagnosis is made by obtaining a history of allergen exposure and by performing serum antibody testing,

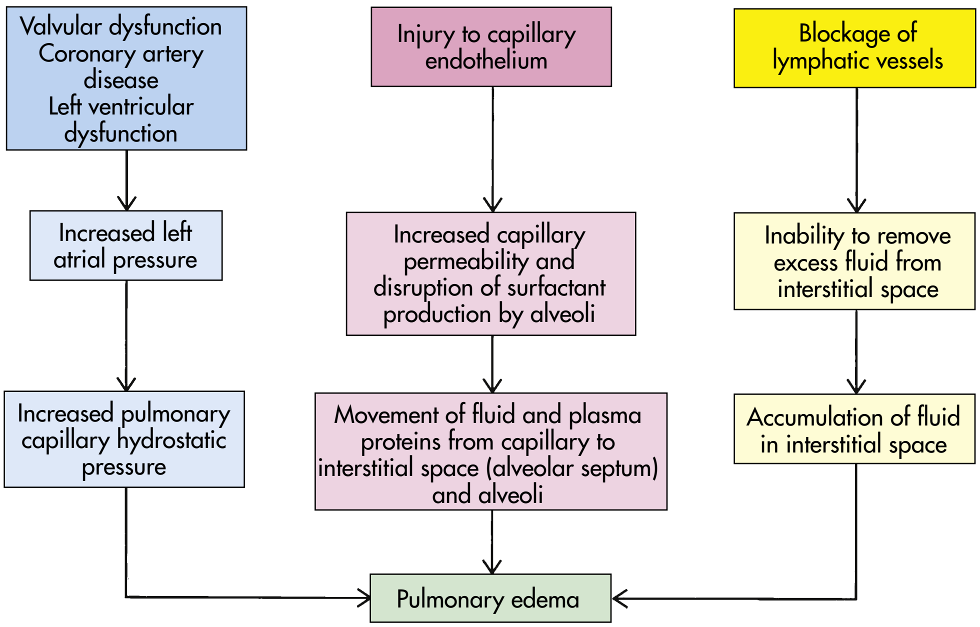

FIGURE 35-7 Pathogenesis of Pulmonary Edema.

chest x-ray, bronchoscopy, CT, and in some cases lung biopsy.[42] Treatment consists of avoidance of the offending agent and corticosteroid administration.

Systemic Disorders and the Lungs

Several systemic diseases affect the airways, pleurae, or lung parenchyma, causing fibrosis, vasculitis, pulmonary hemorrhage, or granuloma formation. Clinical manifestations of lung involvement are usually nonspecific, and the diagnosis is based on involvement of other organs. There is usually no specific treatment, although corticosteroids often are used. Some of the systemic diseases affecting the lung are granulomatous disorders such as sarcoidosis, Wegener granulomatosis, lymphomatoid granulomatosis, and eosinophilic granuloma; connective tissue diseases such as rheumatoid arthritis, systemic lupus erythematosus, scleroderma, polymyositis or dermatomyositis, Sjögren syndrome, and polyarteritis nodosa; angioimmunoblastic or immunoblastic lymphadenopathy (a disease of the lymph nodes); cystic fibrosis (see Chapter 36); and Goodpasture syndrome (a pulmonary and renal disorder).

Pulmonary Edema

Pulmonary edema is excess water in the lung. The normal lung contains very little fluid. It is kept dry by lymphatic drainage and a balance among capillary hydrostatic pressure, capillary oncotic pressure, and capillary permeability. In addition, surfactant lining the alveoli repels water, keeping fluid from entering the alveoli. Predisposing factors for pulmonary edema include heart disease, ARDS, and inhalation of toxic gases. The pathogenesis of pulmonary edema is illustrated in Figure 35-7.

The most common cause of pulmonary edema is left-sided heart disease (see Chapter 32). When the left ventricle fails, filling pressures on the left side of the heart increase and cause a concomitant increase in pulmonary capillary hydrostatic pressure. When the hydrostatic pressure exceeds oncotic pressure, fluid moves into the interstitium, or interstitial space (the space within the alveolar septum between alveolus and capillary). Fluid moves to the lymphatic vessels and is then removed from the lung. When the flow of fluid out of the capillaries exceeds the lymphatic system's ability to remove it, pulmonary edema develops. Pulmonary edema usually begins to develop at a pulmonary capillary wedge pressure or left atrial pressure of 20 mmHg. If the capillary oncotic pressure is decreased for any reason (e.g., anemia or decreased levels of plasma proteins), pulmonary edema develops at a lower hydrostatic pressure.

Another cause of pulmonary edema is capillary injury that increases capillary permeability. Capillary injury causes edema in cases of adult respiratory distress syndrome (ARDS) or inhalation of toxic gases, such as ammonia. Capillary injury causes water and plasma proteins to leak out of the capillary and move into the interstitium. When plasma proteins move into the lung interstitium, they increase the interstitial oncotic pressure, which is usually very low. As the interstitial oncotic pressure begins to equal capillary oncotic pressure, water moves out of the capillary and into the lung. (Mechanisms of edema are discussed in Chapter 3.)

Pulmonary edema also can result from obstruction of the lymphatic system. Drainage can be blocked by compression of lymphatic vessels caused by edema, tumors, and fibrotic tissue or by increased systemic venous pressure that elevates the hydrostatic pressure of the large pulmonary veins into which the pulmonary lymphatic system drains. This can happen in left-sided heart failure.

Postobstructive pulmonary edema (**POPE,** or **negative pressure pulmonary edema**) is a rare life-threatening complication

that can occur after relief of upper airway obstruction (e.g., postextubation laryngospasm after anesthesia, epiglottitis, laryngeal tumor, or obstructive tonsils). Attempted inspiration against an occluded airway creates excessive intrathoracic negative pressure, causing increased venous return and blood flow to the right side of the heart and decreased outflow from the left side of the heart from the increased afterload. This combination of events causes increased pulmonary blood volume and venous pressure and leads to pulmonary edema.[43]

Clinical manifestations of pulmonary edema include dyspnea, orthopnea, hypoxemia, and increased work of breathing. Physical examination may reveal inspiratory crackles (rales), dullness to percussion over the lung bases, and evidence of ventricular dilation (S_3 gallop and cardiomegaly). In severe edema, pink, frothy sputum is expectorated, hypoxemia worsens, and hypoventilation with hypercapnia may develop.

The treatment of pulmonary edema depends on its cause. If the edema is caused by increased hydrostatic pressure resulting from heart failure, therapy is geared toward improving cardiac output and volume status with diuretics, vasodilators, and drugs that improve the contraction of the heart muscle. If edema is the result of increased capillary permeability resulting from injury, the treatment is focused on removing the offending agent and supportive therapy to maintain adequate oxygenation, ventilation, and circulation. POPE is treated with positive end-expiratory pressure ventilation. Individuals with any type of pulmonary edema require supplemental oxygen. Mechanical ventilation may be needed if edema significantly impairs ventilation and oxygenation.

Acute Lung Injury/Acute Respiratory Distress Syndrome

Acute lung injury (ALI)/acute respiratory distress syndrome (ARDS) represents a spectrum of acute lung inflammation and diffuse alveolocapillary injury. In the United States, ALI/ARDS is estimated at 64 to 78 cases per 100,000 people.[44] Advances in therapy have decreased the overall death rate to approximately 42% to 47%, although older people and those who have severe infections or are immunocompromised continue to have a much higher mortality.[45] Most survivors have almost normal lung function 1 year after the acute illness, but may have other health problems, including neurocognitive disorders up to 5 years later.[46] The most common predisposing factors for ARDS are genetic factors, sepsis, and multiple trauma (especially when multiple transfusions are received); however, there are many other causes, including pneumonia, burns, aspiration, cardiopulmonary bypass surgery, pancreatitis, drug overdose, smoke or noxious gas inhalation, oxygen toxicity, radiation therapy, and disseminated intravascular coagulation.[47,48]

PATHOPHYSIOLOGY. All disorders that result in ARDS cause acute injury to the alveolocapillary membrane producing massive pulmonary inflammation, increased capillary permeability, severe pulmonary edema, shunting, $\dot{V}/\dot{Q}$ mismatch, and hypoxemia. The alveolocapillary injury can occur directly, as with the aspiration of highly acidic gastric contents or the inhalation of toxic gases; or indirectly, as from circulating inflammatory mediators released in response to systemic disorders, such as sepsis and trauma. Lung inflammation and injury damages the alveolar epithelium and the vascular endothelium. Because the pulmonary edema is not secondary to heart failure, ARDS is often referred to as *noncardiogenic pulmonary edema*. ARDS progresses through three overlapping phases characterized by histologic changes in the lung: exudative (inflammatory), proliferative, and fibrotic (Figure 35-8).

Exudative (Inflammatory) Phase (Within 72 Hours). The initial lung injury damages the alveolocapillary membrane. Lung injury activates neutrophils, platelets, macrophages, lung epithelial and endothelial cells, and uncontrolled inflammation. Inflammatory mediators include complement, cytokines, arachidonic acid metabolites, platelet-activating factor, reactive oxygen species, and other mediators (specifically tumor necrosis factor [TNF], interleukin-1 [IL-1], and IL-6).[49] Activated complement factors and platelet aggregation result in intravascular microthrombus formation and further damage to lung capillaries.[50] In ARDS caused by sepsis, bacterial toxins are recognized by the CD14 receptors on macrophages and lead to chemotaxis of large numbers of neutrophils to the lungs. A cascade of inflammatory mediators is released by the macrophages, including TNF, IL-1, alpha and beta chemokines, and other interleukins.

The role of neutrophils is central to the development and progression of ARDS. Activated neutrophils release a battery of harmful inflammatory mediators, among them proteolytic enzymes, oxygen free radicals (superoxide radicals, hydrogen peroxide, hydroxyl radicals), arachidonic acid metabolites (prostaglandins, thromboxanes, leukotrienes), and platelet-activating factor. These mediators cause extensive damage to the alveolocapillary membrane and greatly increase capillary membrane permeability. Increased capillary permeability, a hallmark of ARDS, allows fluids, proteins, and blood cells to leak from the capillary bed into the pulmonary interstitium and alveoli (hemorrhagic exudate). The resulting pulmonary edema and hemorrhage severely reduce lung compliance and impair alveolar ventilation (Figure 35-9).

Mediators released by neutrophils, and to a certain extent by macrophages, also cause pulmonary vasoconstriction. Because vasoconstriction occurs more in some vascular beds than others, blood flow to selected areas of the lungs is decreased, resulting in $\dot{V}/\dot{Q}$ mismatching. Pulmonary hypertension occurs early in the course of the disease secondary to vasoconstriction. Thrombi composed of aggregated neutrophils, macrophages, platelets, and fibrin are formed.

Surfactant is inactivated, and its production by type II alveolar cells is impaired as alveoli and respiratory bronchioles fill with fluid or collapse.[51] The lungs become less compliant, the work of breathing increases, ventilation of alveoli decreases, and hypercapnia develops.

Proliferative Phase (4 to 21 Days). Within 1 to 3 weeks after the initial lung injury, there is resolution of the pulmonary edema and proliferation of type II pneumocytes, fibroblasts, and myofibroblasts. The intra-alveolar hemorrhagic exudate becomes a cellular granulation tissue appearing as hyaline membranes and there is progressive hypoxemia.

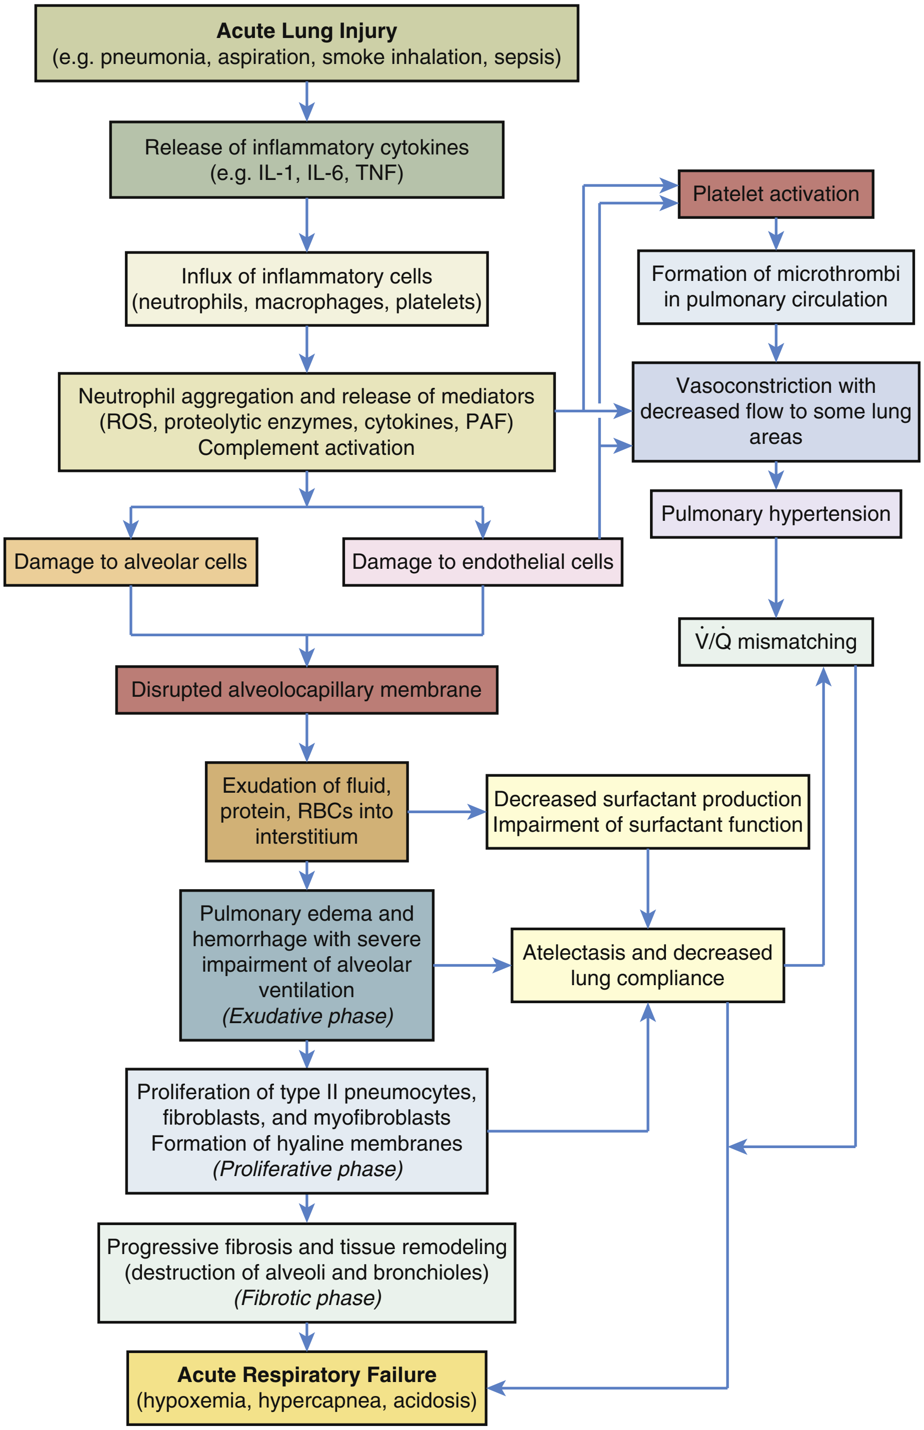

FIGURE 35-8 Pathogenesis of Acute Respiratory Distress Syndrome (ARDS). *IL-1,* Interleukin-1; *IL-6,* interleukin-6; *PAF,* platelet-activating factor; *RBCs,* red blood cells; *ROS,* reactive oxygen species; *TNF,* tumor necrosis factor.

Fibrotic Phase (14 to 21 Days). About 2 to 3 weeks after the initial injury, remodeling and fibrosis occur. The fibrosis progressively obliterates the alveoli, respiratory bronchioles, and interstitium, leading to a decrease in functional residual capacity (FRC) and continuing $\dot{V}/\dot{Q}$ mismatch with severe right-to-left shunt. The result of this overwhelming inflammatory response by the lungs is acute respiratory failure.

The same chemical mediators responsible for the alveolocapillary damage of ARDS often cause inflammation, endothelial damage, and capillary permeability throughout the body, resulting in the systemic inflammatory response syndrome (SIRS). SIRS then leads to multiple organ dysfunction syndrome (MODS). In fact, death may not be caused by respiratory failure alone, but by MODS associated with ARDS. (MODS is discussed in Chapter 48.)

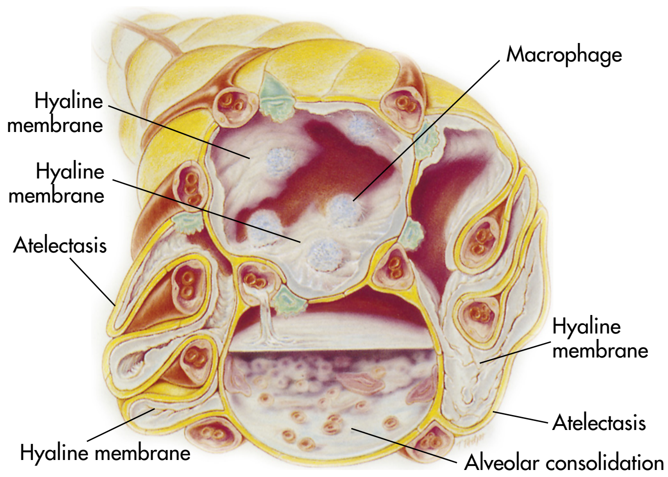

FIGURE 35-9 Acute Respiratory Distress Syndrome (ARDS). Cross-sectional view of alveoli in ARDS. (Modified from Des Jardins T, Burton GG: *Clinical manifestations and assessment of respiratory disease,* ed 3, St Louis, 1995, Mosby.)

CLINICAL MANIFESTATIONS. The clinical manifestations of ARDS are progressive as follows:

Dyspnea and hypoxemia with poor response to oxygen supplementation
↓
Hyperventilation and respiratory alkalosis
↓
Decreased tissue perfusion, metabolic acidosis, and organ dysfunction
↓
Increased work of breathing, decreased tidal volume, and hypoventilation
↓
Hypercapnia, respiratory acidosis, and worsening hypoxemia
↓
Decreased cardiac output, hypotension, and death

The new Berlin definition of ARDS provides categories of severity based on hypoxemia: mild (200 mmHg $< PaO_2/FIO_2 \leq$ 300 mmHg), moderate (100 mmHg $< PaO_2/FIO_2 \leq$ 200 mmHg), and severe ($PaO_2/FIO_2 \leq$ 100 mm Hg).[51a]

Worsening hypoxemia and hypercapnia lead to respiratory failure. Decreased oxygen delivery to tissues results in metabolic acidosis and organ dysfunction (e.g., decreased urine output and a decline in cognitive functioning). Decreased cardiac output and hypotension eventually lead to death.

EVALUATION AND TREATMENT. Diagnosis is made on the basis of a history of lung injury, physical examination, analysis of arterial blood gases, and chest radiographs. ALI/ARDS is defined as: (1) the acute onset of bilateral infiltrates on chest radiograph, (2) a low ratio of partial pressure of arterial oxygen to the fraction of inhaled oxygen, and (3) the absence of clinical evidence of left atrial hypertension.[52] Initial physical examination may show fine inspiratory crackles. Over the first 24 to 48 hours after injury, interstitial and alveolar infiltrates appear on chest radiographs. Serum biomarkers, such as TNF, brain natriuretic peptide (BNP), IL-6 and IL-8, and surfactant proteins, are being studied.[53]

Treatment strategies include early detection and management of contributing etiologies, supportive therapy to prevent progression of lung injury, and prevention of complications such as pneumonia and stress ulcer.[54,55] Traditional therapy includes mechanical ventilation with PEEP and high oxygen concentrations. Alternative modalities of ventilation are being evaluated, including low-volume ventilation, noninvasive positive-pressure ventilation, permissive hypercapnia, prone positioning, extracorporeal gas exchange, and partial liquid ventilation; some of these methods have shown reductions in death rates.[44]

Many studies are investigating new ways to prevent or treat ARDS.[56] Although recombinant human activated protein C was initially found to improve outcomes in individuals with shock and ARDS, more recent reviews found it to have no effect on mortality and the drug was removed from the market.[57] Prophylactic immunotherapy, antibodies against endotoxins, antioxidants, surfactant replacement, nitric oxide inhalation, and inhibition of various inflammatory mediators are among other possibilities being tested. High-dose corticosteroid administration is no longer recommended, but low-dose therapy improves outcomes.[58]

Obstructive Pulmonary Disease

Obstructive pulmonary disease is characterized by airway obstruction that is worse with expiration. More force (i.e., use of accessory muscles of expiration) or more time is required to expire a given volume of air and emptying of the lungs is slowed. The unifying symptom of obstructive pulmonary disease is dyspnea; the unifying sign is wheezing. Individuals have an increased work of breathing, ventilation-perfusion mismatching, and a decreased forced expiratory volume in one second (FEV_1). The most common obstructive diseases are asthma, chronic bronchitis, and emphysema. Because many individuals have chronic bronchitis with emphysema, these diseases together are often called COPD.

Asthma

Asthma is a chronic inflammatory disorder of the bronchial mucosa that causes bronchial hyperresponsiveness, constriction of the airways, and variable airflow obstruction that is reversible.[59] Asthma occurs at all ages, with approximately half of all cases developing during childhood (see Chapter 36) and another third before age 40. In the United States, it is estimated that 24.6 million people have asthma and the prevalence continues to increase. Death rates are highest for adult females, black persons, and adults older than 65.[60]

Asthma is most commonly a familial disorder and more than 100 genes have been identified that may play a role in the susceptibility and pathogenesis of asthma, including those that influence the production of IL-4, IL-5, and IL-13; IgE; eosinophils; mast cells; adrenergic receptors; leukotrienes; nitric oxide; and transmembrane proteins in the endoplasmic reticulum.[61] Specific gene expression may impart associated phenotypes, such as inflammation, sensitization to allergens, airway fibroblasts, airway remodeling, and responsiveness to asthma therapies[62,63] (see Chapter 36, p. 1309, for What's New? Asthma Phenotypes). Other risk factors include allergen exposure; urban residence; exposure to air pollution, tobacco smoke, and environmental

tobacco smoke; recurrent respiratory tract viral infections; esophageal reflux; and obesity.[59,64] These factors cause epigenetic changes that influence the function of asthma susceptibility genes.[65-67] Exposure to high levels of certain allergens during childhood increases the risk for asthma. Furthermore, decreased exposure to certain infectious organisms appears to create an immunologic imbalance that favors the development of allergy and asthma in some individuals. This complex relationship has been called the *hygiene hypothesis* (see the Asthma section on p. 1308 in Chapter 36 for more detail).[68]

PATHOPHYSIOLOGY. Airway epithelial exposure to antigen initiates both an innate and an adaptive immune response in sensitized individuals (see Chapter 9).[69] Many cells and cellular elements contribute to the persistent inflammation of the bronchial mucosa and hyperresponsiveness of the airways, including macrophages (dendritic cells), T helper 2 (Th2) lymphocytes, B lymphocytes, mast cells, neutrophils, eosinophils, and basophils. There is both an immediate (early asthmatic response) and a late (delayed) response.

During the *early asthmatic response,* antigen exposure to the bronchial mucosa activates dendritic cells (antigen-presenting cells) to present the antigen to CD4+ T cells, which differentiate into Th2 cells (see Chapter 9). These Th2 cells release numerous cytokines including IL-4, IL-5, IL-8, IL-13, IL-17, and IL-22. IL-4 stimulates B-cell activation, proliferation, and production of antigen-specific IgE. IL-5 stimulates the activation, migration, and proliferation of eosinophils, which cause direct tissue injury and release of toxic neuropeptides that contribute to increased bronchial hyperresponsiveness, fibroblast proliferation, epithelial injury, and airway scarring. IL-8 activates neutrophils that contribute to a more exaggerated inflammatory response. IL-13 impairs mucociliary clearance, enhances fibroblast secretion, and contributes to bronchoconstriction and airway remodeling.[70] IL-17 increases neutrophilic inflammation and IL-22 stimulates airway epithelial cells, which play an important role in stimulating further innate and adaptive immune responses.[71,72]

The Fc portion of preformed IgE binds to receptors on the surface of mast cells. Once bound to antigen, the IgE causes the mast cells to degranulate, releasing a large number of inflammatory mediators[73] (see Figure 7-11 for additional details regarding mast cells). Together these mediators cause vasodilation, increased capillary permeability, mucosal edema, bronchial smooth muscle contraction (bronchospasm), and tenacious mucus secretion from mucosal goblet cells with narrowing of the airways and obstruction to airflow[69] (Figures 35-10, 35-11, and 35-12).

The *late asthmatic response* begins 4 to 8 hours after the early response. Chemotactic recruitment of lymphocytes, eosinophils, and neutrophils during the acute response causes a latent release of inflammatory mediators, again inciting bronchospasm, edema, and mucus secretion with obstruction to airflow. Synthesis of leukotrienes contributes to prolonged smooth muscle contraction. Eosinophil mediators cause direct tissue injury with fibroblast proliferation and airway scarring. Release of toxic neuropeptides contribute to increased bronchial hyperresponsiveness. Damage to ciliated epithelial cells contributes

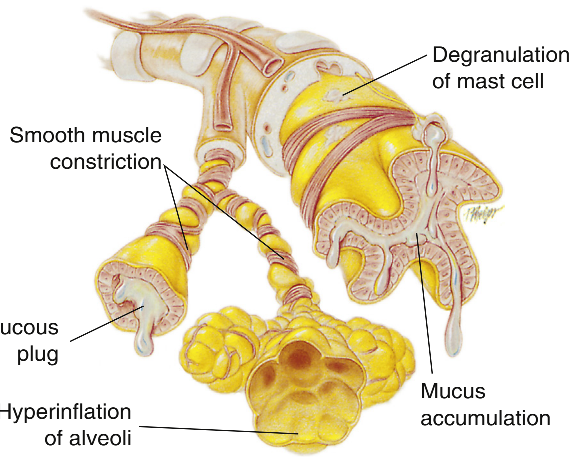

FIGURE 35-10 **Bronchial Asthma.** Thick mucus, mucosal edema, and smooth muscle spasm cause obstruction of small airways; breathing becomes labored and expiration is difficult. (Modified from Des Jardins T, Burton GG: *Clinical manifestations and assessment of respiratory disease,* ed 3, St Louis, 1995, Mosby.)

to impaired mucociliary function with accumulation of mucus and cellular debris forming plugs in the airways (increased synthesis of nitric oxide contributes to oxidative injury and chronic inflammation).[74] A decrease in the number or function of T regulatory (Treg) cells are associated with asthma.[69] Untreated inflammation can lead to long-term airway damage that is irreversible, known as *airway remodeling* (subepithelial fibrosis, smooth muscle and mucous gland hypertrophy).[75]

Airway obstruction increases resistance to airflow and decreases flow rates, especially expiratory flow. Impaired expiration causes air trapping, hyperinflation distal to obstructions and increased work of breathing. Changes in resistance to airflow are not uniform throughout the lungs and the distribution of inspired air is uneven, with more air flowing to the less resistant portions. Continued air trapping increases intrapleural and alveolar gas pressures and causes decreased perfusion of the alveoli. Increased alveolar gas pressure, decreased ventilation, and decreased perfusion lead to variable and uneven ventilation-perfusion relationships within different lung segments. Hyperventilation is triggered by lung receptors responding to increased lung volume and obstruction. The result is early hypoxemia without CO_2 retention. Hypoxemia further increases hyperventilation through stimulation of the respiratory center, causing $Paco_2$ to decrease and pH to increase (respiratory alkalosis). With progressive obstruction of expiratory airflow, air trapping becomes more severe and the lungs and thorax become hyperexpanded, putting the respiratory muscles at a mechanical disadvantage. This leads to a fall in tidal volume with increasing CO_2 retention and respiratory acidosis. Respiratory acidosis signals respiratory failure, especially when left ventricular filling and, thus, cardiac output become compromised because of severe hyperinflation.

CLINICAL MANIFESTATIONS. Individuals are asymptomatic between attacks and pulmonary function tests are normal. No clinical symptoms are present during partial remission, but pulmonary function tests are abnormal. At the beginning of an attack, the individual experiences chest constriction, expiratory

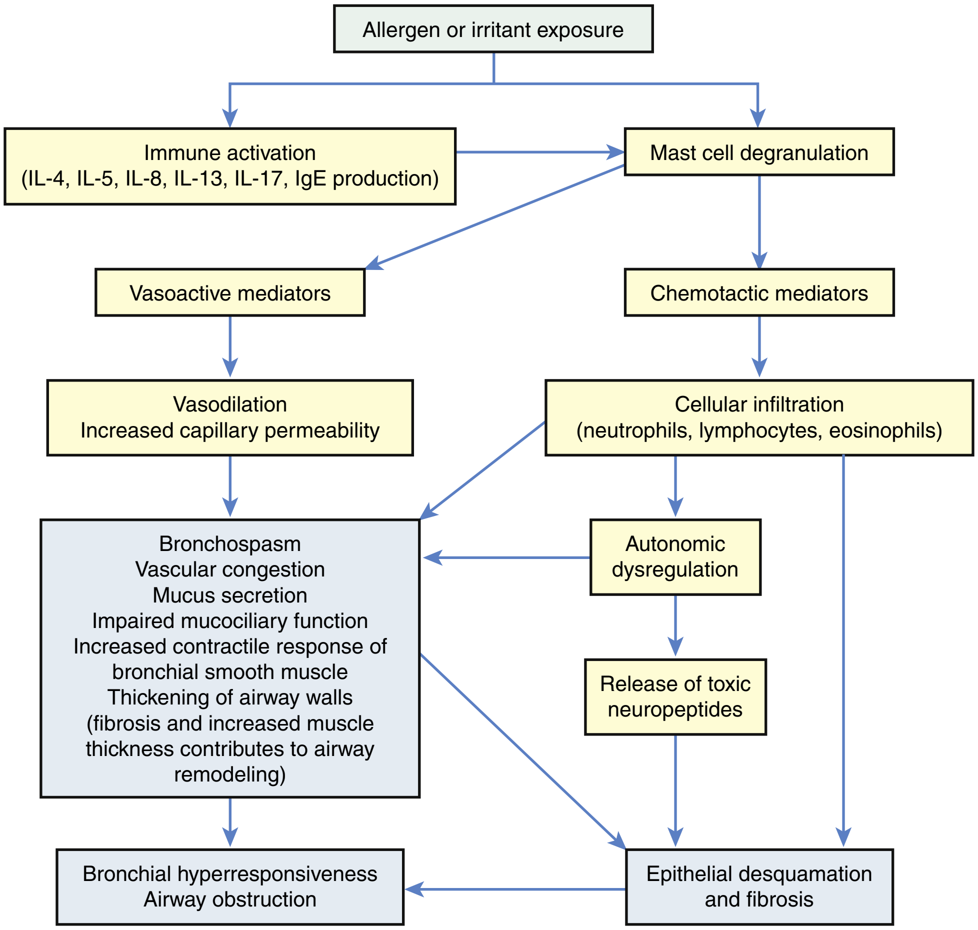

FIGURE 35-11 **Pathophysiology of Asthma.** Allergen or irritant exposure results in a cascade of inflammatory events leading to acute and chronic airway dysfunction. *IgE,* Immunoglobulin E; *IL,* interleukin.

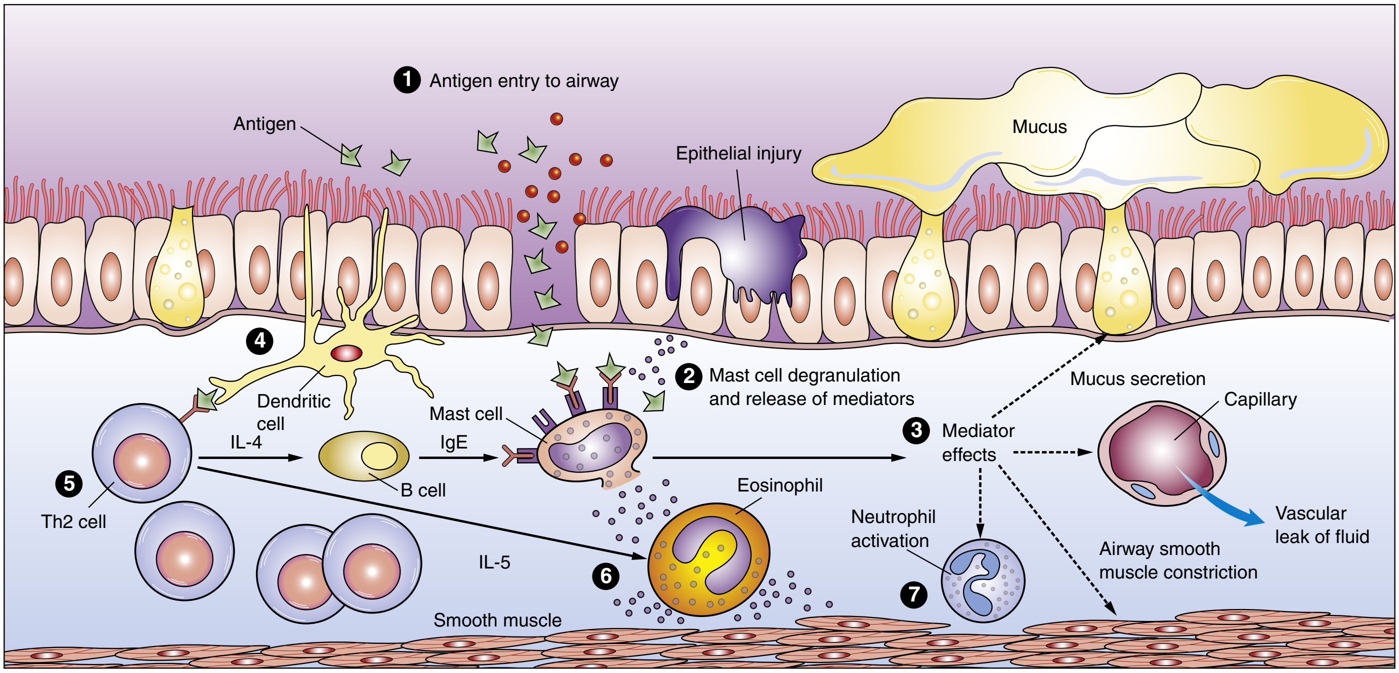

FIGURE 35-12 **Acute Asthmatic Responses.** Inhaled antigen **(1)** binds to mast cells covered with preformed IgE. Mast cells degranulate **(2)** and release inflammatory mediators such as histamine, bradykinins, leukotrienes, prostaglandins, platelet-activating factor, and interleukins. Secreted mediators **(3)** induce active bronchospasm (airway smooth muscle constriction), edema from increased capillary permeability, and airway mucus secretion from goblet cells. At the same time, antigen is detected by **(4)** dendritic cells that process and present it to Th2 cells **(5),** which produce interleukin-4 *(IL-4)* and many other interleukins (see text). IL-4 promotes switching of B cells to favor immunoglobulin E *(IgE)* production. Th2 cells also produce IL-5 **(6),** which activates eosinophils. Eosinophil products, such as major basic protein and eosinophilic cationic protein, damage the respiratory epithelium. Many inflammatory cells, including neutrophils **(7),** also contribute to the inflammatory process. *IgE,* Immunoglobulin E.

wheezing, dyspnea, nonproductive coughing, prolonged expiration, tachycardia, and tachypnea. Severe attacks involve the use of accessory muscles of respiration, and wheezing is heard during both inspiration and expiration. A **pulsus paradoxus** (decrease in systolic blood pressure during inspiration of more than 10 mmHg) may be noted. Peak flow measurements should be obtained. Because the severity of blood gas alterations is difficult to evaluate by clinical signs alone, arterial blood gas tensions should be measured if oxygen saturation falls below 90%. Usual findings are hypoxemia with an associated respiratory alkalosis. In the *late asthma response,* symptoms can be even more severe than the initial attack.

If bronchospasm is not reversed by usual measures, the individual is considered to have severe bronchospasm or **status asthmaticus.** If status asthmaticus continues, hypoxemia worsens, expiratory flows decrease further, and effective ventilation decreases. Acidosis develops as arterial $Paco_2$ begins to rise. Asthma becomes life threatening at this point if treatment does not reverse this process quickly. A silent chest (no audible air movement) and a $Paco_2$ greater than 70 mmHg are ominous signs of impending death.

EVALUATION AND TREATMENT. The diagnosis of asthma is supported by a history of allergies and recurrent episodes of wheezing, dyspnea and cough, or exercise intolerance. Further evaluation includes spirometry, which may document reversible decreases in FEV_1 during an induced attack.

The evaluation of an acute asthma attack requires the rapid assessment of arterial blood gases and expiratory flow rates (using a peak flowmeter) and a search for underlying triggers, such as infection. Hypoxemia and respiratory alkalosis are expected early in the course of an acute attack. The development of hypercapnia with respiratory acidosis signals the need for mechanical ventilation. Management of the acute asthma attack requires immediate administration of oxygen and inhaled beta-agonist bronchodilators. In addition, oral corticosteroids should be administered early in the course of management.[59,76] Careful monitoring of gas exchange and airway obstruction in response to therapy provides information necessary to determine whether hospitalization is necessary. Antibiotics are not indicated for acute asthma unless there is a documented bacterial infection.

Management of asthma begins with avoidance of allergens and irritants. Individuals with asthma tend to underestimate the severity of their asthma and extensive education is important, including use of a peak flowmeter and adherence to an action plan should symptoms worsen. In the mildest form of asthma (intermittent), short-acting beta-agonist inhalers are prescribed. For all categories of persistent asthma, anti-inflammatory medications are essential and inhaled corticosteroids are the mainstay of therapy. In individuals whose symptoms are not adequately controlled using inhaled corticosteroids, leukotriene antagonists can be considered. In more severe asthma, long-acting beta agonists can be used to control persistent bronchospasm; however, these agonists can actually worsen asthma in some individuals with certain genetic polymorphisms (see What's New? Pharmacogenetics and Beta Agonists in the Treatment of Asthma). Immunotherapy has been shown to be an important tool in reducing asthma exacerbations and can now be given sublingually. Monoclonal antibodies to IgE (omalizumab) have been found to be helpful in selected individuals.[77,78] The National Asthma Education and Prevention Program offers stepwise guidelines for the diagnosis and management of chronic asthma based on clinical severity, and they may be reviewed at www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm. Biomarkers and epigenetic markers are being evaluated to personalize treatment and reduce mortality.[79]

WHAT'S NEW?

Pharmacogenetics and Beta Agonists in the Treatment of Asthma

In the recent third report of the National Asthma Education and Prevention Program (NAEPP), long-acting beta agonists (LABAs) (salmeterol and formoterol) are recommended to be used in conjunction with inhaled corticosteroids as step 3 therapy for persistent asthma. LABAs have been found to improve symptoms in many individuals, and exert a long-term bronchodilatory and anti-inflammatory effect on the airways. However, the safety of LABAs has been questioned because of the increased mortality in some populations using these drugs and it is recommended they be withdrawn once asthma is controlled by combination therapy. One explanation is that those individuals who had worsening symptoms while taking LABAs were using them instead of (rather in conjunction with) inhaled corticosteroids and thus were simply masking ongoing inflammation and airway damage. LABAs should not be used in the absence of inhaled corticosteroids. New evidence suggests that some persons have a polymorphism of the β-adrenergic receptor gene *(ADRβ2)*. This is known as the Arg16Arg genotype and places those individuals at risk for worsening bronchospasm, increased hospitalizations, and increased mortality when using LABAs. This genotype is more frequent in blacks and may explain some of the differences in asthma treatment response and mortality among these individuals. Studies continue to evaluate other genes and their relationship to medication response, a field of study known as pharmacogenetics.

Data from Erdinç M, Brozek JL et al: Long-acting β2-agonist step-off in patients with controlled asthma, *Arch Intern Med* 172(18):1365-1375, 2012; Mysore S, Ruffin RE: *Drugs* 71(16):2091–2097, 2011; Wechsler ME et al: *Am J Respir Crit Care Med* 184(11):1247–1253, 2011; Wells KE et al: *J Allergy Clin Immunol* 129(5):1274–1279, 2012.

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is defined as a "preventable and treatable disease with some significant extrapulmonary effects that may contribute to the severity in individual patients. Its pulmonary component is characterized by airflow limitation that is not fully reversible. The airflow limitation is usually progressive and associated with an abnormal inflammatory response of the lung to noxious particles or gases."[80] COPD is the third leading cause of death in the United States and is the sixth leading cause of death worldwide.[80] Overall mortality from COPD has increased in the United States over the past 30 years; however, mortality in women has increased more than twice that much.[81] Risk factors for COPD include tobacco smoke (cigarette, pipe, cigar, and environmental tobacco smoke), occupational dusts and chemicals (vapors, irritants, and fumes), indoor air pollution from biomass fuel used for cooking and heating (in poorly vented dwellings), outdoor air pollution, and any factor that affects lung growth

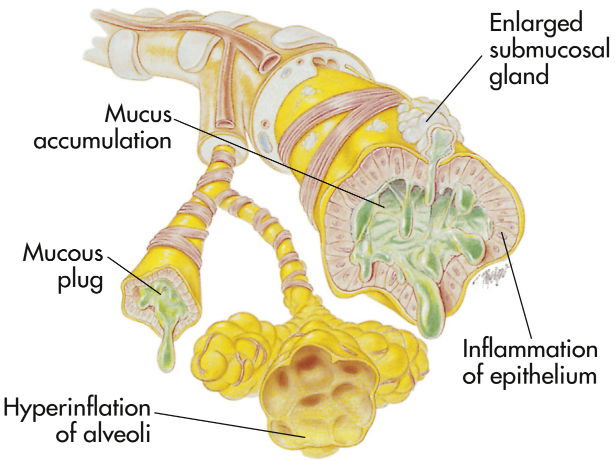

FIGURE 35-13 Chronic Bronchitis. Inflammation and thickening of mucous membrane with accumulation of mucus and pus leading to obstruction characterized by productive cough. (Modified from Des Jardins T, Burton GG: *Clinical manifestations and assessment of respiratory disease,* ed 3, St Louis, 1995, Mosby.)

during gestation and childhood (low birth weight, respiratory tract infections).[80] Genetic susceptibilities have been identified, including polymorphisms of genes that code for tumor necrosis factor, surfactant, proteases, antiproteases, and risks for lung cancer. The clinical phenotypes of COPD are chronic bronchitis and emphysema.[82] An inherited mutation in the α_1-antitrypsin gene results in the development of COPD (emphysema) at an early age, even in nonsmokers.[83,84]

The pathologic changes of COPD occur in large central airways, small peripheral airways, and the lung parenchyma, the dominant features of chronic bronchitis and emphysema. Chronic irritant exposure recruits macrophages, neutrophils, and lymphocytes to the lung, resulting in progressive damage from oxidative stress, inflammation, extracellular matrix proteolysis, and apoptotic and autophagic cell death.[85,86] Systemic abnormalities, such as renal and hormonal abnormalities, malnutrition, muscle wasting, osteoporosis, and anemia, are associated with COPD.[87]

Chronic Bronchitis. **Chronic bronchitis** is defined as hypersecretion of mucus and chronic productive cough that continues for at least 3 months of the year (usually the winter months) for at least 2 consecutive years.

PATHOPHYSIOLOGY. Inspired irritants result in airway inflammation with infiltration of neutrophils, macrophages, and lymphocytes into the bronchial wall. Tobacco smoke directly injures airway epithelial cells. Continual bronchial inflammation causes bronchial edema and increases the size and number of mucous glands and goblet cells in the airway epithelium. Thick, tenacious mucus is produced and cannot be cleared because of impaired ciliary function (Figure 35-13). The lung's defense mechanisms are, therefore, compromised, increasing susceptibility to pulmonary infection, which contributes to airway injury.[88] Frequent infectious exacerbations are complicated by bronchospasm with dyspnea and productive cough.[89] The pathogenesis of chronic bronchitis is shown in Figure 35-14.

Initially chronic bronchitis affects only the larger bronchi, but eventually all airways are involved. The thick mucus and hypertrophied bronchial smooth muscle narrow the airways and lead to obstruction, particularly during expiration when the airways are constricted. Obstruction eventually leads to ventilation-perfusion mismatch with hypoxemia. The airways collapse early in expiration, trapping gas in the distal portions of the lung (Figure 35-15). Air trapping expands the thorax, putting the respiratory muscles at a mechanical disadvantage. This leads to decreased tidal volume, hypoventilation, and hypercapnia.

CLINICAL MANIFESTATIONS. The common symptoms of chronic bronchitis include decreased exercise tolerance, wheezing, and shortness of breath. Individuals usually have a productive cough ("smoker's cough"), and evidence of airway obstruction (decreased FEV_1) is shown by spirometry. Hypoxemia may occur with exercise. As the disease progresses, copious amounts of sputum are produced, accompanied by frequent pulmonary infections.[90] FVC and FEV_1 values become markedly reduced, and FRC and residual volume (RV) measurements are increased as airway obstruction and air trapping become more pronounced.

Airway obstruction results in decreased alveolar ventilation and increased $Paco_2$. Marked hypoxemia leads to polycythemia (overproduction of erythrocytes) and cyanosis. If not reversed, hypoxemia leads to pulmonary hypertension and eventually results in cor pulmonale (see p. 1278) and can lead to severe disability or death. (Table 35-3 lists the common clinical manifestations of chronic bronchitis.)

EVALUATION AND TREATMENT. Diagnosis is based on history of symptoms, physical examination, chest radiograph, pulmonary function tests, and blood gas analyses; these tests reflect the progressive nature of the disease. Prevention of chronic bronchitis is the best treatment because pathologic changes are not reversible. By the time an individual seeks medical care for symptoms, considerable airway damage is present. If the individual stops smoking, disease progression can be halted.

Bronchodilators (long-acting inhaled anticholinergics or long-acting inhaled beta agonists for symptomatic persons with COPD and FEV_1 <60% predicted) and expectorants are prescribed to reduce dyspnea and control cough. Chest physical therapy may be helpful and includes deep breathing and postural drainage. During acute exacerbations (infection and bronchospasm), individuals require treatment with antibiotics and corticosteroids and may need mechanical ventilation. Chronic oral corticosteroids may be needed late in the course of the disease, but should be considered a last resort. Individuals with severe hypoxemia will require continuous oxygen therapy. Teaching includes nutritional counseling, respiratory hygiene, recognition of the early signs of infection, and techniques that relieve dyspnea, such as pursed-lip breathing, all of which may be useful in the treatment of chronic bronchitis in selected individuals.[91,92] (see Nutrition & Disease: Chronic Obstructive Pulmonary Disease). Oxygen is administered with care to individuals with severe hypoxemia and CO_2 retention. Chronic elevation of $Paco_2$ diminishes the sensitivity of central chemoreceptors and they no longer act as the primary stimulus for breathing. (Chemoreceptors are described in Chapter 34.) This role is taken over by the peripheral chemoreceptors, which are sensitive to changes in Pao_2. Peripheral chemoreceptors do not

stimulate breathing if the Pao_2 is much more than 60 mmHg. Therefore, if oxygen therapy causes Pao_2 to exceed 60 mmHg, the stimulus to breathe decreases, $Paco_2$ increases, and apnea results. However, severe hypoxemia must be reversed, especially if there are comorbidities (e.g., heart disease, tissue injury) that require adequate tissue oxygenation. If titration of oxygen therapy cannot be achieved without causing respiratory depression, the individual's lungs must be mechanically ventilated.[93]

Emphysema. **Emphysema** is abnormal permanent enlargement of gas-exchange airways (acini) accompanied by destruction of alveolar walls without obvious fibrosis. The major mechanism of airflow limitation in emphysema is loss of elastic recoil. Some degree of emphysema is considered normal in older adults, but results in a slow and predictable decline in lung function with aging.

Primary emphysema, which accounts for 1% to 3% of all cases of emphysema, is commonly linked to an inherited deficiency of the enzyme α_1-antitrypsin.[94] Normally α_1-antitrypsin inhibits the action of many proteolytic enzymes (enzymes that break down proteins). Individuals who have α_1-antitrypsin deficiency (an autosomal recessive trait) have an increased likelihood of developing emphysema, because proteolysis in lung tissues is not inhibited. Homozygous individuals have a 70% to 80% likelihood of developing lung disease. (Mechanisms of genetic inheritance are described in Chapter 4.) Persons with α_1-antitrypsin deficiency who smoke are even more

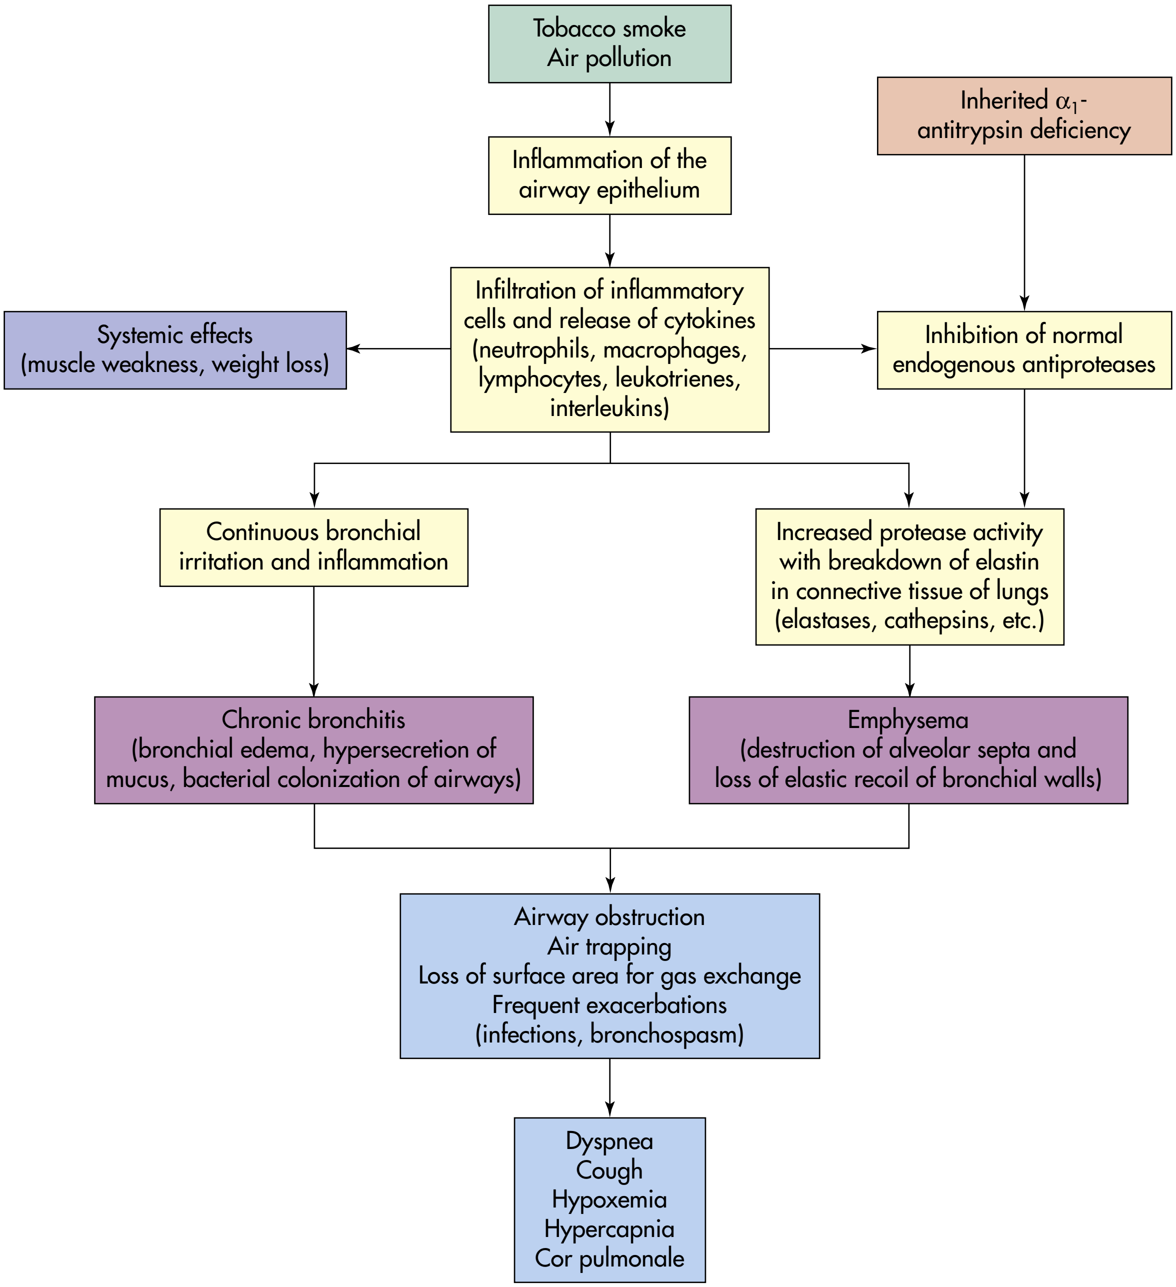

FIGURE 35-14 Pathogenesis of Chronic Bronchitis and Emphysema (Chronic Obstructive Pulmonary Disease [COPD]).

susceptible to emphysema than those with the deficiency alone. α_1-Antitrypsin deficiency is suggested in nonsmokers and individuals who develop emphysema before age 40 years (or in their early forties).

The major cause of secondary emphysema is the inhalation of cigarette smoke, although air pollution, occupational exposures, and childhood respiratory tract infections are known to be contributing factors. Not all smokers develop emphysema, but approximately 15% to 20% are especially susceptible and develop significant lung damage, if they continue to smoke.[95]

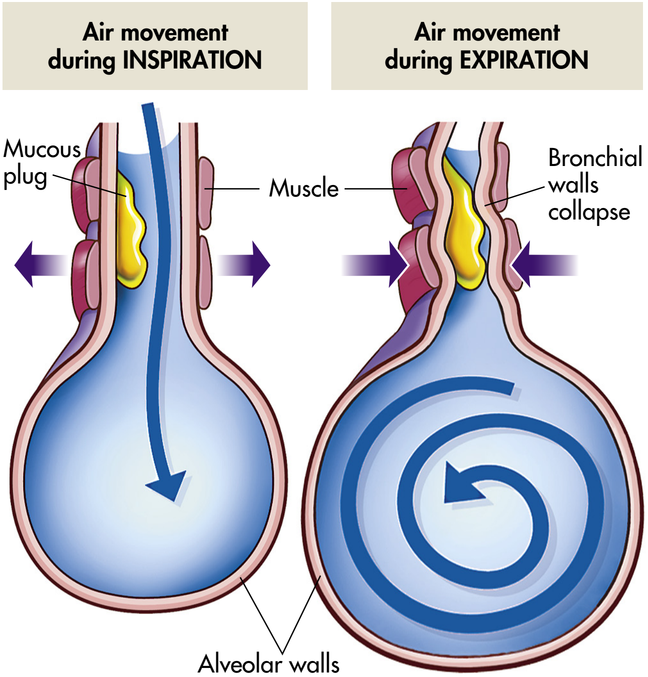

FIGURE 35-15 Mechanisms of Air Trapping in Chronic Obstructive Pulmonary Disease (COPD). Mucous plugs and narrowed airways cause air trapping and hyperinflation on expiration. During inspiration the airways are pulled open, allowing gas to flow past the obstruction. During expiration decreased elastic recoil of the bronchial walls results in collapse of the airways and prevents normal expiratory airflow.

TABLE 35-3 CLINICAL MANIFESTATIONS OF CHRONIC PULMONARY DISEASE

CLINICAL MANIFESTATIONS	CHRONIC BRONCHITIS	EMPHYSEMA
Productive cough	Classic sign	Late in course with infection
Dyspnea	Late in course	Common
Wheezing	Intermittent	Minimal
History of smoking	Common	Common
Barrel chest	Occasionally	Classic
Prolonged expiration	Always present	Always present
Cyanosis	Common	Uncommon
Chronic hypoventilation	Common	Late in course
Polycythemia	Common	Late in course
Cor pulmonale	Common	Late in course

PATHOPHYSIOLOGY. Emphysema is characterized by destruction of alveoli through the breakdown of elastin within the septa by an imbalance between proteases and antiproteases, oxidative stress, and apoptosis of lung structural cells[87,96] (see Figure 35-14). Cellular apoptosis and early cellular senescence contribute to loss of alveolar cells and reduced surface area for gas exchange. Alveolar destruction also produces large air spaces within the lung parenchyma (bullae) and air spaces adjacent to pleurae (blebs). Bullae and blebs are not effective in gas exchange and combined with loss of portions of the pulmonary capillary bed, there is significant ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatching and hypoxemia. Expiration becomes difficult because loss of elastic recoil reduces the volume of air that can be expired passively and air is trapped in the lungs (see Figure 35-15). **Air trapping** causes hyperexpansion of the chest, which puts the muscles of respiration at a mechanical disadvantage. This results in increased work of breathing, so that many individuals will develop hypoventilation and hypercapnia late in the course of the disease. Persistent inflammation in the airways can result in hyperreactivity of the bronchi with bronchoconstriction, which may be partially reversible with bronchodilators. Chronic inflammation also can have significant systemic effects including weight loss, muscle weakness, and increased susceptibility to comorbidities, such as infection.

Emphysema can be centriacinar (centrilobular) or panacinar (panlobular) (Figure 35-16), depending on the site of involvement. In **centriacinar emphysema** septal destruction occurs in the respiratory bronchioles and alveolar ducts, usually in the upper lobes of the lung. The alveolar sac (alveoli distal to the respiratory bronchiole) remains intact. It tends to occur

NUTRITION & DISEASE

Chronic Obstructive Pulmonary Disease

Malnutrition occurs in up to one third of individuals with chronic obstructive pulmonary disease (COPD) and is a major concern because these individuals have increased work of breathing and energy expenditure, decreased energy intake, and impaired oxygenation. The disproportionate muscle wasting is similar to what occurs with other chronic diseases, such as cancer, heart failure, and acquired immunodeficiency syndrome (AIDS). Systemic inflammatory mediators may impair appetite and contribute to hypermetabolism. Malnutrition (1) adversely affects exercise tolerance by limiting skeletal and respiratory muscle strength and aerobic capacity, (2) limits surfactant production, (3) reduces cell-mediated immune responses, (4) decreases protein synthesis, and (5) increases morbidity and mortality. The medical nutrition therapy goal is to maintain an acceptable and stable weight for the person. This can be accomplished through high-energy foods, oral nutritional support, frequent snacking, soft foods and beverages, assistance with shopping, and meal preparation. Reducing the amount of carbohydrates while providing adequate protein and lipids may improve carbon dioxide balance. Increasing omega-3 fatty acids and antioxidant intake may modulate the effects of systemic inflammation. Vitamin D and calcium supplementation is indicated to improve bone health. Serum phosphate levels also should be monitored to prevent hypophosphatemia, which can contribute to muscle weakness.

in smokers with chronic bronchitis. **Panacinar emphysema** involves the entire acinus, with damage more randomly distributed and involving the lower lobes of the lung (Figure 35-17). It tends to occur in older adults and in those with α_1-antitrypsin deficiency.[97]

CLINICAL MANIFESTATIONS. Dyspnea on exertion that later progresses to marked dyspnea, even at rest, is the most common symptom of emphysema (see Table 35-3). Little coughing and very little sputum are produced. Often the individual is thin, has tachypnea with prolonged expiration, and must use accessory muscles for ventilation. The anteroposterior diameter of the chest is increased (barrel chest), and the chest has a hyperresonant sound with percussion. To increase lung capacity, the individual often leans forward with arms extended and braced on knees when sitting. In addition, people with emphysema often exhale through pursed lips which helps prevent expiratory airway collapse.

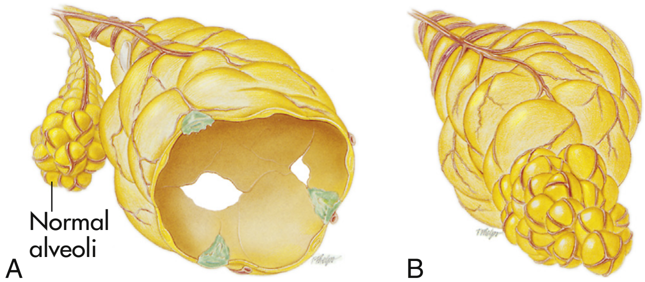

FIGURE 35-16 Emphysema. Enlargement and destruction of alveolar walls with loss of elasticity and trapping of air. **A,** Panlobular emphysema showing abnormal weakening and enlargement of all air spaces distal to the terminal bronchioles (normal alveoli shown for comparison only); **B,** centrilobular emphysema showing abnormal weakening and enlargement of the respiratory bronchioles in the proximal portion of the acinus. (Modified from Des Jardins T, Burton GG: *Clinical manifestations and assessment of respiratory disease,* ed 3, St Louis, 1995, Mosby.)

EVALUATION AND TREATMENT. Emphysema is usually diagnosed and staged by pulmonary function measures. In COPD, pulmonary function tests indicate obstruction to gas flow during expiration with a marked decrease in FEV_1. Airway collapse and air trapping in distal portions of the lung lead to a decrease in FVC (but less so than FEV_1) and an increase in FRC, residual volume (RV), and total lung capacity (TLC). Diffusing capacity is decreased because of destruction of the alveolocapillary membranes. On radiographs the diaphragm appears flattened and the lung fields appear overdistended. In individuals for whom pulmonary function testing is not definitive for the diagnosis, high-resolution CT scanning may be indicated.[98] Arterial blood gas measurements reveal varying degrees of hypoxemia and/or hypercapnia. The disease course is usually prolonged, with increasing dyspnea and intermittent bouts of infection that culminate in failure of the right side of the heart (cor pulmonale) and death.[99]

Management of acute exacerbations of emphysema is similar to that for chronic bronchitis and requires obtaining a chest radiograph, serum white blood cell count, arterial blood gas, and sputum sample. Individuals should receive oxygen and may require noninvasive positive-pressure ventilation or mechanical ventilation. Inhaled bronchodilators should be administered by either inhaler or nebulizer. Oral corticosteroids and antibiotics should be prescribed immediately.[87] Chronic management

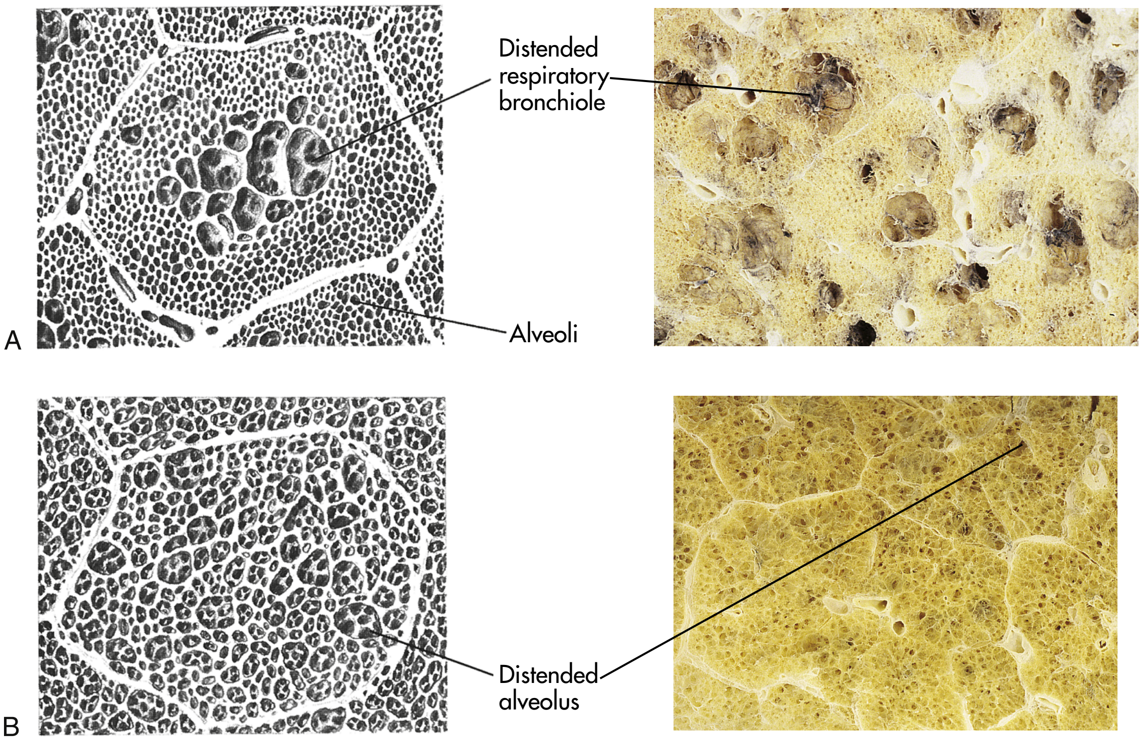

FIGURE 35-17 Micrographs of Types of Emphysema. **A,** Centriacinar emphysema. **B,** Panacinar emphysema. (Micrographs from Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

of emphysema begins with smoking cessation. Pharmacologic management is based on clinical severity, defined by the Global Initiative for Chronic Obstructive Lung Disease (GOLD), as mild, moderate, severe, or very severe. Inhaled anticholinergic agents and beta agonists should be prescribed. Inhaled corticosteroids added to long-acting anticholinergics of beta agonists diminish the number of acute exacerbations, slow the rate of decline in quality of life, and reduce the rate of decline in FEV_1; however, their use must be weighed against the potential side effects (oropharyngeal candidiasis and hoarseness, and risk of pneumonia).[100] Long-term therapy with oral corticosteroids should be avoided, if possible. Pulmonary rehabilitation, improved nutrition, and breathing techniques can all improve symptoms. Oxygen therapy is indicated in chronic hypoxemia, but must be administered with care. Progressive pulmonary dysfunction with hypoxemia and hypercapnia may require long-term oxygen therapy and ventilation, if indicated.[101] In selected patients, lung volume reduction surgery or transplantation can be considered.[102] The recently approved phosphodiesterase E4 (PDE4) inhibitor roflumilast reduces airway inflammation and is proving to be effective in selected individuals with severe COPD.[103] α_1-Antitrypsin augmentation may be indicated for primary emphysema.[91,104]

Respiratory Tract Infections

Respiratory tract infections are the most common cause of short-term disability in the United States. Most of these infections—the common cold, pharyngitis (sore throat), and laryngitis—involve only the upper airways. Although the lungs have direct contact with the atmosphere, they remain sterile under most circumstances. Infections of the lower respiratory tract occur most often in the very young, the very old, or individuals with impaired immunity or underlying disease. In all cases the body's normal defense mechanisms are impaired.

Pneumonia

Pneumonia is infection of the lower respiratory tract caused by bacteria, viruses, fungi, protozoa, or parasites. It is the sixth leading cause of death in the United States and is responsible for more disease and death than any other infection.[105] More than half of those hospitalized for pneumonia are older than age 65; mortality from pneumonia is highest in older adults. Risk factors for pneumonia include advanced age, immunocompromised status, underlying lung disease (especially COPD), alcoholism, altered consciousness, impaired swallowing, smoking, endotracheal intubation, malnutrition, immobilization, underlying cardiac or liver disease, and residence in a nursing home.

Pneumonia can be categorized as community-acquired (CAP), healthcare-associated (HCAP), hospital-acquired (HAP), or ventilator-associated (VAP). CAP is one of the most common reasons for hospitalization in the United States. HCAP is defined as occurring in individuals with recent hospitalization, residence in a nursing home or extended care facility, home infusion therapy, chronic dialysis, or home wound care. It is estimated that nearly one third of all hospital admissions for pneumonia are now considered HCAP. HAP is the second most common nosocomial infection (urinary tract infection [UTI] most common), but has the greatest mortality (overall 20% to 50% mortality). VAP occurs in 9% to 27% of individuals who require intubation and mechanical ventilation.[106-108] The microorganisms that most commonly cause CAP are different from those infections that cause HCAP, HAP, and VAP (Box 35-1). In addition, the characteristics of the individual are important in determining which etiologic microorganism is likely; for example, immunocompromised persons tend to be susceptible to opportunistic infections that are uncommon in normal adults (see Box 35-1).

PATHOPHYSIOLOGY. Aspiration of oropharyngeal secretions is the most common route of lower respiratory tract infection; thus the nasopharynx and oropharynx constitute the first line of defense for most infectious agents. Another route of infection is through the inhalation of microorganisms that have been released into the air when an infected individual coughs, sneezes, or talks, or from aerosolized water, such as that from contaminated respiratory therapy equipment. This route of infection is most important in viral and mycobacterial pneumonias and in *Legionella* outbreaks. Endotracheal tubes become colonized with bacteria that form biofilms (protected colonies of bacteria that are resistant to host defenses and treatment with antibiotics) and can seed the lung with microorganisms, especially during endotracheal suctioning.[109] Pneumonia also can occur when bacteria are spread to the lungs in the blood from bacteremia that can result from infection elsewhere in the body or from intravenous drug use.

In healthy individuals, pathogens that reach the lungs are expelled or held in check by mechanisms of self-defense (see Chapters 7, 8, and 34). If a microorganism enters the upper airway defense mechanisms, such as the cough reflex and mucociliary clearance, the next line of defense is the airway epithelial

BOX 35-1 ETIOLOGIC MICROORGANISMS FOR PNEUMONIA IN ADULTS

cell. Airway epithelial cells can recognize some pathogens directly (e.g., *Pseudomonas aeruginosa* and *Staphylococcus aureus*). However, the most important guardian cell of the lower respiratory tract is the alveolar macrophage and it recognizes pathogens through its pattern-recognition receptors (e.g., Toll-like receptors). Macrophages present infectious antigens to the adaptive immune system, activating T cells and B cells with the induction of cellular and humoral immunity. Release of TNF-α and IL-1 from macrophages and chemokines and chemotactic signals from mast cells and fibroblasts contributes to widespread inflammation in the lung with recruitment of neutrophils from the capillaries of the lungs into the alveoli. Neutrophils are critical phagocytes that kill microbes through the formation of phagolysosomes filled with degradative enzymes, antimicrobial proteins, and toxic oxygen free radicals.[110]

Neutrophils have also been found to extrude a meshwork of proteins called a neutrophil extracellular trap (NET) that can capture any bacteria that have not yet been phagocytosed. Unfortunately, many pathogens, such as the pneumococcus, can release a DNase that cleaves the NET and thus escape neutrophil defense.[111] The release of inflammatory mediators and immune complexes can damage bronchial mucous membranes and alveolocapillary membranes, causing the acini and terminal bronchioles to fill with infectious debris and exudate. In addition, some microorganisms release toxins from their cell walls that can cause further lung damage. The accumulation of exudate in the acinus leads to dyspnea and to $\dot{V}/\dot{Q}$ mismatching and hypoxemia.

Pneumococcal Pneumonia. The pathogenesis of pneumococcal pneumonia *(Streptococcus pneumoniae)* has been well documented and serves as a model for understanding other forms of bacterial pneumonia (Figure 35-18). *S. pneumoniae* microorganisms initiate innate and adaptive immune responses (see Chapters 7 and 8). The immune response includes complement activation and the production of antibodies, which are crucial for opsonizing the encapsulated bacterium. Rapid lysis of pneumococcal bacteria (as occurs with antibiotic treatment) results in the release of intracellular bacterial proteins that can be toxic. The best known of these proteins is pneumolysin, which is cytotoxic to virtually every cell in the lung and is partially responsible for the worsening in clinical symptoms sometimes seen in individuals immediately after they begin antibiotic treatment.[112] Inflammatory cytokines and cells are released that cause alveolar edema. Edema creates a medium for the multiplication of bacteria and aids in the spread of infection into adjacent portions of the lung. The involved lobe undergoes consolidation, which alveoli fill with blood cells, fibrin, edematous fluid, and pneumococci, giving lung tissue a red appearance. This passes into the stage in which affected tissues become gray because of fibrin deposition over the pleural surfaces and the presence of fibrin and neutrophils in the consolidated alveoli, where phagocytosis is rapidly taking place. With resolution, increasing numbers of macrophages appear in the alveolar spaces, the neutrophils degenerate, and the fibrin threads and remaining bacteria are digested by macrophages and removed by lymphatic vessels. Usually infection is limited to one or two lobes.

Viral Pneumonia

Viral pneumonia is seasonal, usually mild and self-limiting, but it can set the stage for a secondary bacterial infection (especially by *S. aureus* and *Streptococcus pneumoniae*) by providing an ideal environment for bacterial growth and by damaging ciliated epithelial cells, which normally prevent pathogens from reaching the lower airways.[113] Viral pneumonia can be a primary infection (e.g., influenza pneumonia) or a complication of another viral illness (e.g., chickenpox, measles). Influenza virus is the most common viral cause of pneumonia. The virus not only destroys the ciliated epithelial cells, but also invades the goblet cells and bronchial mucous glands. Sloughing of destroyed bronchial epithelium occurs throughout the respiratory tract, preventing mucociliary clearance. Bronchial walls become edematous and infiltrated with leukocytes.[114]

Some forms of viral pneumonia can progress to severe systemic illness with many complications and a high morbidity and mortality. Severe viral pneumonia can include common types of influenza that can be fatal, especially in older adults.[115] Other severe viral infections are considered opportunistic infections, such as cytomegalovirus pneumonia in immunocompromised individuals. New or atypical forms of viral infection, such as swine influenza A (H1N1) virus, avian influenza A (H5N1) virus, and the coronavirus that causes severe acute respiratory syndrome (SARS), are affecting previously healthy populations and pose a considerable threat for pandemics.[116,117]

CLINICAL MANIFESTATIONS. Most cases of pneumonia are preceded by an upper respiratory tract infection, which is usually viral. This is then followed by the onset of cough, dyspnea, and fever. The cough is often productive, but may be nonproductive, especially in viral pneumonia. Other symptoms include chills, malaise, and pleuritic chest pain. Physical examination may reveal signs of pulmonary consolidation, such as inspiratory crackles, increased tactile fremitus, egophony, and whispered pectoriloquy. Individuals also may demonstrate symptoms and signs of underlying systemic disease or sepsis.

EVALUATION AND TREATMENT. Diagnosis is made on the basis of history, physical examination (tachypnea, tachycardia, crackles, bronchial breath sounds, and findings of pleural effusion), white blood cell count, chest x-ray, stains and cultures of blood, and cultures of respiratory secretions. The white blood cell count is usually elevated, although it may be low if the individual is debilitated, immunocompromised, or has overwhelming infection.[118] Chest radiographs show infiltrates that may involve a single lobe of the lung or may be more diffuse. Once the diagnosis of pneumonia has been made, the pathogen is identified by means of sputum characteristics (Gram stain, color, odor) and cultures or, if sputum is absent, blood cultures. Because many pathogens exist in the normal oropharyngeal flora, the specimen may be contaminated with pathogens from oral secretions. If sputum studies fail to identify the pathogen, the individual is immunocompromised, or the individual's condition worsens, further diagnostic studies may include molecular testing of blood or urine, bronchoscopy, or lung biopsy.[119,120]

Prevention of pneumonia includes prevention of aspiration, respiratory isolation of immunocompromised individuals, vaccination for appropriate populations, and reduction of ventilator-associated pulmonary infections through a variety of dental and endotracheal tube interventions.[109,121,122] The first step in the management of pneumonia is establishing adequate ventilation and oxygenation. Most individuals have hypoxemia and a respiratory alkalosis, although persons with underlying lung disease may require ventilation. Adequate hydration and good pulmonary hygiene (e.g., deep breathing, coughing, chest physical therapy) are also important.

Antibiotics are used to treat bacterial pneumonia; however, resistant strains of *Pneumococcus* are becoming more prevalent.[123] In individuals for whom a specific microorganism is not identified, empirical antibiotics are chosen based on the likely causative microorganism.[124,125] Viral pneumonia is usually treated with supportive therapy alone (unless secondary bacterial infection is present); however, antivirals may be needed in severe cases. Infections with opportunistic microorganisms may be polymicrobial and require multiple drugs, including antifungals.

Tuberculosis

Tuberculosis (TB) is an infection caused by *Mycobacterium tuberculosis*, an acid-fast bacillus that usually affects the lungs, but may invade other body systems. TB is the leading cause of death from a curable infectious disease throughout the world. TB cases increased greatly during the mid-1990s because of AIDS. Individuals with AIDS are highly susceptible to respiratory tract infections, including multidrug-resistant TB.[126] Many ambitious programs for prevention and treatment have been initiated worldwide and the World Health Organization (WHO) *2011 Global Tuberculosis Control Report* indicates that global TB incidence and prevalence have declined in most regions of the world in recent years.[127] In the United States, the incidence of TB has reached its lowest level since 1953, but the rate of decline has begun to slow with more than half of new cases of TB occurring in foreign-born individuals, especially among non-Hispanic Asians, non-Hispanic blacks, and Hispanics.[128]

PATHOPHYSIOLOGY. TB is highly contagious and is transmitted from person-to-person in airborne droplets. Host susceptibility to infection is influenced by host and parasite genetic polymorphisms, including those that affect macrophages, tumor necrosis factor, and interleukins.[129] In immunocompetent individuals, the microorganism usually is contained by the inflammatory and immune response systems, and latent TB infection (LTBI) develops with no clinical evidence of disease.[130] Microorganisms lodge in the lung periphery, usually in the upper lobe. Once the bacilli are inspired into the lung, they multiply and cause nonspecific pneumonitis (lung inflammation). Some bacilli migrate through the lymphatics and become lodged in the lymph nodes, where they encounter lymphocytes and initiate the immune response. Inflammation in the lung causes neutrophils and macrophages to migrate to the area. These cells are phagocytes that engulf the bacilli and begin the process by which the body's defense mechanisms isolate the bacilli, preventing their spread. However, the bacterium is successful as a pathogen because it can survive within macrophages, resist lysosomal killing, multiply within the cell, form well-organized

granulomas creating a confined environment, terminate its own central metabolism, stop replication, and transit into a stage of dormancy rendering itself extremely resistant to host defense and drug treatment.[131,132] In defense, macrophages and lymphocytes release interferon, which inhibits the replication of the microorganisms and stimulates more macrophages to attack the bacterium. Apoptotic infected macrophages also can activate cytotoxic T cells (CD8). Neutrophils, lymphocytes, and macrophages seal off the colonies of bacilli, forming a granulomatous lesion called a *tubercle*.[133] Infected tissues within the tubercle die, forming cheeselike material called *caseation necrosis.* (Necrosis is described in Chapter 2.) Collagenous scar tissue then grows around the tubercle, completing isolation of the bacilli. The immune response is complete after about 10 days, preventing further multiplication of the bacilli.

Once the bacilli are isolated in tubercles and immunity develops, TB may remain dormant for life.[134] If the immune system is impaired, progressive active disease occurs and may spread through the blood and lymphatics to other organs. Infection with human immunodeficiency virus (HIV) is the single greatest risk factor for reactivation of tuberculosis infection. Cancer, immunosuppressive medications, poor nutritional status, renal failure, and other debilitating diseases can reactivate disease.

CLINICAL MANIFESTATIONS. Latent TB infection is asymptomatic. Symptoms of active disease develop so gradually that they are not noticed until the disease is advanced. However, symptoms can appear in immunosuppressed individuals within weeks of exposure to the bacillus. Common clinical manifestations include fatigue, weight loss, lethargy, anorexia (loss of appetite), a low-grade fever that usually occurs in the afternoon, and night sweats. (These are common signs and symptoms of all chronic infections.) A cough that produces purulent sputum develops slowly and becomes more frequent over several weeks or months. Dyspnea, chest pain, and hemoptysis also may occur as the disease progresses. Extrapulmonary TB disease is common in HIV-infected individuals and may cause neurologic deficits, meningitis symptoms, bone pain, and urinary symptoms.

EVALUATION AND TREATMENT. TB is diagnosed by a positive tuberculin skin test (TST; purified protein derivative [PPD]), sputum culture, immunoassays, and chest radiographs.[135,136] A positive tuberculin skin test indicates the need for yearly chest radiographs to detect active disease. The skin test does not differentiate between past, latent, or active forms of the disease. In addition, those individuals who have received the TB vaccine with bacille Calmette-Guérin (BCG) will have a positive TST even if they have never had TB. When active pulmonary disease is present, the tubercle bacillus can be cultured from the sputum and may be seen with an acid-fast stain. However, sputum culture can take up to 6 weeks to become positive. Chest radiographs of individuals with current or previous active disease demonstrate characteristic changes. Nodules, calcifications, cavities, and hilar enlargement (enlarged mediastinal lymph nodes) commonly are seen in the upper lobes. Two immunoassays (enzyme-linked immunospot and quantitative blood interferon-gamma assay) are available. These new tests are more sensitive and specific for the diagnosis of latent TB and are not confounded by previous BCG vaccination. However, they are often not available in high poverty populations and new techniques need to be developed for cost-effective and simple to use diagnostic tests.[137] Prevention of tuberculosis infection is a complex challenge. Isolating individuals with active tuberculosis, limiting use of immunosuppressive medications, and treating underlying immunocompromising diseases, such as AIDS, are all critical steps. Development of an effective TB vaccine has been elusive and vaccines are currently in clinical development.[138]

Treatment consists of combinations of antibiotics (isoniazid, rifampin, pyrazinamide, and ethambutol) to control active disease or prevent reactivation of latent TB infection. The choice of drugs and the duration of treatment depend on the individual's health history, the likelihood of bacterial resistance to certain drugs, and the presence of active disease. The waxy coat of *M. tuberculosis* renders it impermeable to many common drugs. For drug-resistant bacilli, the recommended treatment is administration for an 18-month timeframe of a combination of at least four drugs to which the microorganism is susceptible, including a review of drug effectiveness at 6 months.[139] New drugs and drug combinations are being tested to overcome drug resistance, including immune amplifiers.[140,141]

Abscess Formation and Cavitation

An **abscess** is a circumscribed area of suppuration and destruction of lung parenchyma. Abscess formation follows **consolidation** of lung tissue, in which inflammation causes alveoli to fill with fluid, pus, and microorganisms. Necrosis (death and decay) of consolidated tissue may progress proximally until it communicates with a bronchus. If this occurs, the abscess empties into the bronchus, leaving a cavity that has a radiographic appearance similar to that of a lesion of tuberculosis.

Pneumonia caused by aspiration or by exposure to *Klebsiella* or *Staphylococcus* is the most common cause of abscess formation. Aspiration abscess is usually associated with alcohol abuse, seizure disorders, general anesthesia, and swallowing disorders. Immunocompromised individuals also are at greater risk for lung abscesses and may be infected with opportunistic microorganisms, such as fungi and mycobacteria. The clinical manifestations of abscess formation are similar to those of pneumonitis: fever, cough, chills, excessive sputum production, and pleural pain. Abscess communication with a bronchus causes a severe cough, copious amounts of often foul-smelling sputum, and occasionally hemoptysis. **Cavitation** is the process of abscess emptying and cavity formation. Diagnosis is made by radiography. Treatment includes the administration of appropriate antibiotics and chest physical therapy, including chest percussion and postural drainage. Bronchoscopy may be performed to drain the abscess.[142]

Acute Bronchitis

Acute bronchitis is acute infection or inflammation of the airways or bronchi. The vast majority of cases of acute bronchitis are caused by viruses. Many of the clinical manifestations are similar to those of pneumonia (i.e., cough, fever, chills, malaise), but physical examination does not reveal signs of pulmonary consolidation and chest radiographs do not show

FIGURE 35-19 **Pulmonary Embolus.** The embolus extends into major branches of the pulmonary artery. (From Kumar V et al: *Robbins & Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.)

infiltrates. Individuals with viral bronchitis usually have a nonproductive cough that occurs in paroxysms and is aggravated by cold, dry, or dusty air. However, purulent sputum may be produced with some viral infections. Chest pain often develops from the effort of coughing. Treatment consists of rest, aspirin, humidity, and a cough suppressant, such as codeine.

Individuals with bacterial bronchitis have a productive cough, fever, and pain behind the sternum (breast bone) that is aggravated by coughing. It is rare in previously healthy adults except after viral infection, but is common in those with COPD. Bacterial bronchitis is treated with rest, aspirin, humidity, and antibiotics.[143]

Pulmonary Vascular Disease

Blood flow through the lungs can be disrupted by a number of disorders that result in occlusion of the vessels, an increase in pulmonary vascular resistance, or destruction of the vascular bed. The consequences of altered pulmonary blood flow may be of no functional significance or can result in severe and life-threatening changes in ventilation-perfusion ratios. Major disorders that result from pulmonary vascular diseases include pulmonary embolism, pulmonary hypertension, and cor pulmonale.

Pulmonary Embolism

Pulmonary embolism (PE) is occlusion or partial occlusion of the pulmonary artery or its branches by an embolus. PE most commonly results from embolization of a clot from deep venous thrombosis involving the lower leg (see Chapter 32). Other less common nonthrombotic emboli include tissue fragments, lipids (fats), a foreign body, or an air bubble (Figure 35-19). Risk factors for PE include conditions and disorders that promote blood clotting as a result of *venous stasis* (immobilization, heart failure), *hypercoagulability* (inherited coagulation disorders, malignancy, hormone replacement, oral contraceptives, pregnancy), and *endothelial injury* to the cells that line the vessels (trauma, caustic intravenous infusions). Increased risk for thrombosis associated with hemodynamic stasis, hypercoagulability, and endothelial injury is known as Virchow's triad[144] (see Chapter 32). Genetic risks include factor V Leiden mutation (activated protein C resistance), antithrombin II deficiency, protein S deficiency, protein C deficiency, and prothrombin *20210* gene mutations. No matter its source, a blood clot becomes an embolus when all or part of it breaks away from the site of formation and begins to travel in the bloodstream.[145,146] Thromboembolism is described further in Chapter 32.

PATHOPHYSIOLOGY. The effect of the embolus depends on the extent of pulmonary blood flow obstruction, the size of the affected vessels, the nature of the embolus, and the secondary effects.[147] Pulmonary emboli can result in any of the following:

1. Embolus with infarction: an embolus that causes infarction (death) of a portion of lung tissue
2. Embolus without infarction: an embolus that does not cause permanent lung injury (perfusion of the affected lung segment is maintained by the bronchial circulation)
3. Massive occlusion: an embolus that occludes a major portion of the pulmonary circulation (i.e., main pulmonary artery embolus)
4. Multiple pulmonary emboli: multiple emboli may be chronic or recurrent

As a result of the thrombus lodging in the pulmonary circulation, there is a release both of neurohumoral substances, such as serotonin, histamine, catecholamines, and angiotensin II, and of inflammatory mediators, such as endothelin, leukotrienes, thromboxanes, and toxic oxygen free radicals. This causes widespread vasoconstriction that further impedes blood flow to the lung. Hemodynamically, this results in increased pulmonary artery pressures and can lead to right heart failure.[148] Absent blood flow to a lung segment causes a ventilation-perfusion mismatch (increased dead space) and a decrease in surfactant production. The resulting atelectasis of the affected lung segments further contributes to hypoxemia. If the thrombus is large enough, infarction of lung tissue, dysrhythmias, decreased cardiac output, shock, and death are possible.[149] The pathogenesis of venous thromboembolism is summarized in Figure 35-20.

If the embolus does not cause infarction, the clot is dissolved by the fibrinolytic system (see Chapter 27) and pulmonary function returns to normal. If pulmonary infarction occurs, shrinking and scarring develop in the affected area of the lung. The risk of recurrent venous thromboembolism is 30% over the next 10 years, and is much higher in those individuals who have irreversible risk factors for the disease.[150]

CLINICAL MANIFESTATIONS. In most cases the clinical manifestations of PE are nonspecific; therefore, evaluation of risk factors and predisposing factors is an important aspect of diagnosis. Consequently, the recognition of individuals at high risk for PE is crucial to assessing the clinical presentation. A list of an individual's predisposing factors for venous thromboembolism can be inserted into one of several clinical prediction models (e.g., Wells Prediction Rule model) to obtain a prediction score that helps determine risk probability.[151] In suspected PE, assessment for DVT may indicate the presence of a lower extremity source for the thromboembolism. Calf pain and tenderness, along with calf asymmetry when documented with a tape measure, are some of the most important findings in DVT. Unfortunately, DVT is often asymptomatic and clinical examination has low

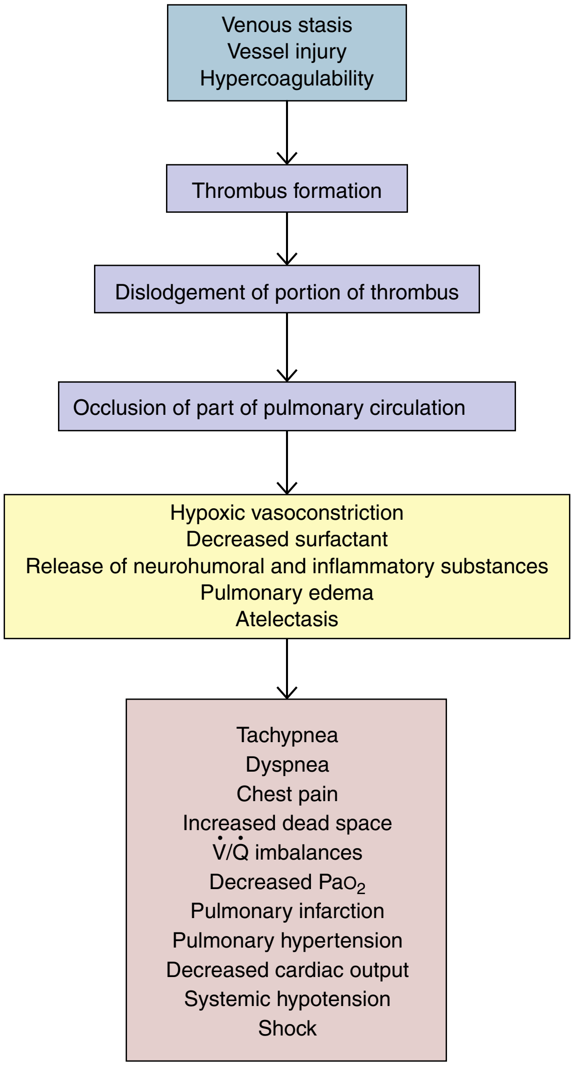

FIGURE 35-20 Pathogenesis of Massive Pulmonary Embolism Caused by a Thrombus (Pulmonary Thromboembolism).

sensitivity for the presence of a clot, especially in the thigh and pelvis. Therefore, the lack of clinical indicators for DVT does not rule out the possibility for PE.

An individual with PE usually presents with the sudden onset of pleuritic chest pain, dyspnea, tachypnea, tachycardia, and unexplained anxiety. Occasionally syncope (fainting) or hemoptysis occurs. With large emboli, a pleural friction rub, pleural effusion, fever, and leukocytosis may be noted. Recurrent pulmonary emboli occur in individuals with a history of previous emboli. Recurrent small emboli may not be detected until progressive incapacitation, precordial pain, anxiety, dyspnea, and right ventricular enlargement are exhibited. Massive occlusion causes profound shock, hypotension, tachypnea, tachycardia, severe pulmonary hypertension, and chest pain.

EVALUATION AND TREATMENT. When an individual is suspected of having a PE based on the presence of risk factors, symptoms, and physical findings, a chest x-ray, arterial blood gas, and electrocardiogram (ECG) are obtained immediately. Chest x-ray findings are nonspecific in PE and often can be normal for the first 24 hours until atelectasis occurs in the lung. The arterial blood gas results commonly reveal hypoxemia with a respiratory alkalosis (most individuals will hyperventilate in response to PE). The ECG may show evidence of strain on the right side of the heart. The serum D-dimer level measures a product of thrombus degradation by the fibrinolytic system and, if normal, makes the presence of a PE highly unlikely. Further evaluation is conducted using single or multidetector spiral CT arteriography.[152,153] This highly sensitive and specific test has replaced the radionucleotide ventilation-perfusion scan in most hospitals. Magnetic resonance imaging (MRI) is used in some centers. In rare cases, a pulmonary angiogram is necessary to confirm the diagnosis of PE. Recently, the measurement of elevated serum troponin I levels has been useful in stratifying the risk and severity of PE because it increases with right ventricular strain or failure.[154] Diagnostic algorithms guide diagnosis and treatment.[153]

The ideal treatment of PE is prevention through risk factor recognition and elimination of predisposing factors. Venous stasis in hospitalized individuals is minimized by bed exercises, frequent position changes, early ambulation, and pneumatic calf compression.[155] Most at-risk individuals also will receive prophylactic anticoagulation with unfractionated heparin, low-molecular-weight heparin, warfarin, or fondaparinux.[156] In individuals who have contraindications to anticoagulation, the placement of a filter in the inferior vena cava can prevent emboli from reaching the lungs.[157]

Management of PE begins with administration of oxygen and hemodynamic stabilization with fluids, if needed, followed by rapid administration of anticoagulation, usually unfractionated or low-molecular-weight heparin and factor Xa inhibitors (fondaparinux, idraparinux, rivaroxaban, and apixaban).[155,157] If a massive life-threatening embolism occurs, a fibrinolytic agent, such as streptokinase, can be used and may be infused through a pulmonary artery catheter. Some individuals require emergent percutaneous or surgical embolectomy.[158] Reversal of the underlying cause of the thrombus is important in preventing recurrent venous thromboembolism.

Pulmonary Artery Hypertension

Pulmonary artery hypertension (PAH) is defined as a mean pulmonary artery pressure greater than 25 mmHg at rest.[159] Pulmonary artery pressure is lower than systemic arterial pressure and is normally 15 to 18 mmHg. Box 35-2 contains the WHO clinical categories for PAH. Idiopathic PAH (IPAH) is rare and usually occurs in women between the ages of 20 and 40 years.[159,160] Familial PAH (FPAH) is caused by mutations in the gene encoding the bone morphogenetic protein receptor type II (BMPR2).[160,161] Associated PAH (APAH) is a leading cause of mortality in many connective tissue disorders (e.g., scleroderma) and affects up to 1 in 200 individuals infected with HIV.[160] Diet drugs, amphetamines, and cocaine also have been linked to an increased risk for PAH. Pulmonary artery hypertension associated with left heart failure or valvular disease is caused by increased pulmonary venous pressure and is discussed in Chapter 32. COPD is the most common lung disease associated with PAH, but any condition that causes chronic hypoxemia can result in pulmonary hypertension. Recurrent pulmonary embolism may be subclinical in

BOX 35-2 CLASSIFICATION OF PULMONARY HYPERTENSION (DANA POINT, 2008)

1. Pulmonary artery hypertension (PAH)
   1.1 Idiopathic (IPAH)
   1.2 Heritable
      1.2.1 BMPR2
      1.2.2 ALK1, endoglin (with or without hereditary hemorrhagic telangiectasia)
      1.2.3 Unknown
   1.3 Drug and toxin induced
   1.4 Associated with (APAH)
      1.4.1 Connective tissue disease
      1.4.2 HIV infection
      1.4.3 Portal hypertension
      1.4.4 Congenital heart disease

its presentation and unrecognized until the signs and symptoms of PAH are detected.

PATHOPHYSIOLOGY. Idiopathic PAH is characterized by endothelial dysfunction with overproduction of vasoconstrictors (e.g., thromboxane and endothelin) and decreased production of vasodilators (e.g., nitric oxide and prostacyclin).[159,160] Release of growth factors causes proliferation of endothelial cells, smooth muscle cells, and fibroblasts, resulting in patchy changes in precapillary pulmonary arteries (resistance vessels). This process results in luminal narrowing and abnormal vasoconstriction and is called *remodeling.*[162] Increased cytosolic calcium (vasoconstriction), phosphodiesterases (modulate cellular proliferation), serotonin (vasoconstrictor), and adrenomedullin (vasodilator) also play a role in the pathogenesis of this disorder. These combined changes cause resistance to pulmonary artery blood flow, thus increasing the pressure in the pulmonary arteries. As resistance and pressure increase, the workload of the right ventricle increases and subsequent right ventricular hypertrophy, followed by failure, may occur (cor pulmonale). Gas exchange is reduced with restriction in lung volumes. In individuals with *BMPR2* gene mutations, intracellular signaling abnormalities result in vascular proliferation. Eventually death results in most individuals with PAH. The pathogenesis of pulmonary artery hypertension and cor pulmonale, resulting from disease of the respiratory system or hypoxia, is shown in Figure 35-21.

Pulmonary hypertension associated with lung respiratory disease or hypoxia, or both, is a serious complication of many acute and chronic pulmonary disorders, such as COPD and hypoventilation associated with obesity. These conditions are complicated by hypoxic pulmonary vasoconstriction, which further increases pulmonary artery pressures.[163]

CLINICAL MANIFESTATIONS. Pulmonary artery hypertension may not be detected until it is quite severe. The symptoms are often masked by primary pulmonary or cardiovascular disease. The first indication of pulmonary hypertension is often an abnormality seen on a chest radiograph (enlarged pulmonary arteries

and right heart border) or an electrocardiogram that shows right ventricular hypertrophy. Symptoms of fatigue, chest discomfort, tachypnea and dyspnea on exertion, palpitations, and cough are common. Examination may reveal peripheral edema, jugular venous distention, a precordial heave, and accentuation of the pulmonary compartment of the second heart sound.[164]

EVALUATION AND TREATMENT. Definitive diagnosis and accurate assessment of pulmonary artery pressure can be made only with right-sided heart catheterization. Common diagnostic modalities used to determine the cause include chest x-ray, echocardiography, and computed tomography. The diagnosis of IPAH is made when all other causes of pulmonary hypertension have been ruled out.

Laboratory studies, including arterial blood gas testing, liver function testing, HIV serology, electrocardiography, chest x-ray and CT scanning, pulmonary function testing, polysomnography, ventilation-perfusion scanning, and echocardiography, are used to detect underlying causes of PAH.[159,160] Disease severity is quantified using the New York Heart Association or WHO classification of functional status of patients with pulmonary artery hypertension.[165]

General therapies for PAH include administration of oxygen, diuretics, and anticoagulants and avoidance of contributing factors such as air travel, decongestant medications, nonsteroidal anti-inflammatory medications, pregnancy, and tobacco use. Medications used in the treatment of PAH include prostacyclin analogs (epoprostenol, beraprost, iloprost), endothelin receptor antagonists (bosentan, ambrisentan), and phosphodiesterase-5 inhibitors.[166] Those who fail medical therapy may be candidates for lung transplantation.

The most effective treatment for secondary pulmonary artery hypertension is treatment of the primary disorder. However, once pulmonary hypertension has persisted long enough for hypertrophy of the medial smooth muscle layer to develop (as it does with chronic hypoxemia), it is no longer reversible. Treatment relies on the use of supplemental oxygen to reverse hypoxic vasoconstriction.

Cor Pulmonale

Cor pulmonale is secondary to pulmonary artery hypertension and consists of right ventricular enlargement (hypertrophy, dilation, or both).[167]

PATHOPHYSIOLOGY. Cor pulmonale develops as pulmonary artery hypertension creates chronic pressure overload in the right ventricle similar to that created in the left ventricle by systemic hypertension. (Systemic hypertension is discussed in Chapter 32.) Pressure overload increases the work of the right ventricle, causes hypertrophy of the normally thin-walled heart muscle, and compromises right ventricular myocardial perfusion. Acute hypoxemia, such as might occur with pneumonia, can exaggerate pulmonary hypertension and dilate the ventricle as well. Right ventricular filling pressures are normal until failure occurs. The right ventricle usually fails when pulmonary artery pressure equals systemic blood pressure.

CLINICAL MANIFESTATIONS. The clinical manifestations of cor pulmonale may be obscured by primary respiratory disease and appear only during exercise testing. The heart appears normal at rest, but with exercise, cardiac output falls. The electrocardiogram shows right ventricular hypertrophy. Chest pain is common. The pulmonary component of the second heart sound, which represents closure of the pulmonic valve, may be accentuated, and a pulmonic valve murmur also may be present. Tricuspid valve murmur may accompany the development of right ventricular failure. Peripheral edema, hepatic congestion, and jugular venous distention often may be detected.

EVALUATION AND TREATMENT. Diagnosis is made on the basis of physical examination, radiologic examination, and electrocardiogram or echocardiogram, or both. The goal of treatment for cor pulmonale is to decrease the workload of the right ventricle by lowering pulmonary artery pressure. Treatment is the same as for pulmonary artery hypertension, and its success depends on reversal of the underlying lung disease.

Malignancies of the Respiratory Tract

Laryngeal Cancer

Cancer of the larynx represents approximately 2% to 3% of all cancers in the United States. There were an estimated 12,260 new cases and 3630 deaths in 2013.[168]

The risk of **laryngeal cancer** is increased by the amount of tobacco smoked; risk is further heightened with the combination of smoking and alcohol consumption. Gastroesophageal reflux disease is also a risk factor.[169] The human papillomavirus (HPV) has been linked to both benign and malignant disease of the larynx.[170] The highest incidence is in men between 50 and 75 years of age.

PATHOPHYSIOLOGY. Carcinoma of the true vocal cords (glottis) is more common than that of the supraglottic structures (epiglottis, aryepiglottic folds, arytenoids, and false cords). Tumors of the subglottic area are rare. Squamous cell carcinoma is the most common cell type, although small cell carcinomas also occur (Figure 35-22). Laryngeal dysplasia has a high risk of progressing to malignancy. Metastasis develops by spreading to the draining lymph nodes, and distant metastasis, usually to the lung, is rare.

CLINICAL MANIFESTATIONS. The presenting symptoms of laryngeal cancer include hoarseness, dyspnea, and cough. Progressive hoarseness is the most significant symptom and can result in voice loss. Dyspnea is rare in the case of supraglottic tumors, but can be severe in subglottic tumors. Cough occurs less commonly and may follow swallowing. Laryngeal pain or a sore throat is likely to be present with supraglottic lesions.

EVALUATION AND TREATMENT. Evaluation of the larynx includes external inspection and palpation of the larynx and the lymph nodes in the neck. Indirect laryngoscopy provides a stereoscopic view of the structure and movement of the larynx. A biopsy also can be obtained during this procedure. Direct laryngoscopy provides specific visualization of the tumor. Plain films of the larynx and CT facilitate the identification of tumor boundaries and the degree of extension to surrounding tissue. Magnetic resonance imaging (MRI) and positron-emission tomography (PET) can be used for staging.

Combined chemotherapy and radiation can result in cure in selected cases; however, sequelae such as swallowing and speech difficulties may result.[171] Photodynamic therapy improves

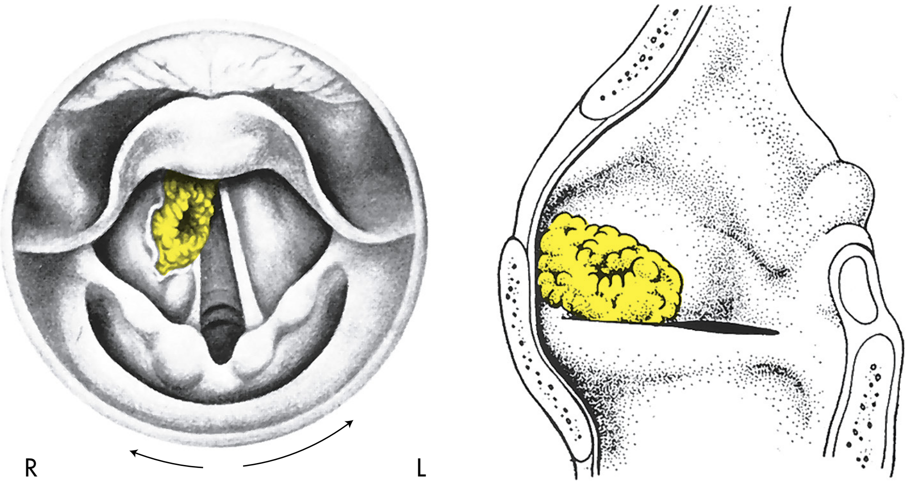

FIGURE 35-22 Laryngeal Cancer. **A,** Mirror view of carcinoma of right false cord partially hiding true cord. **B,** Lateral view. (From del Regato JA, Spjut HJ, Cox JD: *Ackerman and del Regato's cancer,* ed 2, St Louis, 1985, Mosby.)

outcomes while preserving function in many individuals with early stage disease. Partial laryngectomies are the preferred treatment for small supraglottic and subglottic malignancies. Total laryngectomy is required when lesions are extensive and involve the cartilage.[172,173] Swallowing and speech therapy after treatment can significantly improve recovery.

Lung Cancer

Lung cancers (bronchogenic carcinomas) arise from the epithelium of the respiratory tract. As such, the term *lung cancer* excludes other pulmonary tumors, including sarcomas, lymphomas, blastomas, hematomas, and mesotheliomas. Important trends in lung cancer are summarized in Box 35-3. The most common cause of lung cancer is tobacco smoking, and approximately 10% to 15% of active smokers will develop lung cancer. About 10% to 25% of lung cancers occur in never-smokers and it is estimated that one fourth of lung cancer cases among never-smokers could be attributed to exposure to passive tobacco smoke.[174] Tobacco smoke contains several organ-specific carcinogens, and smoking has been causally related to carcinogenesis at several sites, including the larynx, oral cavity, esophagus, and urinary bladder. Many genetic mechanisms have been implicated in the risk for lung cancer including gene mutations, gene amplification, increases in protein expression, losses in protein expression, tumor-suppressing alterations, tumor-acquired DNA methylation, and chromosomal aberrations[175] (see What's New? Genetic and Immunologic Breakthroughs in Lung Cancer Treatment). Theories of carcinogenesis are discussed in Chapter 12. Currently there are no specific tools for predicting risk for or rate of progression of lung cancer.[176]

Environmental or occupational risk factors associated with lung cancer include benzopyrene, radon gas, metals (chromium, cadmium, arsenic), asbestos fibers, diesel exhaust, nitrogen mustard gases, nickel, silica, vinyl chloride, and chloromethyl methyl ether.[168] Primary lung cancers arise from cells that line the bronchi within the lungs and are therefore called *bronchogenic carcinomas*. It is now believed that most of these

BOX 35-3 IMPORTANT TRENDS FOR LUNG CANCER

Incidence
An estimated 22,190 new cases in 2013: 118,080 in men and 110,100 in women.

Mortality
An estimated 159,480 deaths in 2012: 87,260 in men and 72,200 in women. The death rate in men is declining but continues to rise for women, and lung cancer remains by far the greatest cancer killer of men and women.

Risk Factors
Cigarette smoking is the number one risk factor. Environmental smoke exposure (exposure to someone else's cigarette smoke) increases the risk of lung cancer. Occupational risk factors include exposure to asbestos dust, arsenic, chromium, nickel, ionizing radiation, chloromethyl methyl ether, coal products, mustard gas, and vinyl chloride.

Warning Signs
A persistent cough, sputum streaked with blood, chest pain, recurring attacks of pneumonia or bronchitis, weight loss, hard nodes in neck or axilla.

Early Detection and Prevention
Lung cancer is very difficult to detect early. Periodic chest x-ray films, sputum cytologic analysis, and computed tomography can detect presymptomatic, early stage lung cancers, particularly of the squamous cell type; however, no conclusive evidence of reduction in lung cancer mortality as a consequence of screening has been found.

Treatment
Surgical resection of the entire tumor is the only treatment that results in cure; however, the disease is often too advanced by the time of diagnosis for surgery to be indicated. Radiation therapy and chemotherapy can be used as adjunctive or palliative treatment modalities. New treatments include gene and immunotherapies.

Survival
Although the stage of cancer progression at the time of diagnosis greatly affects prognosis, overall only 20% of individuals live 5 or more years after diagnosis.

Data from American Cancer Society: *Cancer facts and figures 2013*. Available at www.cancer.org/research/cancerfactsfigures/cancerfactsfigures/cancer-facts-figures-2013.

WHAT'S NEW?

Genetic and Immunologic Breakthroughs in Lung Cancer Treatment

New chemotherapeutic agents have slightly improved outcomes in the management of lung cancer, but overall survival rates for advanced stage disease remain poor and the toxicities of these regimens limit their use. New understandings of the genetic and immunologic features of lung cancer cells have led to new treatments. Gene therapy is emerging as a way of inducing tumor apoptosis, restoring normal tumor-suppressor gene function (e.g., *p53*), promoting tumor-suicide gene expression, and increasing tumor responsiveness to chemoradiation through gene transfer, thereby restoring normal DNA methylation patterns and altering microRNA function. Immunologic therapies include vaccines that stimulate tumor-specific antibodies, antibodies to epidermal growth factor receptors (erlotinib, gefitinib, and cetuximab), and anti-angiogenesis drugs; direct tumor delivery of activating cytokines; and blocking tumor immunosuppression. The effectiveness of these strategies, the timing of delivery, optimal drug combinations and their side effects are still being evaluated, but new knowledge is leading to new opportunities for treatment.

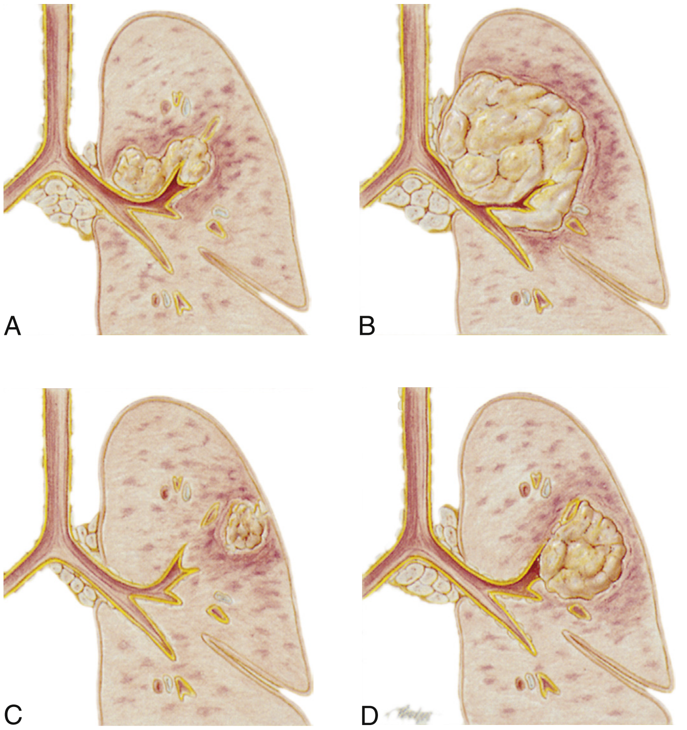

FIGURE 35-23 Cancer of the Lung. **A,** Squamous (epidermoid) cell carcinoma. **B,** Small cell (oat cell) carcinoma. **C,** Adenocarcinoma. **D,** Large cell carcinoma. (From Des Jardins T, Burton GG: *Clinical manifestations and assessment of respiratory disease,* ed 3, St Louis, 1995, Mosby.)

cancers arise from mutated epithelial stem cells. Although there are many types of lung cancer, they are divided into two major categories based on cell histology: non–small cell lung carcinoma (NSCLC, about 85% of all lung cancers) and neuroendocrine tumors (about 14% of all lung cancers). NSCLC can be subdivided into three common types of lung cancer: squamous cell carcinoma, adenocarcinoma, and large cell undifferentiated carcinoma, and they each have cellular subtypes.[177] Neuroendocrine tumors of the lung can be divided into small cell carcinoma, large cell neuroendocrine carcinoma, typical carcinoid tumors, and atypical carcinoid tumors. Small cell carcinoma is the most common of these neuroendocrine tumors. The clinical and pathologic features that most commonly characterize these cancer types are illustrated in Figure 35-23 and described in Table 35-4. Many cancers that arise in other organs of the body metastasize to the lungs; however, these are not considered lung cancers and are categorized by their primary site of origin.

Non–Small Cell Lung Cancer (NSCLC)

Squamous Cell Carcinoma. Squamous cell carcinoma (SCC) accounts for about 30% of bronchogenic carcinomas, representing a sharp decline in incidence in the past two decades. SCC has the strongest association with smoking. Smokers with COPD have a higher incidence of this tumor type.[178] The tumors are typically located centrally near the hila and project into bronchi. Because of this central location, nonproductive cough or hemoptysis is common. Pneumonia and atelectasis are often associated with squamous cell carcinoma (Figure 35-24, *A*). Chest pain is a late symptom associated with large tumors. These tumors can remain fairly well localized and tend not to metastasize until late in the course of the disease.

Adenocarcinoma. Adenocarcinoma (tumor arising from glands) of the lung constitutes 35% to 40% of all bronchogenic carcinomas (Figure 35-24, *B*). Adenocarcinoma occurs more frequently in women, in non-smokers, and in Asians. Environmental tobacco smoke, occupational carcinogens, viruses, hormones, and positive family history are associated with this tumor type.[179] *Epidermal growth factor receptor (EGFR)* mutations are also common in this type of lung cancer.[180] These tumors, which are usually smaller than 4 cm, more commonly arise in the peripheral regions of the pulmonary parenchyma. Pulmonary adenocarcinoma develops in a stepwise fashion through atypical adenomatous hyperplasia, adenocarcinoma in situ, and minimally invasive adenocarcinoma to invasive carcinoma. They may be asymptomatic and discovered by routine chest roentgenogram in the early stages, or the individual may seek treatment for pleuritic chest pain and shortness of breath from pleural involvement by the tumor.

Included in the category of adenocarcinoma is bronchoalveolar cell carcinoma. These tumors tend to arise from the terminal bronchioles and alveoli. They are slow-growing tumors with an unpredictable pattern of metastasis. Metastasis occurs through the pulmonary arterial system and mediastinal lymph nodes. This cell type has the weakest association with smoking.[181]

Diagnosis of NSCLC requires cytologic analysis from biopsy, and therapy is based on histologic and molecular markers (e.g., EGFR tyrosine kinase inhibitors for adenocarcinoma) for a targeted approach to therapy. Surgical resection is possible in a high proportion of adenocarcinoma cases, but because metastasis occurs early (70% of lung cancers present in advanced stages), the 5-year survival rate remains below 15%.[182] Clinical trials are in progress to develop immunotherapies/vaccines for NSCLC.[183]

TABLE 35-4 CHARACTERISTICS OF LUNG CANCERS

TUMOR TYPE	GROWTH RATE	METASTASIS	MEANS OF DIAGNOSIS	CLINICAL MANIFESTATIONS AND TREATMENT
Squamous cell carcinoma	Slow	Late; mostly to hilar lymph nodes	Biopsy, sputum analysis, bronchoscopy, electron microscopy, immunohistochemistry	Cough, sputum production, airway obstruction; treated surgically, chemotherapy adjunctive
Adenocarcinoma	Moderate	Early	Radiography, fiberoptic bronchoscopy, electron microscopy	Pleural effusion; treated surgically, chemotherapy adjunctive
Large cell carcinoma	Rapid	Early and widespread	Sputum analysis, bronchoscopy, electron microscopy (by exclusion of other cell types)	Chest wall pain, pleural effusion, cough, sputum production, hemoptysis, airway obstruction resulting in pneumonia (if airways involved); treated surgically
Small cell (oat cell) carcinoma	Very rapid	Very early; to mediastinum or distally in lung	Radiography, sputum analysis, bronchoscopy, electron microscopy, immunohistochemistry, and clinical manifestations (cough, chest pain, dyspnea, hemoptysis, localized wheezing)	Airway obstruction, signs and symptoms of excessive hormone secretion; treated by chemotherapy and ionizing radiation to thorax and central nervous system

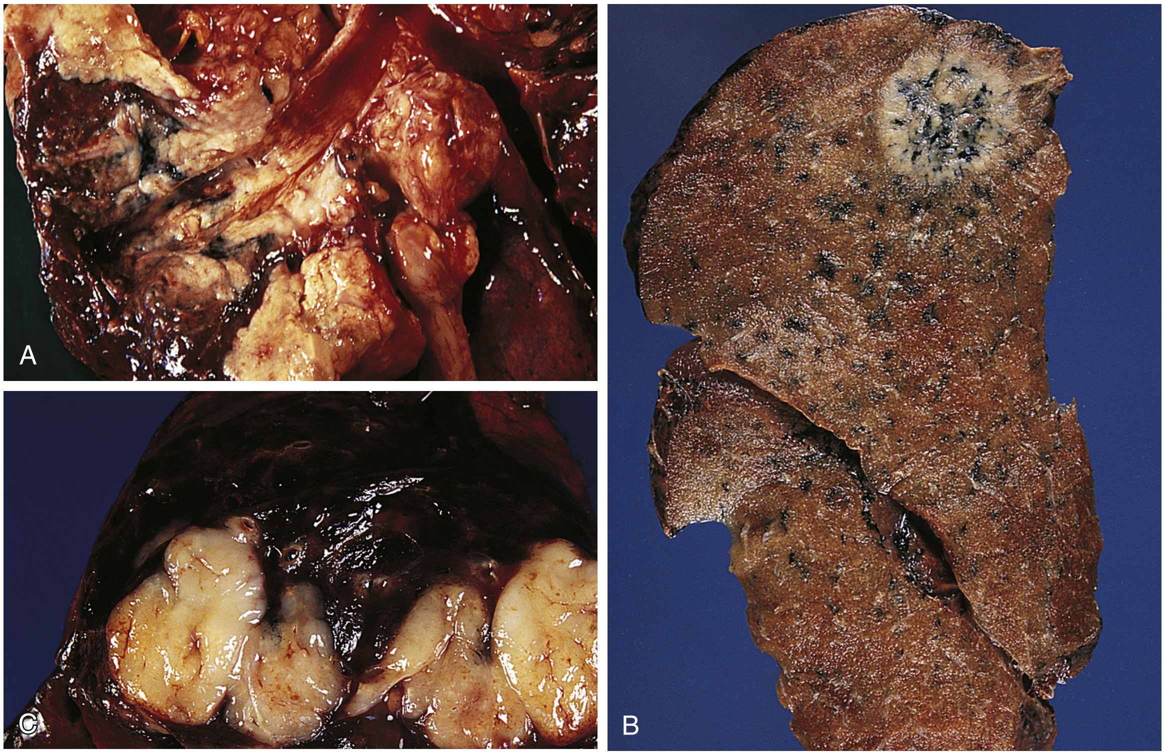

FIGURE 35-24 Lung Cancer. **A,** Squamous cell carcinoma. This hilar tumor originates from the main bronchus. **B,** Peripheral adenocarcinoma. The tumor shows prominent black pigmentation, suggestive of having evolved in an anthracotic scar. **C,** Small cell carcinoma. The tumor forms confluent nodules. On cross sectioning, the nodules have an encephaloid (like brain tissue) appearance. (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

Large Cell Carcinoma (Undifferentiated). **Large cell carcinomas** constitute 10% to 15% of bronchogenic carcinomas. This cell type has lost all evidence of differentiation and is therefore commonly referred to as **undifferentiated large cell anaplastic cancer.** Because large cell carcinomas show none of the histologic findings of squamous cell carcinoma or adenocarcinoma, they are diagnosed by a process of exclusion. The cells are generally larger than leukocytes and contain large, darkly stained nuclei. These tumors commonly arise peripherally but are found centrally and can grow to distort the trachea and cause widening of the carina.

Once metastasis has occurred, surgical therapy is limited to palliative procedures (comfort measures) designed to relieve obstructive pneumonitis or prevent recurrence of pleural

effusion. Neither radiation therapy nor chemotherapy has been successful in increasing survival.

Neuroendocrine Lung Tumors

Small Cell (Oat Cell) Carcinoma. **Small cell lung carcinomas (SCLCs)** are the most common type of neuroendocrine lung tumors and constitute about 14% of bronchogenic carcinomas, but cause 25% of lung cancer deaths.[184] Most tumors arise from the central part of the lung (see Figures 35-23 and 35-24, *C*). Cell sizes range from 6 to 8 μm. This cell type has the strongest correlation with tobacco smoking. Because these tumors show a rapid rate of growth and tend to metastasize early and widely, this type of carcinoma has the worst prognosis of all lung cancers. Staging for small cell carcinoma is divided into only two categories: limited disease (TNM stages I to III: 20% to 30%) and extensive disease (TNM stage IV: 70% to 80%).[185] Survival time for untreated small cell carcinoma is less than 5% at 5 years.[186]

Small cell carcinoma arises from neuroendocrine cells that contain neurosecretory granules and exist throughout the tracheobronchial tree. Thus small cell carcinoma is often associated with tumor-derived hormone production. Hormone production is important to the clinician because resulting signs and symptoms (called *paraneoplastic syndromes*) may be the first manifestation of the underlying cancer. Examples include hyponatremia (antidiuretic hormone), Cushing syndrome (adrenocorticotropic hormone), hypocalcemia (calcitonin), gynecomastia (gonadotropins), and carcinoid syndrome (serotonin).[187]

Bronchial Carcinoid Tumors. **Bronchial carcinoid tumors** are rare, represent about 1% of all lung tumors, are not related to smoking, are slow growing, and have a low potential to metastasize. Carcinoid tumors can occur from childhood through older age. They arise more commonly in the main or segmental bronchi, are easily visualized bronchoscopically, and are found on routine chest radiographs. The tumor cells have dense granules containing neuroendocrine-like hormones, but they rarely produce endocrine symptoms. Cells are not recovered from bronchial washings, because the tumor is covered with normal mucosa. Fifty percent of individuals with bronchial carcinoid tumors are asymptomatic. Local surgical resection is curative if metastasis has not occurred; this can often be done by bronchoscopic resection.[188,189]

Other Lung Cancers. **Adenocystic tumors (cylindromas)** and **mucoepidermoid carcinomas** are rare bronchial gland tumors. They arise predominantly in the trachea or large airways and cause obstruction. They can be malignant and metastasize early, although distal pulmonary metastases are usually slow growing. Thus it is not unusual for an individual to survive 10 to 15 years after diagnosis.

Mesotheliomas are rare tumors associated with asbestos exposure (80%). Most tumors are aggressive malignant tumors arising from mesothelial cells that line the pleural cavities. A long latent interval between exposure to asbestos and appearance of mesothelioma usually occurs, and onset of symptoms may take 20 to 40 years. Clinical manifestations include dyspnea and chest pain that result from tumor-derived pleural fluid and invasion of the chest wall. Early detection is difficult because radiologic studies do not reveal the tumor at an early stage. Diagnosis is made by chest x-ray, CT scan, and thoracentesis with cytologic examination of the pleural fluid. Thoracoscopy also may be used for biopsy. Osteopontin and mesothelin are being explored as potential tumor markers for early diagnosis. Current management of malignant mesothelioma includes a combination of pleuropneumonectomy, chemotherapy, radiation, and hyperthermia.[190,191]

PATHOGENESIS. Environmental carcinogens found in tobacco smoke and asbestos are associated with malignant transformations. Tobacco smoke contains as many as 30 lung carcinogens and is responsible for the vast majority of lung cancers. These carcinogens, along with inherited genetic predisposition to cancers, result in tumor development.[192] Once lung cancer is initiated by these carcinogen-induced mutations, further tumor development is promoted by growth factors that alter cell growth and differentiation, such as epidermal growth factor, and by production of inflammatory mediators, such as toxic oxygen free radicals. The bronchial mucosa suffers multiple carcinogenic "hits" because of repetitive exposure to tobacco smoke, and eventually epithelial cell changes begin to be visible on biopsy. These changes progress from metaplasia to carcinoma in situ and finally to invasive carcinoma.[193] Tumor progression includes invasion of surrounding tissues and, finally, metastasis to distant sites, including the brain, bone marrow, and liver.

CLINICAL MANIFESTATIONS. Symptoms of early stage, localized disease are nonspecific and are likely to be attributed by the individual to the effects of smoking. The clinical manifestations are ambiguous and insidious; they include coughing, chest pain, excessive sputum production, hemoptysis, pneumonia, airway obstruction, pleural effusions, and weight loss. By the time manifestations are severe enough to motivate the individual to seek medical advice, the disease is usually advanced. Symptoms and signs of metastatic disease (e.g., neurologic deficits, bone pain) or paraneoplastic syndromes may be evident.[194]

EVALUATION AND TREATMENT. Although it is clear that diagnosing and treating lung cancer early in its development are crucial for long-term survival, screening for the presence of asymptomatic tumors in high-risk individuals remains controversial. The latest guidelines state that the evidence remains insufficient to recommend screening of asymptomatic individuals with sputum cytologic examination, chest x-ray, or spiral CT. However, many clinicians and researchers continue to examine these and other modalities in an effort to find more effective ways of catching this deadly disease when it is still curable. Screening using low-dose spiral CT scans decreases risk of dying from lung cancer in heavy smokers.[195]

The diagnosis of lung cancer relies on the history of risk factors and symptoms, a careful physical examination, and a constellation of diagnostic tests including sputum cytology, chest x-ray, low-dose CT scanning in high-risk individuals, PET scanning, bronchoscopy, biopsy, testing for epidermal growth factor mutations and other molecular markers, and search for potential metastatic disease.[196] The goal of these evaluations is to (1) establish the presence of a primary lung cancer,

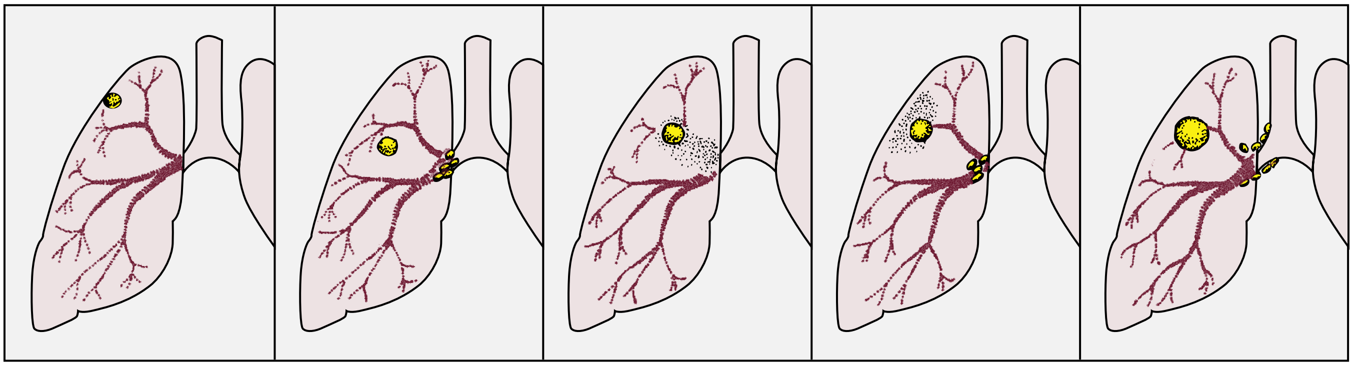

FIGURE 35-25 Staging of Lung Cancer by the TNM Classification System. **A, B,** Stage I disease includes tumors classified as T1, with or without metastasis to the lymph nodes in the ipsilateral hilar region. **C,** Also included in stage I are tumors classified as T2 but having no nodal or distant metastases. **D,** Stage II disease includes those tumors classified as T2, with metastasis only to the ipsilateral hilar lymph nodes. **E,** Stage III includes all tumors more extensive than T2 or any tumor with metastasis to the lymph nodes in the mediastinum or adjacent organs. Stage IV (not shown) involves spread to other organs.

(2) determine its cell type, and (3) stage the tumor. As stated, SCLC is staged as either limited or extensive. The staging of NSCLC uses the **TNM classification system** in which *T* denotes the extent of the primary tumor, *N* indicates nodal involvement, and *M* describes the extent of metastasis, and is illustrated in Figure 35-25.[197] The use of biomarkers is advancing as an approach to early detection and staging of lung cancer and targeted therapies.[198]

For all types of early stage lung carcinoma, the preferred treatment is surgical resection. Once metastasis has taken place, total surgical resection is more difficult and survival rates dramatically decrease. NSCLC is less responsive to chemotherapy than is small cell carcinoma, but chemotherapy (e.g., platinum) and radiation are commonly used as adjuvant or palliative care.[199-201] Small cell carcinoma is usually widely metastasized by the time of diagnosis. Palliative chemotherapy or radiation can improve survival.[202] New treatment modalities, such as dose-intensified radiation radiofrequency ablation, microwave ablation, cryotherapy, and brachytherapy, may be available as primary or palliative treatment for those for whom surgical removal is not an option.[203,204] New and exciting treatments for lung cancer are under investigation, including antiangiogenic therapy, targeting of growth factor receptors, tumor sensitizing agents, gene therapy, and immunotherapy.[205,206] Prevention of lung cancer relies primarily on reduction of exposure to carcinogens. For most individuals this means smoking cessation, and numerous governmental and private organizations are working toward the complete end of cigarette smoking. Other forms of prevention also are being explored, including chemoprevention in the form of dietary supplements and pharmaceuticals.[192,207] Work is in progress to establish the best methods for screening and early detection.[208,209]

SUMMARY REVIEW

Clinical Manifestations of Pulmonary Alterations

1. Dyspnea is a feeling of breathlessness and increased respiratory effort. Orthopnea is dyspnea when a person lies flat. Paroxysmal nocturnal dyspnea occurs at night and requires the person to sit or stand for relief.
2. Coughing is a protective reflex that expels secretions and irritants from the lower airways.
3. Abnormal sputum is a change in the amount, consistency, color, and odor of sputum.
4. Hemoptysis is expectoration of bloody mucus that can be caused by bronchitis, TB, abscess, neoplasms, and other conditions that cause hemorrhage from damaged vessels.
5. Abnormal breathing patterns are adjustments made by the body to minimize the work of respiratory muscles. They include Kussmaul, obstructed, restricted, gasping, and/or Cheyne-Stokes respirations, and sighing.
6. Hypoventilation is decreased alveolar ventilation caused by airway obstruction, chest wall restriction, or altered neurologic control of breathing. Hypoventilation causes increased $Paco_2$.
7. Hyperventilation is increased alveolar ventilation produced by anxiety, head injury, or severe hypoxemia. Hyperventilation causes decreased $Paco_2$.
8. Cyanosis is a bluish discoloration of the skin caused by desaturation of hemoglobin, polycythemia, or peripheral vasoconstriction.
9. Clubbing of the fingertips is associated with diseases that interfere with oxygenation of the tissues.
10. Chest pain can result from inflamed pleurae, trachea, bronchi, or respiratory muscles.
11. Hypercapnia is increased $Paco_2$ caused by a decrease in minute volume (respiratory rate × tidal volume).

SUMMARY REVIEW—cont'd

12. Hypoxemia is a reduced Pa_{O_2} caused by (a) decreased oxygen content of inspired gas, (b) hypoventilation, (c) diffusion abnormality, (d) ventilation-perfusion mismatch, or (e) shunting.
13. Acute respiratory failure is caused by inadequate gas exchange or ventilation (Pa_{O_2} ≤50 mmHg or Pa_{CO_2} ≥50 mmHg and pH ≥7.25).

Disorders of the Chest Wall and Pleura

1. Chest wall compliance is diminished by obesity and kyphoscoliosis, which compress the lungs, and by neuromuscular diseases that impair chest wall muscle function.
2. Flail chest results from rib or sternal fractures that disrupt the mechanics of breathing.
3. Pneumothorax is the accumulation of air in the pleural space. It can be caused by spontaneous rupture of weakened areas of the pleura or can be secondary to pleural damage caused by disease, trauma, or mechanical ventilation.
4. Tension pneumothorax is a life-threatening condition caused by trapping of air in the pleural space.
5. Pleural effusion is the accumulation of fluid in the pleural space, usually resulting from disorders that promote transudation or exudation from capillaries underlying the pleura but occasionally resulting from blockage or injury that causes lymphatic vessels to drain into the pleural space.
6. Empyema is the presence of pus in the pleural space (infected pleural effusion). The source of the pus is usually lymphatic drainage from sites of bacterial pneumonia.

Pulmonary Disorders

1. Aspiration is passage of fluid and solid particles into the lung, usually from impaired swallowing and coughing. It frequently results in pneumonitis and pulmonary infection.
2. Atelectasis is the collapse of alveoli resulting from compression of the lung tissue or absorption of gas from obstructed alveoli.
3. Bronchiectasis is abnormal dilation of the bronchi secondary to another pulmonary disorder, usually infection or inflammation.
4. Bronchiolitis is the inflammatory obstruction of small airways. It is most common in children.
5. Pulmonary fibrosis is an excessive amount of connective tissue in the lung. It diminishes lung compliance and may be idiopathic or caused by disease.
6. Inhalation of noxious gases or prolonged exposure to high concentrations of oxygen can damage the bronchial mucosa or alveolocapillary membrane and cause inflammation or acute respiratory failure.
7. Pneumoconiosis, which is caused by inhalation of dust particles in the workplace, including coal dust, silica, and asbestos, can cause chronic inflammation, pulmonary fibrosis, and susceptibility to lower airway infection and tumor formation.
8. Silicosis is a type of pneumoconiosis caused by inhalation of silica.
9. Hypersensitivity pneumonitis (extrinsic allergic alveolitis) is an allergic or hypersensitivity reaction to many allergens.
10. Pulmonary edema is excess water in the lung caused by disturbances of capillary hydrostatic pressure, capillary oncotic pressure, or capillary permeability. A common cause is left-sided heart failure that increases the hydrostatic pressure in the pulmonary circulation.
11. ARDS results from an acute, diffuse injury to the alveolocapillary membrane and decreased surfactant production, which increases membrane permeability and causes edema and atelectasis.
12. Obstructive pulmonary disease is characterized by airway obstruction that causes difficult expiration. Obstructive disease can be acute or chronic and includes asthma, chronic bronchitis, and emphysema.
13. Asthma is a chronic inflammatory disorder of the bronchial mucosa that causes bronchial hyperresponsiveness, mucosal edema, airway constriction, and variable obstruction to airflow. Obstruction is caused by episodic attacks of bronchospasm, bronchial inflammation, mucosal edema, and increased mucus production.
14. COPD is the coexistence of chronic bronchitis and emphysema.
15. Chronic bronchitis is a chronic inflammation of the bronchi that causes airway obstruction resulting from bronchial smooth muscle hypertrophy and production of thick, tenacious mucus.
16. Emphysema results from destruction of the alveolar septa and loss of passive elastic recoil, leading to airway collapse and obstruction to gas flow during expiration and air trapping.
17. Emphysema in which septal deterioration is caused by α_1-antitrypsin deficiency or old age tends to be panacinar.
18. Emphysema in which septal deterioration results from smoking tends to be centriacinar.
19. Upper respiratory tract infections are the most common cause of short-term disability in the United States and include rhinitis (the common cold), pharyngitis, and laryngitis.
20. Serious lower respiratory tract infections, which occur most often in older adults and individuals with impaired immunity or underlying disease, include pneumonia and tuberculosis.
21. Pneumonia can be categorized as community-acquired (CAP), healthcare-associated (HCAP), hospital-acquired (HAP), or ventilator-associated (VAP).
22. Pneumococcal pneumonia is an acute lung infection resulting in an inflammatory response with four phases: (a) consolidation, (b) red hepatization, (c) gray hepatization, and (d) resolution.
23. Viral pneumonia is an acute, self-limiting lung infection usually caused by the influenza virus.
24. TB is a lung infection caused by *M. tuberculosis* (tubercle bacillus).

SUMMARY REVIEW—cont'd

25. In TB the inflammatory response isolates colonies of bacilli by enclosing them in tubercles and surrounding the tubercles with scar tissue.
26. Bacilli may remain dormant within the tubercles for life, or if the immune system becomes compromised, they may cause recurrence of active disease.
27. Abscesses are circumscribed areas of destruction of lung parenchyma with suppuration usually resulting from aspiration pneumonia.
28. Acute bronchitis is acute infection or inflammation of the airways or bronchi usually caused by a virus.
29. Pulmonary vascular diseases are caused by embolism or hypertension in the pulmonary circulation.
30. PE is occlusion of a portion of the pulmonary vascular bed by a thrombus (most common), a tissue fragment, or an air bubble. Depending on its size and location, the embolus can cause hypoxic vasoconstriction, pulmonary edema, atelectasis, pulmonary hypertension, shock, and even death.
31. Pulmonary artery hypertension (pulmonary artery pressure 5 to 10 mmHg greater than normal) is caused by (a) elevated left ventricular pressure, (b) increased blood flow through the pulmonary circulation, (c) obliteration or obstruction of the vascular bed, or (d) active constriction of the vascular bed produced by hypoxemia or acidosis.
32. Cor pulmonale is right ventricular enlargement caused by chronic pulmonary hypertension. Cor pulmonale progresses to right ventricular failure if the pulmonary hypertension is not reversed.
33. Laryngeal cancer occurs primarily in men and represents 2% to 3% of all cancers. Squamous cell carcinoma of the true vocal cords is most common and manifests with a clinical symptom of progressive hoarseness.
34. Lung cancer, the most frequent cause of cancer death in the United States, is commonly caused by cigarette tobacco smoking.
35. Cancer cell types include non–small cell lung cancer (squamous cell carcinoma, adenocarcinoma, large cell undifferentiated carcinoma) and neuroendocrine tumors (small cell carcinoma and bronchial carcinoid tumors). Other tumors include small cell (oat cell) carcinoma, bronchial adenoma, adenocystic tumors (cylindromas), mucoepidermoid carcinomas (bronchial tumors), and mesothelioma. Each type arises in a characteristic site or type of tissue, causes distinctive clinical manifestations, and differs in likelihood of metastasis and prognosis.

KEY TERMS

Abscess, 1274
Absorption atelectasis, 1256
Acute cough, 1249
Acute lung injury (ALI), 1261
Acute respiratory distress syndrome (ARDS), 1261
Adenocarcinoma, 1280
Adenocystic tumor (cylindroma), 1282
Air trapping, 1269
Alveolar dead space, 1252
Asbestosis, 1256
Asbestos exposure, 1259
Aspiration, 1255
Asthma, 1263
Atelectasis, 1256
Bronchial carcinoid tumor, 1282
Bronchiectasis, 1256
Bronchiolitis, 1258
Bronchiolitis obliterans, 1258
Bronchiolitis obliterans organizing pneumonia (BOOP), 1258
Cavitation, 1274
Centriacinar emphysema, 1269
Cheyne-Stokes respiration, 1250
Chronic bronchitis, 1267
Chronic cough, 1249
Chronic obstructive pulmonary disease (COPD), 1266
Chylothorax, 1255

CHAPTER OUTLINE

Alterations of respiratory function in children are influenced by age, development, gender, race, genetic dominance, and environmental conditions. Newborns, premature newborns in particular, are especially vulnerable to a variety of upper and lower airway infections caused by immaturity of the airways, circulation, chest wall, and the immune system. Structural differences in infants and children also render them less competent to tolerate conditions that cause increased work of breathing. Access to health care and timeliness of immunizations influence the incidence and severity of pulmonary disorders.

STRUCTURE AND FUNCTION

A number of structural characteristics of the pulmonary system influence the way in which infants and children respond to respiratory disturbances. These include structural characteristics of the upper and lower respiratory tracts, chest wall and lung dynamics, metabolic requirements, immunologic immaturity, and physiologic control of respiration.

Upper Airway

All conducting airways (the portions of airway that do not participate in gas exchange) are present at birth and change only in size throughout childhood. Branching of the bronchial tree is in fact complete by the sixteenth week of fetal life.

Because infants and children naturally have smaller-diameter airways than adults, they suffer more obstruction for a given degree of mucosal edema or secretion accumulation. The relative sizes of tonsils, adenoids, and epiglottis likewise are proportionately greater in the young child and with swelling can impose a significant site of obstruction. Infants up to 2 to 3 months of age are "obligatory nose breathers" and are unable to breathe in through their mouths. Nasal congestion is therefore a serious threat to a young infant.

Lower Airways and Lung Parenchyma

During fetal development the lung is transformed from a somewhat dense organ to one that is more delicately structured to facilitate air exchange. Beginning in the second trimester, there

is loss of interstitial (mesenchymal) tissue with concomitant expansion of the future air spaces. Capillaries grow into the distal respiratory units that keep subdividing (alveolarization) to maximize surface area for gas exchange. The number of alveoli continues to increase during the first 5 to 8 years of life, after which the alveoli increase in size and complexity. In addition to the structural development of the lung in utero, there is accompanying functional maturation during which specialized cell types, such as type II cells, manifest. (Figure 36-1 contains a summary of alveolar development and stages of fetal lung development.)

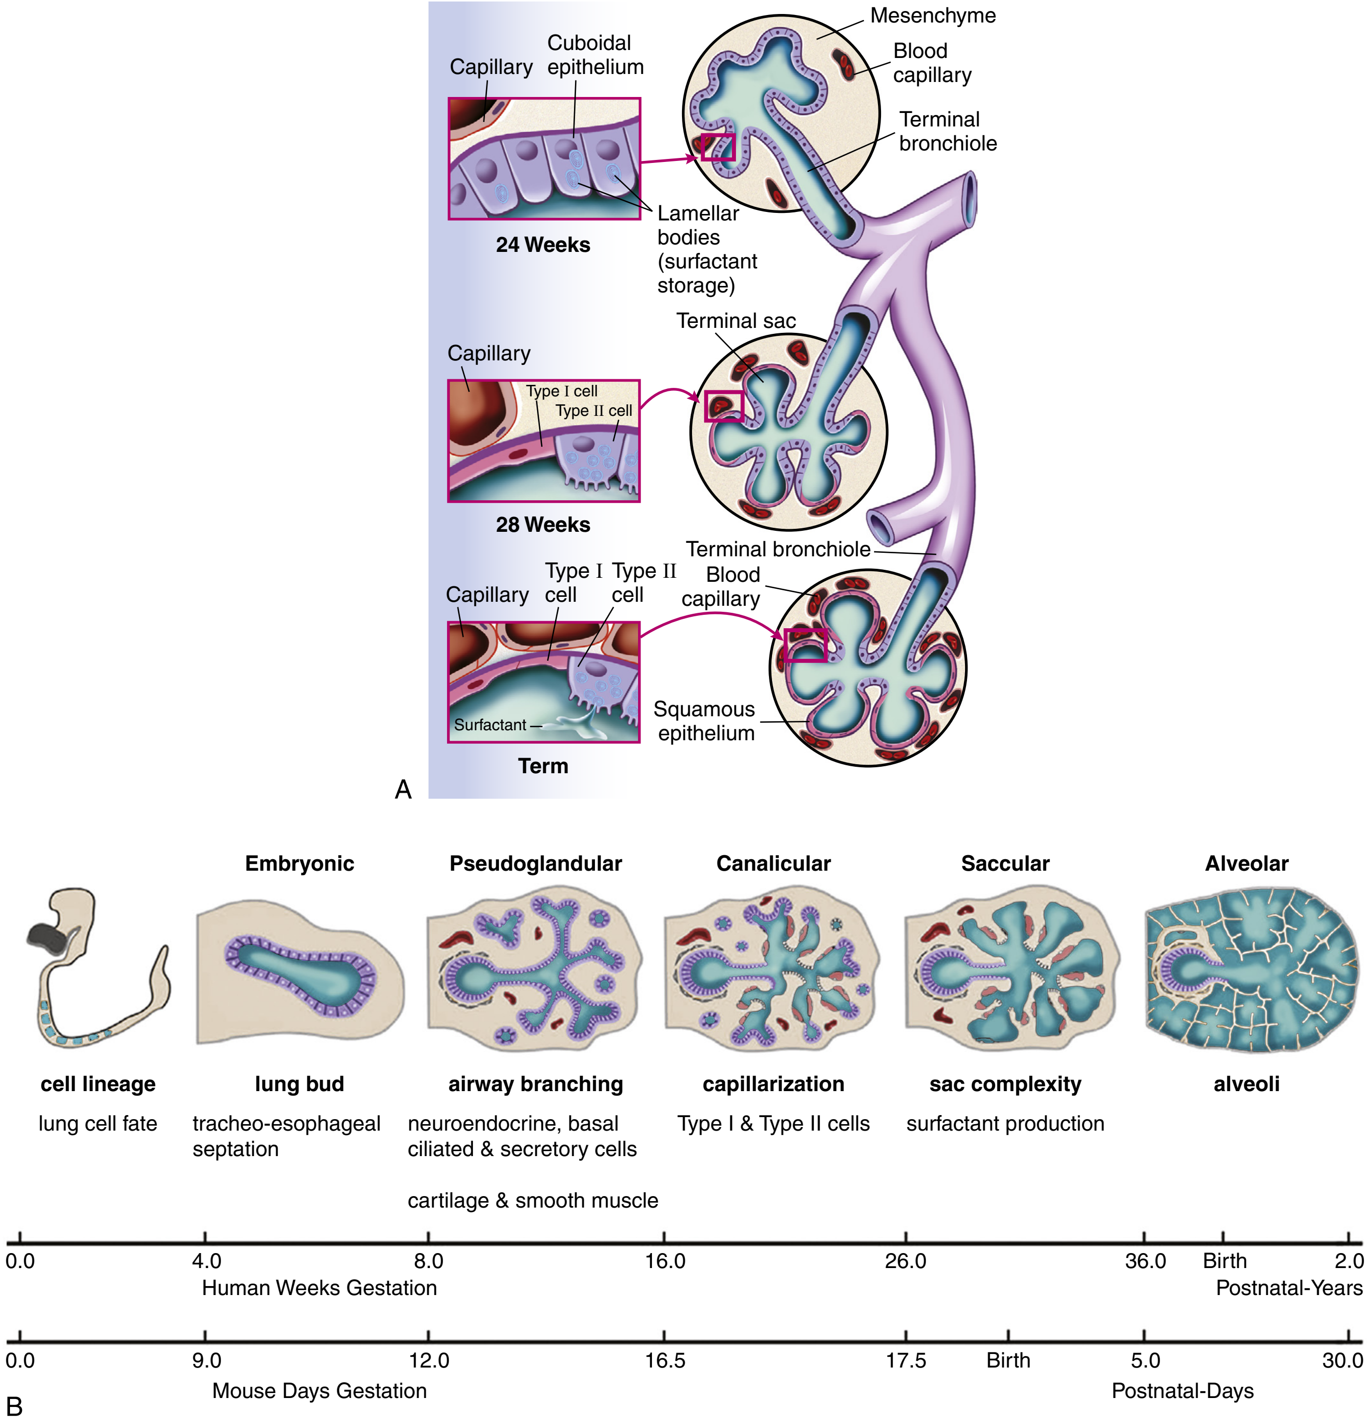

FIGURE 36-1 **Prenatal Development of the Alveolar Unit and Stages of Lung Development. A,** Epithelial cells differentiate into type II and type I cells. Mature type II cells are cuboidal, have apical microvilli, and contain lamellar bodies for surfactant storage and secretion. Type I cells are derived from type II cells and consist of flattened epithelium overlying capillaries, thus forming part of the desired thin air-blood barrier. During fetal development the pulmonary capillaries initially are randomly distributed in mesenchyme. They progressively arrange around the epithelial tubes and establish close contacts to the lining epithelium. Overall the volume of mesenchyme decreases and that of the potential air space increases. **B,** Stages of fetal lung development. (**B** adapted from Gleason CA, Devaskar S: *Avery's diseases of the newborn,* ed 9, Philadelphia, 2012, Saunders.)

Surfactant is a lipid-protein mix that is produced by type II alveolar cells and is critical for maintaining alveolar expansion (thus allowing normal gas exchange). It lines alveoli and reduces surface tension, preventing alveolar collapse at the end of each exhalation. Without surfactant the alveoli tend to stay closed, demanding greater inspiratory force and work of breathing to reexpand on the next breath. Deficiency of surfactant is often seen in premature infants and causes respiratory distress syndrome (RDS), also known as hyaline membrane disease. Surfactant is produced by 20 to 24 weeks of gestation and is secreted into the fetal airways by 30 weeks. The more premature the infant, the higher the risk of RDS.

Chest Wall Dynamics

Chest wall compliance is high in infants, particularly premature infants. The cartilaginous structures of the thoracic cage are not yet well ossified (ossification continues to occur throughout childhood), and the chest wall is easily collapsible. During inspiration in the young child, air is drawn in by the downward movement of the diaphragm, but the resulting negative pressure causes the "soft" chest wall to be drawn *inward* (Figure 36-2); this produces so-called *paradoxic breathing,* or *diaphragmatic breathing.* Paradoxic breathing is especially seen during rapid eye movement (REM) sleep of premature infants. With pulmonary compromise the accessory muscles are drawn inward, creating retraction of the intercostal and supraclavicular spaces (Figure 36-3).

Resting lung volume, or **functional residual capacity (FRC),** represents the balance point between the natural elastic recoil of the lungs (to collapse) and the elastic recoil of the chest wall (to expand). In the face of an overly compliant chest wall, infants up to about 1 year of age are thought to maintain their FRC and avoid atelectasis by muscular "braking" of their expiration. This may occur either by active glottic narrowing or by increased activity of the inspiratory intercostal muscles.

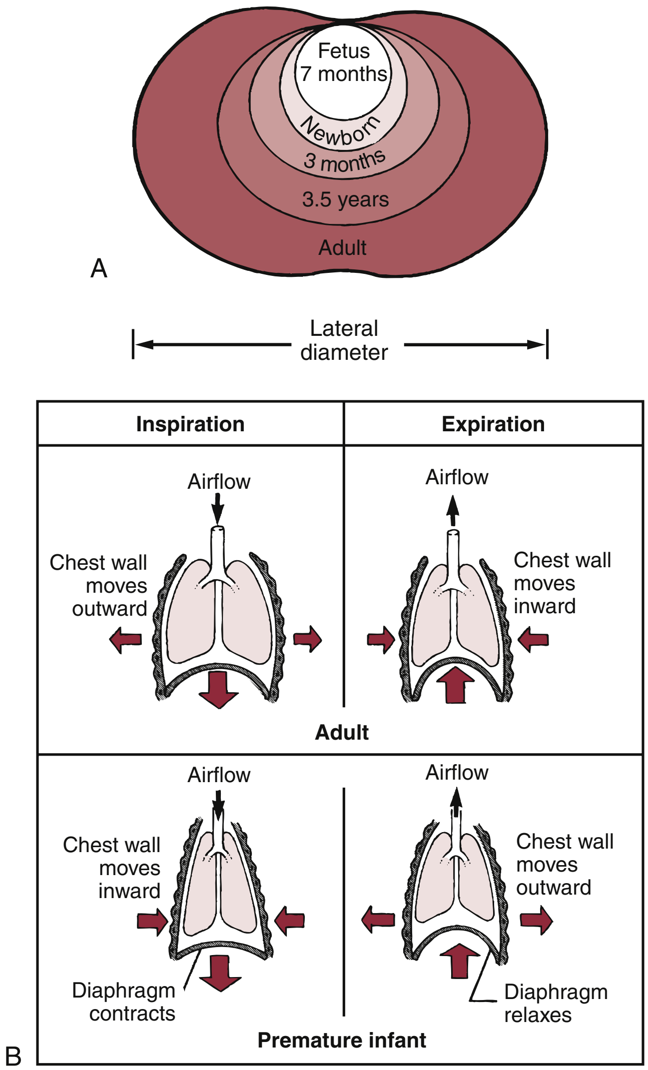

FIGURE 36-2 Developmental Differences in the Chest Wall and Lung Mechanics. **A,** Changes in chest wall shape with age. **B,** Differences in lung mechanics caused by differences in chest wall compliance (degree of rigidity) in premature infants and adults. (Arrows indicate direction of airflow, chest wall movement, and diaphragm movement.)

Metabolic Characteristics

The basal metabolic rate of a child is greater than that of an adult, and thus oxygen consumption (VO_2) is greater per unit of body weight. The VO_2 of the child's normal breathing accounts for up to 25% of the total VO_2. The work of breathing increases VO_2 exponentially with respiratory distress. Children have less muscle glycogen reserve, which limits the efficiency of accessory muscles, such that fatigue with lactic acidosis can occur quickly. Children also have a high proportion of extracellular fluid and therefore more quickly lose fluid and become dehydrated as a result of fever, from environmental heat, or in association with tachypnea (which causes evaporation from the respiratory tract).

Immunologic Incompetence

Passive immunity with immunoglobulin G (IgG) is normally conveyed transplacentally from the mother to the fetus

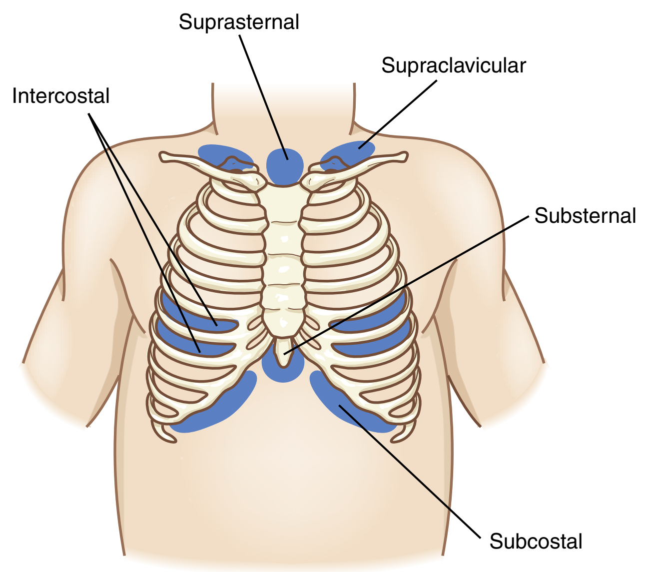

FIGURE 36-3 Areas of Chest Muscle Retraction.

beginning at 20 weeks of gestation; thus IgG levels are lower in preterm than term infants. Breast-feeding allows transfer of secretory IgA, IgG, and IgM after birth. Because IgG has a half-life of approximately 21 days, the placentally transferred antibodies are depleted after just a few months. Infants are able to synthesize IgG, IgM, and IgA, and the levels of these immunoglobulins increase slowly with age. Cell-mediated immunity is also not fully developed in the neonate, which creates a situation of enhanced susceptibility to viral and fungal infections.

Physiologic Control of Respiration

For up to 3 weeks of age, the newborn has a blunted ventilatory response to hypoxia compared with older children and adults. The mechanisms for this are not well understood but may reflect reduced activity of the peripheral chemoreceptors (in the carotid body) and nonadaptive responses in the respiratory center (in the brainstem). Ventilatory response to hypercarbia is normal in term infants but may be reduced in premature infants. Congenital or acquired lesions of the central nervous system may cause hypoventilation or apnea. Exposure to maternal smoking both during and after fetal development can have significant deleterious effects on lung development and subsequent susceptibility to pulmonary disorders (see What's New? Maternal Smoking: Fetal Lung Development and Lung Disease).

DISORDERS OF THE UPPER AIRWAYS

Pulmonary dysfunction can be categorized into disorders of either the upper airway or the lower airway. Signs of acute respiratory failure are the same regardless of etiology. These include the following:

- Increased respiratory effort with retractions (see Figure 36-3) or gasping (apnea in some conditions)
- Cyanosis or pallor
- Agitation
- Decreased level of consciousness
- Cardiovascular signs: tachycardia, mottled color, or bradycardia
- Physiologic compromise reflected by hemoglobin desaturation, hypoxemia, hypercarbia, and acidosis

WHAT'S NEW?

Maternal Smoking: Fetal Lung Development and Lung Disease

Maternal smoking during pregnancy is a risk factor for several adverse developmental outcomes, including abnormal fetal lung development. Lung development is most critical during late fetal and early postnatal life—the saccular and alveolar developmental phases. Abnormalities occurring during these stages can have long-term effects on lung function, contributing to the development of asthma in children and lung disease in adults. Maternal smoking and altered fetal pulmonary structure are related to nicotine that crosses the placenta and is expressed in breast milk. There is up-regulation of nicotinic acetylcholine receptors in the fetal lung. Animal models have demonstrated alterations in lung structure including decreased alveolarization, thickening of the alveolocapillary membrane, decreased synthesis of surfactant, decreased airway diameter, decreased vessel density, and increased airway hyperresponsiveness. Smoke exposure also changes the genetics that control lung growth and maintenance of lung structure, and accelerates lung aging. Prevention of maternal smoking during pregnancy and lactation is required and nicotine replacement therapy is not advised for these women.

Data from Abbott LC, Winzer-Serhan UH: *Crit Rev Toxicol* 42(4):279–303, 2012; Harding R, Maritz G: *Semin Fetal Neonatal Med* 17(2):67–72, 2012; Kajeka R: *Pharmacol Ther* 114:129–145, 2007; Maritz GS, Harding R: *Int J Environ Res Public Health* 8(3):875–898, 2011; Wongtrakool C et al: *Am J Respir Cell Mol Biol* 46(5):695–702, 2012.

Upper Airway Obstruction

The crucial issue in the upper airways is patency. The most common causes of *acute-onset* **upper airway obstruction (UAO)** in children are infections, foreign body aspiration, angioedema, obstructive sleep apnea, and trauma. *Chronic UAO* has many etiologies, including congenital malformations affecting the airway, cartilaginous weakness, vocal cord paralysis, and subglottic stenosis. Chronic upper airway symptoms should prompt referral to a pediatric pulmonologist or an otolaryngologist because specialized diagnostic studies may be needed. A list of causes of pediatric UAO can be found in Box 36-1.

The site and nature of the obstruction are often discernible by assessing the noise associated with breathing, the quality of the voice or cry, and the presence of feeding difficulties. This assessment often can be made without even touching the child. Likewise, the severity of the problem often can be judged by visual observation of signs, including retractions, nasal flaring, gasping or obstructed breaths, anxiety, restlessness, or need to maintain a specific head or body position. Agitation should be regarded as a likely sign of hypoxemia or obstruction. In acute UAO, increasing the child's anxiety by excessive physical examination can worsen the condition. The child should be kept as calm as possible. The clinician should never attempt a pharyngeal examination if there is any suspicion of epiglottitis or retropharyngeal abscess because this maneuver may precipitate acute obstruction of the airway.

The sounds of the child's breathing can provide key clues (Figure 36-4). A sonorous, snoring noise is typical for nasopharyngeal obstruction, such as adenotonsillar hypertrophy. A common sign of pediatric UAO is **stridor,** a harsh, vibratory sound of variable pitch caused by turbulent flow through the partially obstructed airway. A diagnostic approach to stridor is outlined in Figure 36-5. Whether it is present in inspiration, expiration, or both reflects the site of the problem. In general, *inspiratory* stridor is generated with obstruction of the *extrathoracic* airway (above the thoracic inlet), which includes the supraglottic structures, the larynx, the subglottic space, and the upper trachea. *Expiratory* stridor or a monophonic wheeze may be generated by an obstruction in the *intrathoracic* airway (the middle to lower trachea and central bronchi). Biphasic stridor typically reflects obstruction at the glottis (e.g., vocal cord paralysis) itself or a *fixed* rather than a *dynamic* lesion in the subglottic space (e.g., hemangioma or subglottic stenosis). Biphasic noise may sometimes mean abnormalities of both the extrathoracic and intrathoracic trachea (long-segment stenosis or malacia).

BOX 36-1 CAUSES OF UPPER AIRWAY OBSTRUCTION IN CHILDREN ACCORDING TO SITE OF OBSTRUCTION

Nose and Pharynx
Choanal atresia
Lingual thyroid or thyroglossal cyst
Macroglossia
Micrognathia
Hypertrophic tonsils/adenoids
Retropharyngeal or peritonsillar abscess

Larynx
Laryngomalacia
Laryngeal web, cyst, or laryngocele
Laryngotracheobronchitis (viral croup)
Acute spasmodic laryngitis (spasmodic croup)
Epiglottitis
Vocal cord paralysis
Laryngotracheal stenosis
Intubation

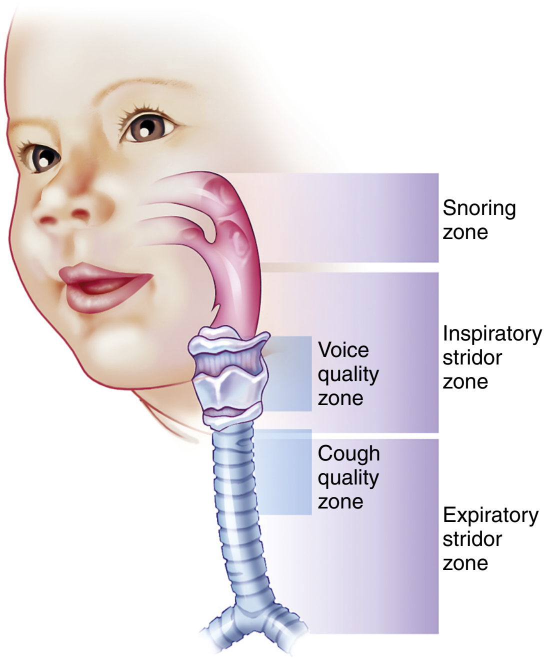

FIGURE 36-4 Listening Can Help Locate the Site of Airway Obstruction. A loud, gasping snore suggests enlarged tonsils or adenoids. Stridor during inspiration suggests the airway is compromised at the level of the supralaryngeal structures (epiglottis and arytenoid cartilages), vocal cords, subglottic region, or upper trachea. With forced inspiration, intrathoracic pressure becomes quite negative and is less than atmospheric pressure, promoting collapse at or just above the site of obstruction. Expiratory stridor or central wheeze results from narrowing or collapse of the lower trachea or bronchi. During forced exhalation, rising pleural pressure may exceed intratracheal pressure. Airway noise during both inspiration and expiration often represents a fixed obstruction of the vocal cords or subglottic space. Hoarseness or a weak cry is a byproduct of obstruction at the vocal cords. If a cough is croupy or low pitched, suspect tracheal pathology. (Redrawn from Eavey RD: *Contemp Pediatr* 3[6]:78, 1986; used with permission; original illustration by Paul Singh-Roy.)

Abnormalities of voice or cry (weak or hoarse) suggest problems at the larynx, such as vocal cord paralysis. Muffling of the voice, especially in an acute condition, suggests supralaryngeal obstruction, such as epiglottitis or retropharyngeal abscess. Pronounced cough may be an irritative symptom, such as that produced by an aspirated foreign body, or may be a sign of tracheal obstruction. The cough associated with croup or tracheal foreign body is usually harsh and barking.

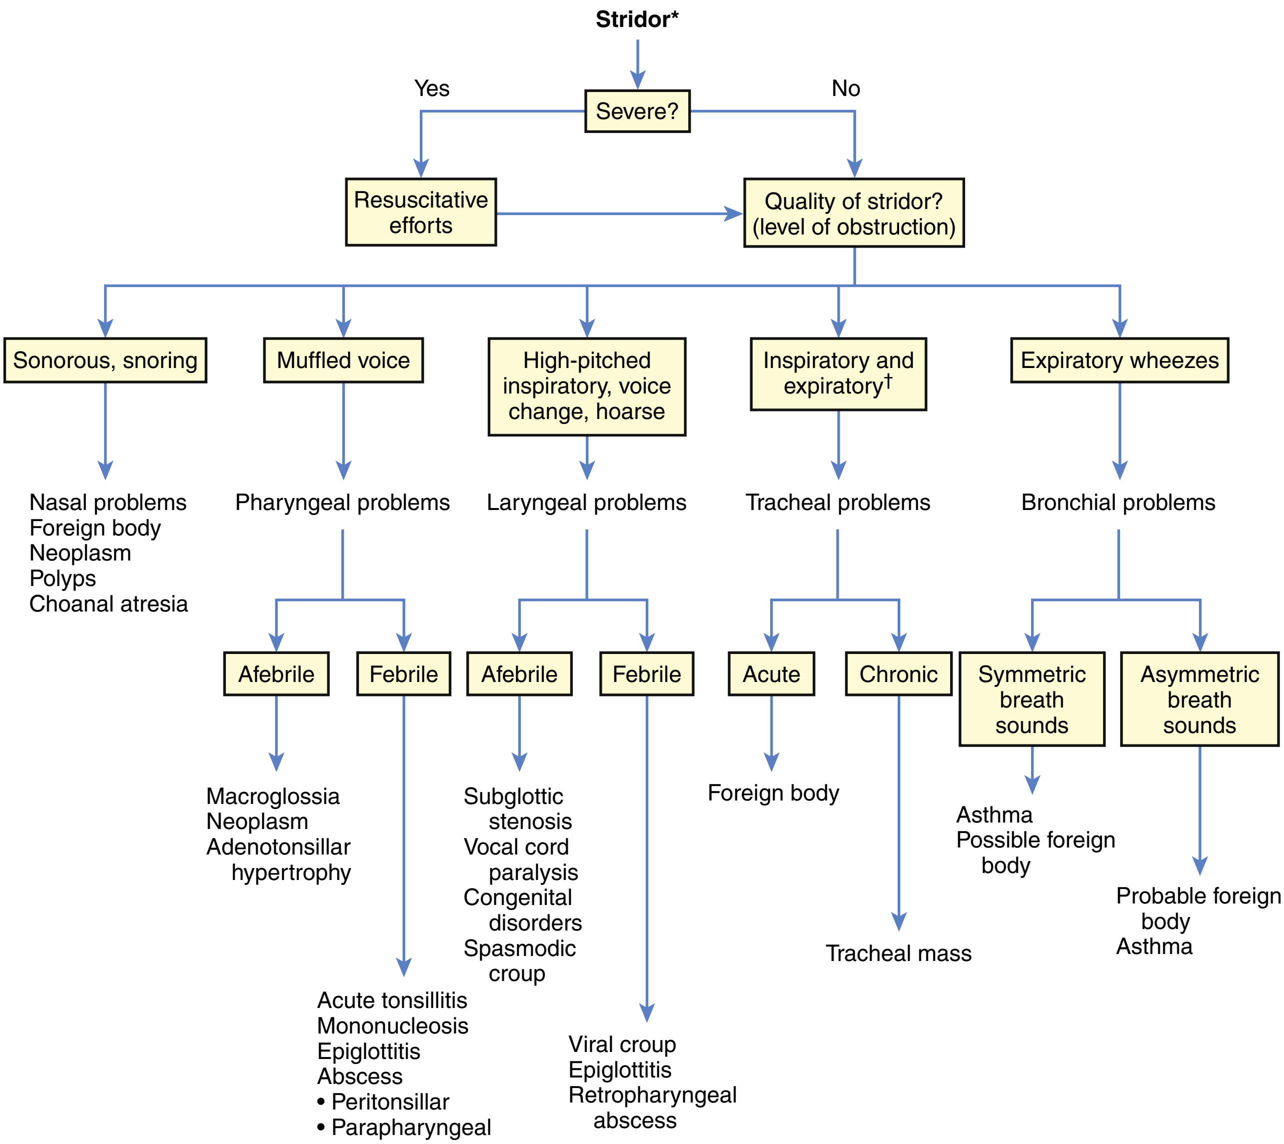
Airway obstruction occurs sooner in infants than in older children. Obviously, airway luminal size is smaller in accordance with smaller body size, but any decrease in luminal diameter will be much more significant. This is because airway resistance is proportional to the inverse of the *fourth* power of the radius; thus a decrease to half the original diameter increases resistance 16-fold. Furthermore, an infant's cartilaginous structures are more collapsible and thus are prone to creating or contributing to a situation of UAO.

Infections

Infections of the upper airway (Table 36-1) are common in children; some have the potential to cause life-threatening emergencies. Recognition and rapid evaluation of these problems are crucial pediatric care skills.

Croup. Croup illnesses can be divided into two categories: (1) acute laryngotracheobronchitis (croup) and (2) spasmodic croup. Diphtheria can be considered a croup illness but is now rare because of vaccinations. Croup illnesses are all characterized by infection and obstruction of the upper airways.[1]

Croup is an acute **laryngotracheobronchitis** and most commonly occurs in children from 6 months to 3 years of age, with peak incidence at 2 years of age.[2] In 85% of cases, croup is caused by a virus, most commonly parainfluenza; however, other viruses such as influenza A virus, respiratory syncytial virus (RSV), rhinovirus, adenovirus, and rubella virus (measles) as well as the atypical bacterium *Mycoplasma pneumoniae* has been associated with causation. The incidence of croup is highest in late autumn and winter, corresponding to the parainfluenza and RSV seasons, respectively. Croup is more common in boys than girls. In a significant portion of affected children, croup is a recurrent problem during childhood, and there is a family history of croup in about 15% of cases. **Spasmodic croup** is characterized by similar hoarseness, barking cough, and stridor, but is of sudden onset, usually at night and without viral



* The age of the patient must be considered in making a specific diagnosis
† Laryngeal problems are frequently associated with inspiratory and expiratory stridor

FIGURE 36-5 Diagnostic Approach to Stridor. (Adapted from Handler SD: Stridor. In Fleisher GR, Ludwig S, editors: *Textbook of pediatric emergency medicine,* Baltimore, 1993, Williams & Wilkins.)

prodrome. It often resolves as quickly as it develops and usually occurs in older children. The etiology is unknown although association with viruses, allergies, asthma, and gastroesophageal reflux disease (GERD) is being investigated.[3]

PATHOPHYSIOLOGY. The pathophysiology of viral croup is caused primarily by subglottic edema from the infection. The mucous membranes of the larynx are tightly adherent to the underlying cartilage, whereas those of the subglottic space are looser and thus allow accumulation of mucosal and submucosal edema (Figure 36-6). Furthermore, the cricoid cartilage is structurally the narrowest point of the airway, making edema in this area critical. As illustrated in Figure 36-7, increased resistance to airflow leads to increased work of breathing, which generates more negative intrathoracic pressure, which in turn may exacerbate dynamic collapse of the upper airway.

CLINICAL MANIFESTATIONS. Typically there is a prodrome of rhinorrhea, sore throat, and low-grade fever for a few days. The child then develops the characteristic harsh (seal-like) barking cough, hoarse voice, and inspiratory stridor. Most cases are mild and resolve spontaneously after several more days. Occasionally, however, UAO becomes severe and requires urgent management.

EVALUATION AND TREATMENT. The degree of symptoms determines the level of treatment. Most children have a barking cough and viral symptoms and may need no specific treatment. However, the presence of stridor (especially at rest), retractions, or agitation suggests a sicker child. The tool most often used for estimating croup severity is the Westley croup score, which provides a cumulative score for the degree of stridor, retractions, air entry, cyanosis, dyspnea, and level of consciousness in the child.[4]

TABLE 36-1 COMPARISON OF UPPER AIRWAY INFECTIONS

CONDITION	AGE	ONSET	ETIOLOGY	PATHOPHYSIOLOGY	SYMPTOMS
Acute laryngotracheobronchitis (croup)	6 mo-3 yr	Usually gradual	Viral (parainfluenza 1 and 3, influenza A, respiratory syncytial virus)	Inflammation from vocal cords to bronchial lumina	Harsh cough; stridor; low-grade fever; may have nasal discharge, conjunctivitis
Acute tracheitis	1-12 yr	Abrupt or following viral illness	*Staphylococcus aureus*/methicillin-resistant *Staphylococcus aureus* (MRSA) *Haemophilus influenzae* type B Group A streptococci	Inflammation of upper trachea	High fever; toxic appearance; thick harsh cough; purulent secretions; may prefer head elevation
Epiglottitis	2-6 yr	Abrupt	*Haemophilus influenzae* type B (Hib) Group A streptococci	Inflammation of supraglottic structures	Severe sore throat; high fever; toxic appearance; muffled voice; may drool; sits erect and quietly
Retropharyngeal abscess	>6 yr	Gradual, 2-5 days; may follow oral trauma	*S. aureus*/MRSA *Streptococcus pyogenes* Anaerobes Group A beta-hemolytic streptococci	Abscess in posterior pharyngeal wall	Similar to epiglottitis
Peritonsillar abscess	>9 yr	May be abrupt	Group A beta-hemolytic streptococci *S. aureus*/MRSA	Abscess within or around tonsil	Similar to epiglottitis; may have trismus

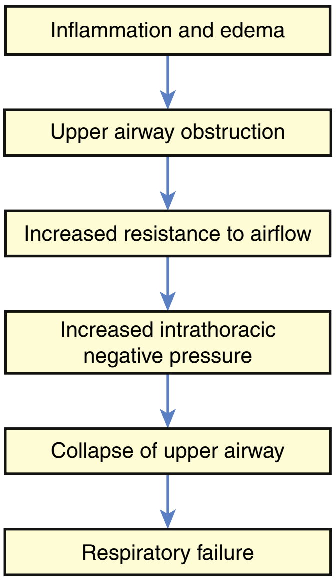

FIGURE 36-7 Upper Airway Obstruction with Croup.

Severity also is classified as mild, moderate, and severe. Most children with croup require no treatment. Inhalation of humidified air does not improve symptoms in mild to moderate croup.[5] Glucocorticoids, either injected or oral (dexamethasone) or nebulized (budesonide), have been shown to improve symptoms within 6 hours. Less sleep is lost by children, less stress is experienced by parents, and fewer children have a need for return healthcare visits or hospitalization when corticosteroids are used.[6] The use of nebulized racemic epinephrine improves outcomes with moderate to severe croup.[2,7] Epinephrine stimulates α- and β-adrenergic receptors and is thought to decrease airway secretions and mucosal edema. It is a temporizing measure until concomitantly given corticosteroids begin to take effect. Thus children who are given nebulized epinephrine should be closely observed for 2 to 3 hours to ensure that they will remain stable. Oxygen also should be administered. Heliox (helium-oxygen mixture of 80:20 or 70:30) may be used for severe cases of croup, although there is lack of scientific evidence to establish use in routine clinical practice.[8]

Acute Epiglottitis. Historically, **acute epiglottitis** was caused by *Haemophilus influenzae* type B (Hib). Since the advent of Hib immunization, the overall incidence of acute epiglottitis in children has decreased significantly, although Hib still accounts for approximately 25% of the cases seen in children. Infants less than 1 year of age are at greater risk.[9] Current pediatric cases usually represent Hib vaccine failures or are caused by alternative pathogens, such as groups A, B, C, F, and

G streptococci, *Streptococcus pneumoniae, Candida* species, *Staphylococcus aureus,* and viral pathogens. Thermal injuries, trauma, and posttransplant lymphoproliferative disorder also have been reported as causes of epiglottitis.[10]

PATHOPHYSIOLOGY. The epiglottis arises from the posterior tongue base and covers the laryngeal inlet during swallowing. It has a rich blood and lymphatic circulation. Bacterial invasion of the mucosa with associated inflammation leads to the rapid development of edema causing severe, life-threatening obstruction of the upper airway.[10]

CLINICAL MANIFESTATIONS. In the classic form of the disease, a child between 2 and 6 years of age suddenly develops high fever, irritability, sore throat, a "hot potato voice," inspiratory stridor, and severe respiratory distress. The child appears ill and classically will adopt a forward-leaning position (tripod position) with drooling and dysphagia (inability to swallow). Examination of the throat may trigger laryngospasm and cause respiratory collapse. Death may occur in a few hours. Pneumonia, cervical lymph node inflammation, otitis, and, rarely, meningitis or septic arthritis may occur during the course of epiglottitis.

EVALUATION AND TREATMENT. Acute epiglottitis is a life-threatening emergency. The essentials are early recognition, avoidance of disturbing the child (which could worsen the obstruction), and securing the airway. Examination of the throat should not be attempted because it may trigger laryngospasm and cause respiratory collapse. Tracheal intubation should be accomplished by the most experienced personnel (usually an anesthesiologist and/or otolaryngologist) using fiberoptic laryngoscopy. Subsequent culture of the airway is obtained and intravenous broad-spectrum antibiotics are administered promptly. Therapy is reevaluated after culture results return. Corticosteroids also are generally used in treatment regimens although there are no published randomized trials to support this practice.[10-12] Despite the severe presentation of epiglottitis, resolution with treatment is usually rapid, with intubation rarely needed for more than a couple of days. When Hib epiglottitis is diagnosed, the American Academy of Pediatrics (AAP) recommends that postexposure prophylaxis with rifampin be administered to household contacts (specific to certain ages of children present).[12] When caused by microorganisms other than *H. influenzae,* as is now the usual situation, epiglottitis may present in ages outside the typical range and with more gradual rather than fulminant onset, thus making diagnosis less obvious. Such cases also may respond more slowly to treatment.

Tonsillar Infections. Tonsillar infections (tonsillitis) are occasionally severe enough to cause UAO.[13] As with other infections of the upper airway, the incidence of tonsillitis secondary to group A beta-hemolytic *Streptococci* (GABHS) and methicillin-resistant *S. aureus* (MRSA) has risen notably in the past 15 years.[14] Significant swelling of the tonsils and pharynx occurs, and a tenacious membrane may cover the mucosa. UAO because of tonsillitis is a well-known complication of infectious mononucleosis, especially in a young child. The development of UAO in tonsillar infections requires the use of appropriately selected antibiotics and may require the use of corticosteroids, especially in the case of mononucleosis.[15] Some children with recurrent tonsillitis benefit from tonsillectomy.

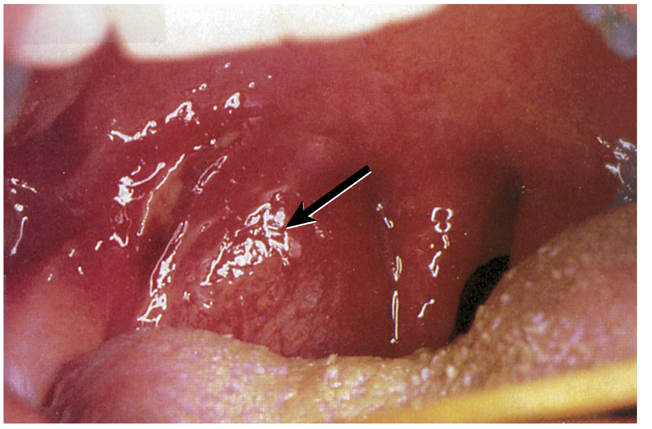

FIGURE 36-8 **Peritonsillar Abscess.** Unilateral bulging of the tonsillar region is evident. (From Whiting JL, Chow AW: *J Crit Ill* 2[7]:36, 1987.)

Peritonsillar abscess is usually unilateral and is most often a complication of acute tonsillitis.[16] The most common causative microorganism is GABHS. Children have fever, sore throat, dysphagia, trismus, pooling of saliva, and muffled voice. Peritonsillar bulging (Figure 36-8) and cervical adenopathy on the same side are usually visible. The abscess must be drained and the child given antibiotics.[17] Death can occur from spontaneous abscess rupture with aspiration or airway obstruction.[18]

Bacterial Tracheitis. **Bacterial tracheitis** is the most common potentially life-threatening upper airway infection in children. It is most often caused by *Staphylococcus aureus (S. aureus)* (including methicillin-resistant [MRSA] strains), *H. influenzae,* group A beta-hemolytic *Streptococcus* (GABHS [*Streptococcus pyogenes*]), or *Moraxella catarrhalis.*[19] It accounts for 5% to 14% of UAOs in children requiring intensive care.[20] A virus or a fungus is more likely to be seen as the source of tracheitis in immunocompromised children.[21] Treatment of viral croup with corticosteroids has increased the risk for serious bacterial tracheitis (especially by GABHS), resulting in death rates between 18% and 40%.[20] The presence of airway edema and copious purulent secretions leads to airway obstruction that can be worsened by the formation of a tracheal pseudomembrane and mucosal sloughing. Increased morbidity can occur because of respiratory and cardiopulmonary arrest, respiratory failure, pneumonia, septic shock, toxic shock syndrome, acute respiratory distress syndrome (ARDS), and multiple organ dysfunction syndrome (MODS). The onset of symptoms may be sudden or may be preceded by a pre-existing viral upper respiratory tract infection or croup. The acute clinical presentation frequently includes tachypnea, stridor, hoarse voice, fever, cough, and/or increased secretions from the mouth and nose. There may be evidence of concurrent infections, such as sinusitis, otitis, pneumonia, or pharyngitis.[22] Children with chronic gastroesophageal reflux are more likely to experience difficulty with these types of concurrent infections. Management requires the rapid administration of broad-spectrum intravenous antibiotics. The majority of children with tracheitis require endotracheal intubation in order to prevent airway obstruction. Corticosteroids (parenteral and inhaled)

are used to decrease tracheal inflammation. Many children recover adequately to be extubated within 72 to 96 hours.[23]

Retropharyngeal Abscess. **Retropharyngeal abscess** can be caused by aerobic, anaerobic, or polymicrobial infection. A decrease in retropharyngeal abscess has been noted in the past several years that is likely related to the use of corticosteroids in the treatment of influenza and croup. There also has been an increase in GABHS strains associated with this condition, and the emergence of MRSA as the offending microorganism is increasingly noted.[24]

Retropharyngeal abscess usually occurs more commonly in male children about 4 years of age and as a consequence of either nasopharyngeal infection or penetrating local injury.[25] Clinical signs include fever, dysphagia, drooling, stridor, respiratory distress, and stiff neck. This condition requires intravenous antibiotics targeted at the suspected microorganism, and sometimes incision and drainage.[26]

Aspiration of Foreign Bodies

Most children who aspirate a foreign object (**foreign body aspiration**) are between 1 and 3 years of age. More than 100,000 cases occur each year.[27] Often the aspiration either is not witnessed or does not seem significant to the parent; thus medical care is often not pursued until after the first 24 hours. At the time of aspiration, the child may cough, choke, gag, or wheeze, and stridor or cyanosis occasionally occurs. This may be followed by a quiescent interval of minutes to even weeks or months before symptoms reappear from resulting local irritation, granulation, bronchial obstruction, or infection (pneumonia or bronchiectasis). Pronounced inspiratory stridor, cough, and wheezing are typical symptoms that prompt the parents to seek medical attention. Examples of common aspirated objects include nuts, sunflower seeds, hot dog chunks, popcorn, coins, and small toys or toy parts. Meat or food impactions are more common in adolescents. Items of particular concern are batteries and multiple magnets. In general, foreign bodies require early intervention secondary to their propensity to cause respiratory symptoms and complications, including esophageal erosions or aortoesophageal fistula (rare).

The symptom history is often the most critical aid in diagnosis.[28] Symptoms are determined by the size of the object and the site in which it is located, as well as the child's age and size (see Figure 36-4). Foreign bodies lodged in the upper trachea typically produce inspiratory stridor, whereas those located in the lower intrathoracic airways more commonly produce wheezing. About 75% of aspirated foreign bodies lodge in a bronchus. Children with an unexplained persistent cough and refractory parenchymal infiltrates also should be considered for unrecognized foreign body aspiration.[29] Many objects are not radiopaque; however, if the object has completely occluded a lung segment, atelectasis will be visible on a chest radiograph. Occasionally, air will accumulate distal to the obstruction if the object is causing a ball-valve effect. This effect can sometimes be documented by inspiratory and expiratory chest films (Figure 36-9). In a younger child, bilateral decubitus films may show failure to compress the obstructed lung when in the "down" position.

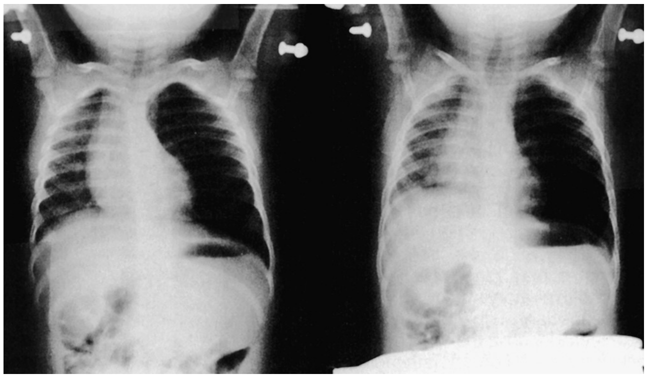

FIGURE 36-9 **Foreign Body Aspiration.** Inspiratory *(left)* and expiratory *(right)* chest radiographs of a child who aspirated a portion of a potato into the left mainstem bronchus. Left lung field is hyperaerated and the mediastinum is shifted to the right on expiration because of left-sided obstructive emphysema. (From Kenna MA, Bluestone CD: *Pediatr Rev* 10[1]:25, 1988.)

Most foreign bodies can be removed by bronchoscopy and only rarely is a pulmonary lobectomy required. Soft particles such as food, as well as hard objects, must be removed because infectious processes will otherwise occur.[30] Objects lodged in the laryngeal or subglottic regions are particularly dangerous because of their potential for complete or near-complete airway occlusion.

Angioedema

Angioedema is a localized edema involving the deep, subcutaneous layers of skin or mucous membranes. Generally, angioedema causes facial swelling first, particularly around the eyes and lips, and may progress to airway swelling.[31] Angioedema is usually secondary to allergic phenomena (e.g., allergy to peanuts, cow's milk, chicken eggs).[32] If airway compromise is apparent, standard treatment includes epinephrine (subcutaneous), antihistamines, and corticosteroids. An occasional cause of pediatric angioedema is use of angiotensin-converting enzyme inhibitors for treatment of hypertension or heart disease. Increased levels of bradykinin appear to mediate this adverse effect by causing vasodilation, increased vascular permeability, and histamine release.[33]

An inherited deficiency of the plasma protein C-1 inhibitor (C-1 INH) causes *hereditary angioneurotic edema* (HAE), a rare but serious problem in children. About 50% of cases occur during childhood.[34] The mean age of onset of initial symptoms is 8 to 12 years but it also may occur as early as the first year of life. This condition is characterized by recurring attacks of angioedema involving subcutaneous tissues (especially limbs, genitalia, and face); abdominal and pelvic viscera; and, much less often, the airway. Laryngeal attacks in these individuals may be life threatening and do not respond reliably to standard measures for airway edema. Complement studies usually provide an accurate diagnosis.[34] The mortality of undiagnosed HAE can be as high as 50%. The mainstays of supportive care are airway monitoring, hydration, pain relief, and control of nausea. Concentrates of C-1 INH appear to produce rapid improvement within 15 to 60 minutes. Short- and long-term prophylaxis can be instituted using antifibrinolytic agents, attenuated androgens, and C-1 INH concentrates.[35]

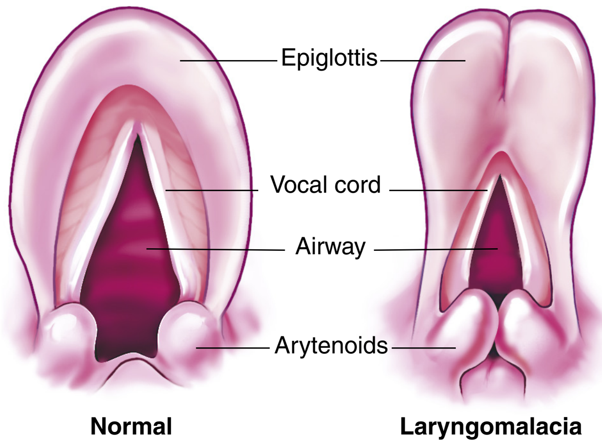

FIGURE 36-10 Laryngomalacia. In the normal larynx *(left),* supralaryngeal structures maintain their upright orientation during inspiration. In contrast, in infants with laryngomalacia *(right),* there is inward prolapse of the arytenoid masses, which include the prominent cuneiform tubercles and the arytenoid cartilages. The glottis becomes partially covered, and airflow is impeded. Sometimes the edges of the epiglottis curl inward, further exacerbating the obstruction. In expiration, these structures are "blown" aside passively.

Congenital Malformations

Congenital malformations can occur at multiple sites from the nasal openings to the subglottis. Anatomic or functional obstruction can cause severe respiratory distress.

Laryngomalacia and Tracheomalacia. **Laryngomalacia** results from abnormally soft laryngeal cartilages and is the most common cause of chronic stridor in infants. Boys are twice as likely as girls to present with symptoms. In laryngomalacia, the epiglottis or arytenoids, or both, fold inward with inspiration, partially covering the glottis (Figure 36-10). The pathophysiology of these abnormalities is still not completely understood. Two primary hypotheses are anatomic or neuromuscular.[36] Anatomically there may be foreshortened or tight aryepiglottic folds or there may be redundant soft tissue in the supraglottis.[37] The neuromuscular hypothesis suggests that there is an abnormality of the sensorimotor integrative function of the brainstem and peripheral reflexes are responsible for laryngeal tone and airway patency.[38] Laryngeal nerve hypertrophy also has been documented.[39] Gastroesophageal reflux disease (GERD) and other comorbidities are associated with laryngomalacia.[40]

Typical signs of laryngomalacia include inspiratory stridor beginning in the first days or weeks of life, accentuated with activity, and sometimes with positional changes (worse in supine or head-flexed positions). Feeding difficulties may be noted, but they are usually mild. Cry is normal. Laryngoscopy is used to confirm the diagnosis. Laryngomalacia is usually mild and improves spontaneously over the first year of life as the supralaryngeal cartilage structures stiffen; thus most cases are managed with watchful waiting. A late-onset variant of this disease has been noted in the literature and should be suspected if the following occurs: potential cause of feeding difficulties in toddlers, sleep apnea in children, and exercise intolerance in teenagers.[41,42]

In **tracheomalacia,** or **tracheobronchomalacia,** the tracheobronchial cartilages are flaccid and tend to collapse during the expiratory cycle, causing stridor. This may be classified as primary (idiopathic) or secondary. When malacia is caused by a secondary source, it is usually related to extrinsic compression of the trachea from a vascular malformation (congenital tracheomalacia). Tracheobronchomalacia presents clinically as a spectrum of respiratory illnesses that range from life-threatening conditions to chronic cough and wheeze conditions. In some cases symptoms may be more subtle than in laryngomalacia. Low-pitched inspiratory stridor may be a sign of malacia of the upper trachea or centrally located, single-pitch (monophonic) wheeze may be present in malacia of the middle to distal trachea. Tracheomalacia can be suspected clinically and confirmed by bronchoscopy. Depending on the type and severity of the lesion, surgical approaches for repair may be indicated.[43]

Vocal Cord Paralysis. Vocal cord paralysis is second to laryngomalacias as a cause of stridor and is a relatively uncommon congenital disorder. The vocal cords should move apart to facilitate inspiration and move together to facilitate vocalization. Paralysis of one or both vocal cords may affect breathing, swallowing, and speech. The etiology of the congenital abnormality is unclear but may be caused by immaturity of the vagus nerve or brainstem, or both. Iatrogenic injury is frequently cited as the major secondary cause of vocal cord paralysis, such as surgical trauma to the recurrent laryngeal nerve during cardiac surgery. Other secondary causes include Arnold-Chiari malformation (the region of the brainstem in which the nucleus ambiguus acts as the "relay station" for laryngeal function), cerebral palsy, hydrocephalus, myelomeningocele, spina bifida, or hypoxia.[44] Other associations include infectious and neoplastic causes, trauma, and inflammatory conditions.[45] In older children and adolescents, exercise has been known to precipitate vocal cord dysfunction (VCD).[46]

Clinical findings of vocal cord paralysis in children less than 1 year include dysphonia, glottic incompetence, GERD, and stridor.[45] It sometimes resolves spontaneously (most often during the first year of life) or with correction of the underlying problem. Flexible laryngoscopy and chest x-ray are common evaluative tools that may help determine the cause. In some individuals, VCD may be misdiagnosed as asthma.[47] Medical therapy may include use of corticosteroids, proton pump inhibitors, and speech therapy. Recurrent pulmonary infections secondary to aspiration may occur and require treatment until the cords are repaired.[48] Severe cases may necessitate endotracheal intubation and tracheostomy. Tracheostomy may be used until the vocal cords are surgically repaired or can be used as a permanent measure for bilateral vocal cord paralysis.[48]

Subglottic Stenosis. Congenital **subglottic stenosis** is the third most common laryngeal anomaly and is defined as a subglottic airway diameter of less than 4 mm at the cricoid region in a full-term infant, and less than 3 mm in a premature infant.[48] Incomplete recanalization of the laryngotracheal tube during the third month of gestation results in this defect. Subglottic stenosis also is associated with eosinophilic esophagitis, Wegener granulomatosis, and neurofibromatosis.[49-51] Traumatic injury to the upper airway with development of subglottic stenosis

is a well-described complication of endotracheal intubation.[52] Factors that contribute to subglottic stenosis include utilization of long-term assisted ventilation, use of an endotracheal tube that is too large, excessive movement of the tube, and susceptibility of the individual.[53] Neonates can tolerate long periods of endotracheal intubation; the overall rate of symptomatic subglottic stenosis in neonates is 0.2%.[53] The occurrence of subglottic stenosis can be minimized by ensuring that the tube size allows a small air leak during inspiration (at a peak inspiratory force of approximately 25 mmHg) and that the tube is securely taped. Sedation is generally required to reduce head movement for children who are intubated. Because of the rapid growth of the lumen of the trachea and cricoid cartilage in the first year (which triples in size), infants may outgrow the obstruction, particularly if mild or moderate.[54] Serial balloon dilation can be effective.[55] For severe subglottic stenosis, laryngotracheal reconstruction (LTR) along with cricotracheal resection and thyrotracheal anastomosis may be required.[56]

Other Congenital Malformations. Congenital malformations of the upper airways, trachea, and bronchial tree are rare and cause airway obstruction. Lesions include coanal atresia; laryngeal atresias, webs, cysts, clefts, and subglottic hemangiomas; and tracheal stenosis. **Coanal atresia** can be unilateral or bilateral and causes lack of patency of the nasal cavity within the nasopharynx. Bilateral coanal atresia can be life threatening in newborns because they are obligate nasal breathers.[57] **Laryngeal atresias** and webs are caused by failure of the larynx to recanalize during embryogenesis. Most of these disorders are in the area of the glottis with extension into the subglottis.[48] **Tracheal stenosis** is a rare malformation characterized by inspiratory and expiratory stridor within the first few weeks of birth. It is usually associated with pulmonary, cardiovascular, and gastrointestinal malformations.[58] Structural abnormalities such as pectus excavatum or abnormalities involving the great vessels also can result in tracheal compression. For example, absent pulmonary valve syndrome dilates the pulmonary artery, which can compress the trachea and bronchi.[59] Tracheal or bronchial compression results in airway symptoms or feeding difficulties, or both, ranging from dysphagia, recurrent respiratory tract infections, wheezing, and stridor to acute respiratory distress or "dying spells." Many older children are first thought to have gastroesophageal reflux or asthma as the principal problem. Surgical management is usually required for these conditions, and some infants may require mechanical ventilation while awaiting surgery.[59]

Obstructive Sleep Apnea Syndrome

Obstructive sleep apnea syndrome (OSAS) is a breathing disorder defined by prolonged partial and/or intermittent complete UAO during sleep with disruption of normal ventilation and normal sleep patterns. Childhood OSAS is common with an estimated prevalence of 2% to 3% among middle-school children and as many as 13% of children ages 3 to 6 years. Prevalence is estimated to be two to four times higher in vulnerable populations (blacks, Hispanics, and preterm infants).[60] Unlike adults, OSAS in children occurs equally among males and females. Infants are at risk because they have both anatomic and physiologic predispositions toward airway obstruction and gas-exchange abnormalities, including a superiorly placed larynx, increased chest wall compliance, ventilation-perfusion mismatching, and ventilatory control instability. Congenital abnormalities of the airway, as described previously in this chapter, may have adverse effects on airway patency. Neck flexion, airway secretions, gastroesophageal reflux, and sleep deprivation can be associated with airway obstruction. Obstructive sleep apnea in infants has been associated with failure to thrive, behavioral deficits, and sudden infant death.[61]

PATHOPHYSIOLOGY. The pathophysiology of childhood OSAS is likely to be multifactorial in origin. The most common predisposing factor is adenotonsillar hypertrophy, which causes physical impingement on the nasopharyngeal airway. OSAS often occurs more frequently in overweight or obese children, as well as in those with orthodontic/craniofacial anomalies, neurologic disorders, allergy, asthma, abnormalities in the motor tone of the upper airways (frequently an issue in neurologically impaired children), abnormal arousal mechanisms, and genetic susceptibility.[62] Recent studies have documented that children with sleep disordered breathing (SDB) have increased inflammation in the upper airway and elevated serum levels of C-reactive protein, particularly in obese children.[63] Activation of inflammatory pathways contributes to end-organ injury with cardiovascular and metabolic morbidities.[64]

CLINICAL MANIFESTATIONS. Common manifestations of OSAS include snoring and labored breathing, restlessness, and sweating during sleep, which can be continuous or intermittent. There may be episodes of increased respiratory effort, but no audible airflow, often terminated by snorting, gasping, repositioning, or arousal. Affected children are often chronic mouth breathers and have large tonsils. They also may exhibit nocturnal enuresis.[65] It appears that there also may be a correlation between OSAS and elevated blood pressure similar to adults.[66] This is further linked to increased body mass index (BMI) and episodes of desaturation and apnea/hypopnea.[67]

OSAS can result in chronic hypoxemia and hypercapnia affecting multiple organ systems. Significant morbidity is associated with OSAS including cognitive problems, neurobehavioral impairment (e.g., inattention, hyperactivity, aggression, conduct problems, attention-deficit/hyperactivity disorder [ADHD]/emotional [mood]), excessive daytime sleepiness, impaired school performance, and poor quality of life.[68] Left untreated it also can cause cardiovascular disease, particularly left ventricular hypertrophy, and insulin resistance, as well as pulmonary complications (upper and lower respiratory tract infections) and reduced somatic growth.[69-71]

EVALUATION AND TREATMENT. All parents should be asked if their child exhibits snoring, a symptom that is often not spontaneously reported to a healthcare provider. The history and physical examination are the most effective means of diagnosis. Screening tools and sleep questionnaires may be helpful in evaluating the presence of SDB.[72] Radiographic images of the upper airway may reveal upper airway narrowing caused by adenoidal hypertrophy, and magnetic resonance imaging (MRI) and acoustic reflectometry may detect reduced upper airway dimensions.[73] The most definitive evaluation

("gold standard") is the polysomnographic sleep study, which documents obstructed breathing and physiologic impairment and may be combined with nocturnal oximetry studies. If obstructive sleep apnea caused by tonsillar enlargement is documented or strongly suspected clinically, children are most often referred for tonsillectomy and adenoidectomy (T&A). For severely affected children who do not respond to T&A or who have different problems, such as obesity that cannot be rapidly remedied, continuous positive airway pressure (CPAP) delivered through a tight-fitting nasal mask may be used during sleep. Treatment is important to prevent associated morbidities. Successful medical or surgical treatment results in improvement in physical, behavioral, and emotional difficulties as well as quality of life.[74-76]

DISORDERS OF THE LOWER AIRWAYS

Lower airway disease is one of the leading causes of morbidity in the first year of life and continues to be an important component of other illnesses. Pulmonary disorders commonly observed include perinatal conditions, such as neonatal RDS, congenital malformations, asthma, cystic fibrosis, infections, aspiration syndrome, and ARDS.

Respiratory Distress Syndrome of the Newborn

Respiratory distress syndrome (RDS) of the newborn (previously known as **hyaline membrane disease [HMD]**) is a major cause of neonatal morbidity and mortality. It occurs almost exclusively in premature infants and the incidence has increased in the United States over the past two decades. Preterm births account for about 12% of all births. Black mothers have 1.5 times the risk of preterm birth and 3.4 times the risk of preterm-related mortality.[77] RDS occurs in 50% to 60% of infants born at 29 weeks of gestation and decreases significantly by 36 weeks. Infants of diabetic mothers and those with cesarean delivery (especially elective C-section) are more likely to develop RDS because the labor-associated catecholamine and steroid surge do not occur, causing decreased pulmonary surfactant release.[78] It is more common in boys than girls and in one cohort it was more common in black infants.[79,80] Death rates have declined significantly since the introduction of antenatal steroid therapy and postnatal surfactant therapy. The major predisposing factor is prematurity because the immature lung is not well structured for gas exchange and has not yet developed adequate surfactant production and secretion. Death rates have declined significantly since the introduction of antenatal steroid therapy and postnatal surfactant therapy. The epidemiology, pathophysiology, and clinical presentation of RDS are outlined in Box 36-2.

PATHOPHYSIOLOGY. RDS is caused by surfactant deficiency, which decreases the alveolar surface area available for gas exchange. Surfactant lipoproteins have a detergent-like effect that separates the liquid molecules inside the alveoli, thereby decreasing alveolar surface tension. Without surfactant, alveoli collapse at the end of each exhalation.[81] Surfactant normally is not secreted by the alveolar cells until approximately 20 to 24 weeks of gestation (see Figure 36-1). Premature infants also are born with underdeveloped and small alveoli that are difficult to inflate. Additionally, the alveoli have thick walls and an inadequate capillary blood supply such that gas exchange is significantly impaired. The infant's chest wall is weak and highly compliant and, thus, the rib cage tends to collapse inward with respiratory effort. The net effect is *atelectasis* (Figure 36-11), resulting in significant hypoxemia. Atelectasis is difficult for the neonate to overcome because it requires a significant negative inspiratory pressure to open the alveoli with each breath. The increased work of breathing and a decrease in tidal volume cause alveolar hypoventilation and hypercapnia. Hypoxia and hypercapnia cause pulmonary vasoconstriction, which increases intrapulmonary resistance and shunting. Increased pulmonary vascular resistance causes a partial return to fetal circulation, with right-to-left shunting of blood through the ductus arteriosus and foramen ovale further compromising pulmonary perfusion. There is decreased surfactant production with inadequate pulmonary perfusion and alveolar ventilation.

Prolonged hypoxemia and inadequate tissue perfusion activates anaerobic glycolysis, producing lactic acid and thus causing metabolic acidosis. Alveolar hypoventilation causes respiratory acidosis. Inadequate alveolar ventilation can be further complicated by increased pulmonary capillary permeability. Additionally, many premature infants with RDS require positive pressure mechanical ventilation with high oxygen content, which damages the alveolar epithelium (e.g., barotrauma and oxygen toxicity). Together these conditions result in the leakage of plasma proteins into the alveoli and pulmonary edema. Fibrin deposits in the air spaces create the appearance of *hyaline membranes* for which the disorder was originally named. The plasma proteins leaked into the air space have the additional adverse effect of inactivating any surfactant that may be present. The pathogenesis of RDS is summarized in Figures 36-11 and 36-12.

CLINICAL MANIFESTATIONS. Signs of RDS appear within minutes of birth. Some neonates require immediate resuscitation because of asphyxia or initial severe respiratory distress. Characteristic signs are tachypnea (respiratory rate more than 60 breaths per minute), expiratory grunting, intercostal and subcostal retractions, nasal flaring, and cyanosis. The natural course is characterized by progressive hypoxemia and dyspnea with severity progressing over the first 2 days of life. Apnea and irregular respirations occur as the infant tires. The severity of the hypoxemia and the difficulty in providing adequate supplemental oxygenation result in the Vermont Oxford Neonatal Network definition of RDS as a Pao_2 less than 50 mmHg in room air, central cyanosis in room air, or a need for supplemental oxygen to maintain Pao_2 greater than 50 mmHg, as well as the classic chest film appearance.[82] Typically, a chest radiograph shows diffuse, fine granular densities within the first 6 hours of life. This "ground glass" appearance is associated with alveolar flooding. In most cases the clinical manifestations reach a peak within 3 days, after which there is gradual improvement with appropriate treatment.

EVALUATION AND TREATMENT. Diagnosis is made on the basis of clinical manifestations, chest radiographs, and, if needed, analysis of amniotic fluid or tracheal aspirates to estimate lung maturity (lecithin/sphingomyelin ratio [L/S ratio]). The

BOX 36-2 NEWBORN RESPIRATORY DISTRESS SYNDROME

Epidemiology
Worldwide
Prematurity predisposes
Cesarean section without labor predisposes
Perinatal asphyxia predisposes
Male > female
White > black
Second-born twin at greater risk
PROM spares
IUGR spares
Maternal stress spares
Maternal diabetes predisposes if less than 37 weeks
Maternal hemorrhage predisposes

Clinical Signs
Onset near the time of birth
Tachypnea
Increased work of breathing:
  Nasal flaring
  Retractions of respiratory muscles
Expiratory grunt
Cyanosis
Systemic hypotension
Characteristic chest film
Course to death or improvement in 3 to 5 days
Fine inspiratory rales
Hypothermia
Peripheral edema
Pulmonary edema

Pathophysiology
Reduced lung compliance
Reduced FRC
Poor lung distensibility
Poor alveolar stability
Right-to-left shunts
Reduced effective pulmonary blood flow
If hypotensive and hypoxic, poor peripheral perfusion, poor renal perfusion, myocardial malfunction
Patent ductus arteriosus contributes

Pathobiochemistry
Respiratory acidosis
Decreased saturated phospholipids
Low amniotic fluid L/S ratio
Low surfactant-associated proteins
Decreased total serum proteins
Decreased fibrinolysis
Low thyroxine levels

Pathology
Atelectasis
Injury to epithelial cells, edema
Membrane contains fibrin and cellular products
No tubular myelin
Osmiophilic lamellar bodies decreased early, increased later

Etiology
Surfactant deficiency during disease
Probable inadequate hormonal (corticoid) stimulus in utero
DPL synthesis impaired and/or destruction increased
Autonomic dysfunction

Prevention
Prenatal glucocorticoids for more than 24 hours
Prevention of asphyxia
Surfactant replacement:
  Prophylactically—within 15 minutes after birth
  Early rescue—within 60 minutes after birth
  Established RDS—within 12 hours after birth
Continuous positive airway pressure

ultimate treatment for RDS would be prevention of premature birth. For women in preterm labor, antenatal treatment with glucocorticoids induces a significant and rapid acceleration of lung maturation and stimulation of surfactant production in the fetus. There is extensive evidence that when there is risk of preterm labor antenatal corticosteroid therapy given between 26 and 34 weeks of gestation reduces the incidence of RDS and death. Repeated courses of corticosteroids may be safe in this setting.[83,84] Glucocorticoids induce a significant and rapid acceleration of lung maturation and stimulation of surfactant production in the fetus. There is extensive evidence that maternal steroid therapy significantly reduces the incidence of RDS, central nervous system hemorrhage, and neonatal mortality.[85,86] Glucocorticoids may not significantly affect respiratory outcomes when given after 34 weeks of gestation.[87,88]

Current recommendations for infants weighing less than 1000 g include prophylaxis beginning within 15 to 30 minutes of birth by administration of exogenous surfactant (either

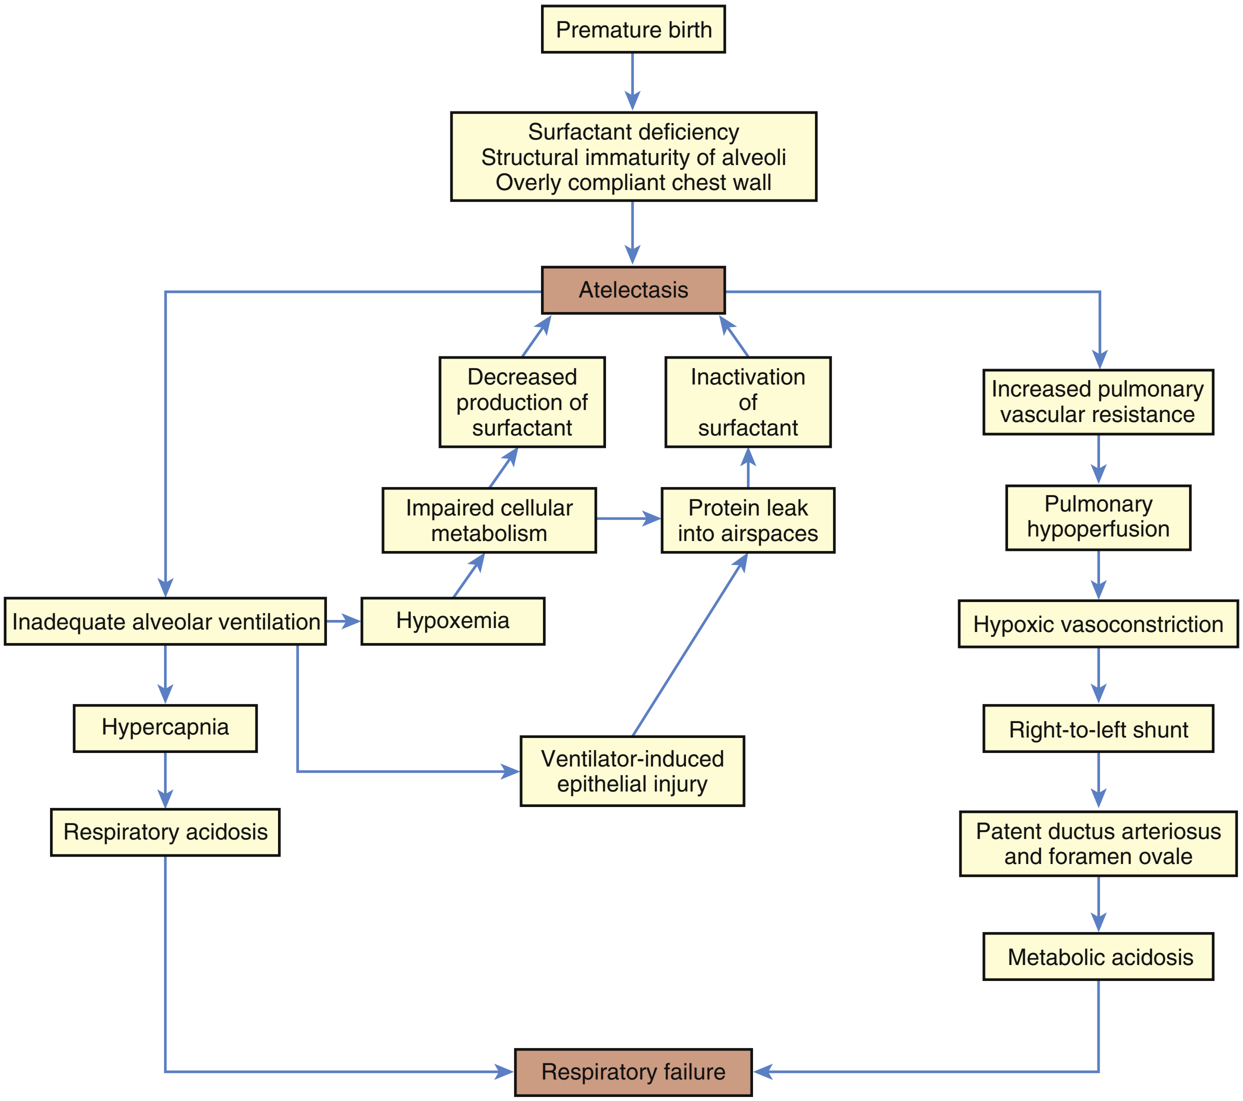

FIGURE 36-12 **Pathogenesis of Respiratory Distress Syndrome (RDS) of the Newborn.** RDS is also known as hyaline membrane disease.

synthetic or natural) through a nebulizer or nasal continuous positive airway pressure (CPAP) ventilation.[81] Repeat doses are given every 12 hours for the first few days. There is usually a dramatic improvement in oxygenation, as well as a decreased incidence of RDS death, pneumothorax, and pulmonary interstitial emphysema.[89,90] For infants weighing more than 1000 g, surfactant replacement is based on clinical need. Surfactant therapy should be considered complementary to antenatal glucocorticoids. The two therapies together appear to have an additive effect on improving lung function.[91] Supplemental inositol also may promote maturation of surfactant and prevent adverse neonatal outcomes.[92]

Supportive care includes oxygen administration and mechanical ventilation. Mechanical ventilation can result in a proinflammatory state that may contribute to the development of chronic lung disease, such as bronchopulmonary dysplasia (BPD). Strategies that are lung protective, such as greater reliance on nasal continuous positive airway pressure (NCPAP) to prevent lung injury, permissive hypercapnia, lower oxygen saturation targets, modulation of tidal volume (V_t) settings, and use of high-frequency oscillation, are being evaluated.[93,94] Mechanical ventilation with mixtures of oxygen and nitric oxide or helium may improve gas exchange and reduce airflow resistance and have improved outcomes.[95-97] Most infants survive RDS and, in many cases, recovery may be complete within 10 to 14 days. However, the incidence of subsequent chronic lung disease is significant among very low birth weight infants.[98,99]

Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD), also known as *chronic lung disease of prematurity,* is the major cause of pulmonary disease in infants. It is associated with premature birth (usually before 28 weeks of gestation), perinatal supplemental oxygen, and positive pressure ventilation. There are approximately 60,000 infants born weighing less than 1500 g in the

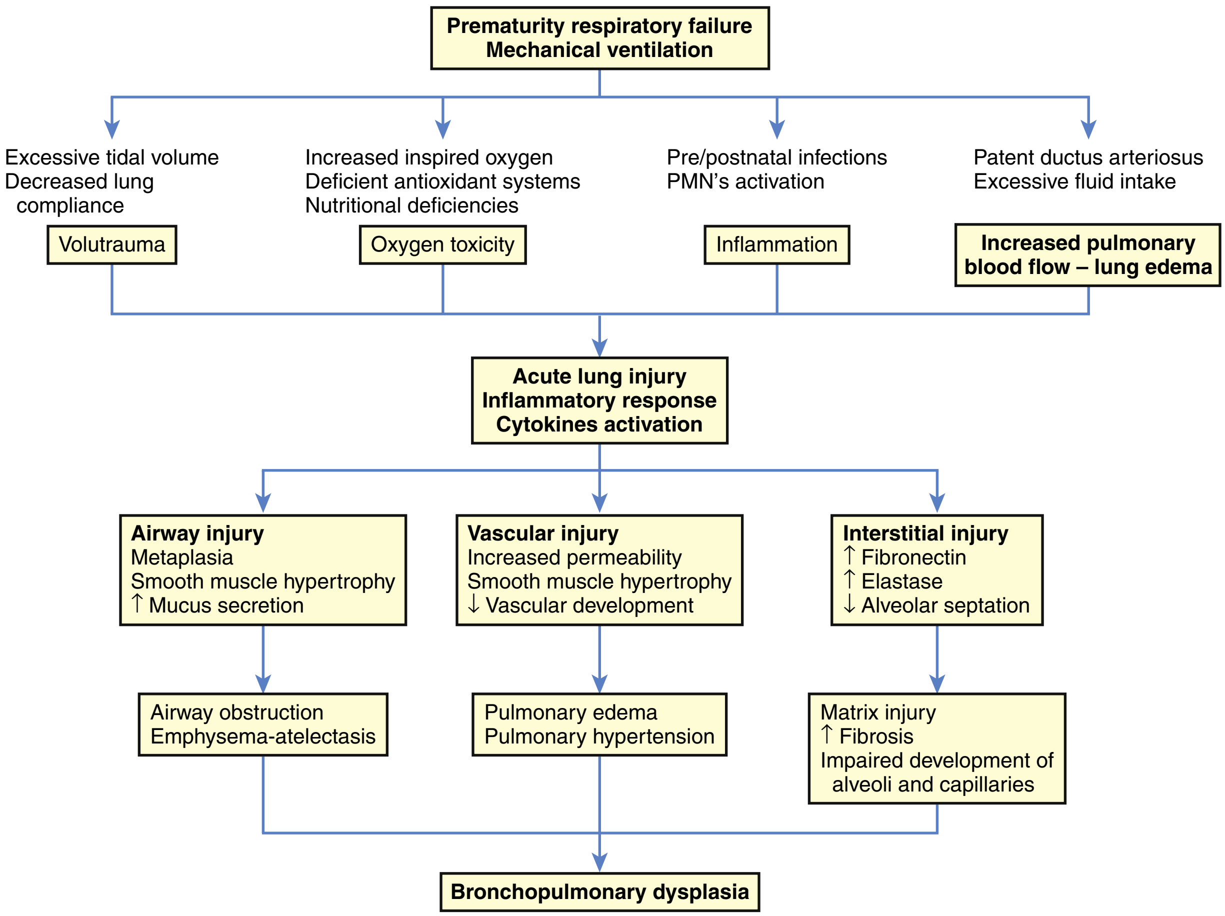

FIGURE 36-13 Pathophysiology of Bronchopulmonary Dysplasia (BPD). (From Polin RA, Fox WW, Abman SH: *Fetal and neonatal physiology,* ed 4, Philadelphia, 2011, Philadelphia.)

United States on an annual basis. About 20% to 30% of very low and extremely low birth weight infants develop BPD.[100,101]

In the current era of neonatology, the widespread use of antenatal glucocorticoids, postnatal surfactant, and NCPAP has lessened the incidence and severity of RDS and thus also reduced the incidence of BPD. Surprisingly, some of the tiny infants who develop BPD have shown few or no clinical signs of RDS at birth or have initially received only low levels of supplemental oxygen or ventilatory support for apnea.[102] The presence of antenatal chorioamnionitis, postnatal sepsis, a patent ductus arteriosus, and genetic susceptibility confer additive risk of developing BPD.[103]

BPD is a multisystem condition and is associated with developmental disorders in other systems, such as growth retardation, pulmonary hypertension, neurodevelopmental delays (e.g., cerebral palsy), hearing defects, and retinopathy of prematurity.[100]

PATHOPHYSIOLOGY. Lung immaturity and inflammation contributes to the development of BPD. In preterm infants born at less than 28 weeks of gestation, the fetal lung is in the *canalicular stage* of development (16 to 28 weeks), a critical period during which type II epithelial cells appear, capillaries grow into the future distal alveolar regions, and the interstitium begins to condense (see Figure 36-1). Ultimately the alveoli must have a very thin interface between the air space and the capillary for appropriate gas exchange. The extensive network of alveoli develops by septation within the terminal respiratory unit, beginning in the *saccular stage,* starting at approximately 26 to 28 weeks. The alveoli are vulnerable to inflammation and impaired growth during this stage.[104]

Before the widespread use of surfactant therapy, BPD was a disease characterized by airway injury, inflammation, and parenchymal fibrosis *(classic BPD)*. Now, after the initiation of surfactant therapy, what is called *new BPD* is most often a form of arrested lung development with poor formation of the alveolar architecture. Alveoli are large and fewer in number, thereby presenting decreased surface area for gas exchange. There is abnormal vascular endothelial growth factor that results in abnormal pulmonary capillary development and mild fibrosis accompanied by persistent inflammation contributing to perfusion mismatch and pulmonary hypertension.[105] Genetic influences on surfactant proteins and inflammatory regulation have been documented in association with the "new BPD."[106]

Levels of proinflammatory cytokines, such as tumor necrosis factor-alpha (TNF-α), interleukin 1 (IL-1), interleukin 6 (IL-6), and interleukin 8 (IL-8), are all elevated in the amniotic fluid or tracheal aspirates, or both, of preterm infants who later develop BPD. Inflammation invites neutrophils and macrophages to release reactive oxygen species and proteolytic enzymes. Interestingly, the predominant mediators of *new BPD* are profibrotic and angiogenic cytokines rather than proinflammatory cytokines.[104,107] Figure 36-13 illustrates the pathophysiology of BPD.

CLINICAL MANIFESTATIONS. The current clinical definition of BPD includes the need for supplemental oxygen at 36 weeks of postmenstrual age (estimated time of conception to birth plus weeks since birth) and for at least 28 days after birth, with a graded severity dependent on required respiratory support at term (divided into mild, moderate, and severe based on oxygen requirements and ventilatory needs). Clinically, the infant exhibits hypoxemia caused by ventilation-perfusion mismatch and diffusion defects. Work of breathing is elevated, resulting in hypercapnia. The ability to feed may be impaired. Intermittent bronchospasm with wheezing, mucus plugging, and pulmonary hypertension characterizes the clinical course of the most severely affected babies.

EVALUATION AND TREATMENT. Infants with severe BPD require prolonged, assisted ventilation with cautious weaning. Prevention of lung damage with "gentle ventilation" (see lung protective strategies of ventilation in RDS section, p. 1303) or early nasal CPAP, or both, is used in clinical situations when permitted. Use of CPAP prevents airway collapse and results in fewer days of oxygen and ventilator requirement by reducing the amount of lung injury as compared with mechanical ventilation.[108] Additionally, oxygen supplementation at lower than previously accepted values (89% to 94% saturations) is a means to reduce oxidant injury to the lungs and retinal vasculature. Diuretics are used to control pulmonary edema, bronchodilators reduce airway resistance, and inhaled corticosteroids improve the rate of extubation and reduce the time that mechanical ventilation is required. Caffeine citrate is used to prevent apnea and for neuroprotection.[109] Supplementation with vitamin A provides antioxidant protection and stimulates lung growth and surfactant production.[110] Careful nutritional and fluid and electrolyte support is routinely used and has resulted in improved outcomes.

Respiratory Tract Infections

Infections may be localized to the bronchioles, bronchi, alveoli, interstitium, or pleura. The cause and site of infections are related to the age of the child, seasonal variables, and environmental exposures. Infants and young children tend to have more viral infections, especially during late autumn to early spring. Environmental factors may play a role, such as the presence of siblings and daycare exposure.

Bronchiolitis

Bronchiolitis is a common viral-induced lower respiratory tract infection of the small airways that occurs in children younger than 2 years of age. The most common associated pathogen is RSV, but it also may be associated with adenovirus, rhinovirus (older children), influenza, parainfluenza virus (PIV), and human metapneumovirus.[1] Bronchiolitis has a peak incidence during winter (late December) and a spike in February, and then tapers off in the spring, paralleling the RSV season. There are distinct regional differences in the United States depending on variation in the viral season based on geography. It is a major reason for hospital admission of children younger than 1 year, particularly children of lower socioeconomic status.[111] Healthy infants usually make a full recovery from RSV bronchiolitis, but infants who are premature (birth weight <2500 g) or who have underlying lung disease, heart disease, or immune deficiency may have a much more severe or even deadly course. Bronchiolitis has been linked to an increased risk for asthma later in childhood.[112,113] Bronchiolitis has a worldwide annual death rate between 160,000 and 600,000 deaths.[114]

PATHOPHYSIOLOGY. Viral infection causes inflammation and necrosis of the bronchial epithelium and destruction of ciliated epithelial cells. There is infiltration with lymphocytes around the bronchioles and a cell-mediated hypersensitivity to viral antigens with release of lymphokines causing inflammation, as well as activation of eosinophils, neutrophils, and monocytes. The submucosa becomes edematous, and cellular debris and fibrin form plugs within the bronchioles. Edema of the bronchiolar wall, accumulation of mucus and cellular debris, and possibly bronchospasm narrow or occlude many peripheral airways. Areas of atelectasis and uneven ventilation lead to ventilation-perfusion mismatch and hypoxemia.

The mechanics of breathing are disrupted by bronchiolitis. Airway narrowing causes obstruction of airflow that is worse with expiration. This leads to air trapping, hyperinflation, and an increase in FRC. Airway resistance and hyperinflation result in decreased lung compliance and increased work of breathing and may cause hypercapnia in severe cases.

CLINICAL MANIFESTATIONS. Symptoms usually begin with significant rhinorrhea followed by a tight cough over the next several days, along with systemic signs of decreased appetite, lethargy, and fever. Infants may have tachypnea, expiratory wheezing, cough, rhinorrhea, mild fever, varying degrees of respiratory distress, and abnormal auscultatory findings of the chest. In severe cases, chest radiographs reveal hyperexpanded lungs, patchy or peribronchial infiltrates, and atelectasis. Severely affected infants appear anxious and distressed because of dyspnea or hypoxemia. The thoracic cage is overexpanded, particularly in its anteroposterior diameter. The infant takes rapid, short breaths, and wheezing and rales are often heard on auscultation. With overexpansion of the lungs, the diaphragm is flattened, causing downward displacement of the liver and spleen. Abdominal distention results from air swallowing. Genetic tendencies have been noted that correlate RSV bronchiolitis with asthma.[115]

EVALUATION AND TREATMENT. Diagnosis of bronchiolitis is made by review of signs and symptoms (e.g., rhinitis, cough, wheezing, crackles, chest retractions and/or hyperinflation, tachypnea) and radiologic examination. Nasal washings/swabbings may be tested for specific viral agents, such as RSV. RSV swabs are positive in 70% of cases of bronchiolitis. In severe cases, chest imaging may be required for diagnosis and follow-up. Ultrasound is a reliable option without risk of irradiation.[116]

Treatment is determined by the severity of the disease and the age of the child.[117] Most cases are mild and are managed at home with supportive care. In more severe cases, supplemental oxygen and increased hydration are commonly used. Inhaled hypertonic saline has been found to decrease clinical severity and length of hospital stay.[67] Inhaled bronchodilators or bronchodilators and corticosteroids benefit infants with underlying lung disease or wheezing.[118-120] Mechanical ventilation

is occasionally necessary and clinical indicators for CPAP are being evaluated.[121,122] Preventive treatment with RSV-specific monoclonal antibody, provided as a monthly injection through the RSV season, is recommended for high-risk infants less than 2 years old who meet specific criteria (e.g., bronchopulmonary dysplasia, recurrent aspiration pneumonitis, cystic fibrosis, or pulmonary malformation). Development of other immunotherapies and a RSV vaccine is in progress.[123,124]

Pneumonia

Pneumonia is infection and inflammation in the terminal airways and alveoli. **Community-acquired pneumonia (CAP)** is one of the most common global infections in the pediatric age group and the leading cause of morbidity and mortality in infants.[125] The incidence of viral and bacterial pneumonia varies according to age, time of year, and geographic location. Viral pneumonias are most common in young children and infections occur most often in winter to early spring. Mortality from respiratory viruses in developed countries is rare but morbidity is significant. In less developed countries, viral pneumonia results in nearly 5 million deaths annually in children younger than the age of 5.[126] Bacterial pneumonias are less common and occur across all age groups. Fungal and anaerobic pneumonias are rare in children.[127] Risk factors for developing CAP include age younger than 2 years, overcrowded living conditions, winter season, recent antibiotic treatment, attendance at daycare centers, and passive smoke exposure. Nutritional status, age, and underlying disease process influence morbidity and mortality related to CAP.

PATHOPHYSIOLOGY. **Viral pneumonia** is two to three times more likely in children than in adults. Viral-bacterial co-infections are common. The most common cause in infants and young children is respiratory syncytial virus (RSV). A number of other viruses are important, including parainfluenza, *Haemophilus influenzae* types A and B, coronaviruses, rhinoviruses, enteroviruses, human metapneumovirus (hMPV), bocavirus, and adenoviruses.

Viral infection is acquired by direct contact, droplet transmission, or aerosol transmission. Viral infection of the lower respiratory tract results in destruction of ciliated epithelium of the distal airway, with sloughing of cellular material. A mononuclear-predominant inflammatory response occurs first in the interstitium and may later involve the alveoli. Certain serotypes of adenovirus can cause necrotizing disease, sometimes leading to obliterative bronchiolitis and significant lung disability.

Early in the course of illness, it is often difficult to determine whether the pneumonia is of viral or bacterial origin. In bacterial pneumonia, the degree of elevated temperature, absolute neutrophil counts, and percent of bands are consistently higher than in those cases of viral etiology.[128] Diagnosis of a viral etiology requires laboratory confirmation (immunofluorescence tests). Development of safe agents to treat and prevent viral pneumonias continues to be a priority, as is development of more effective vaccines.[129]

Bacterial pneumonia beyond the neonatal period is most commonly the result of infection with streptococcal and staphylococcal microorganisms (Table 36-2). Pneumococcal *(S. pneumoniae)* pneumonia is the most common cause of bacterial pneumonia; other causative microorganisms include *Staphylococcus aureus* group A streptococci and atypical bacteria. Bacterial pneumonia most often presents acutely and with variable severity. Pneumococci have specific virulence factors (such as capsules) that increase their survival and proliferation while causing insult to the host.[130] A polyvariant pneumococcal conjugate vaccine (PCV7 or PCV13) is incorporated into routine childhood immunizations and appears to have lessened the incidence of pneumococcal pneumonia in children younger than 2 years of age.[131]

Bacterial pneumonia usually begins with aspiration of one's own nasopharyngeal bacteria into the trachea. A preceding viral infection sometimes sets the stage for bacterial infection by causing epithelial damage and reduced mucociliary clearance in the trachea and major bronchi. Colonization of the trachea then ensues, with the microorganism, host, and environment all playing a role in the development of pneumonia. Once in the alveolar region, bacteria encounter local host defenses, such as antibodies, complement, phagocytes, and cytokines, that prepare bacteria for ingestion by alveolar macrophages.

If these mechanisms fail, neutrophils will be recruited and an intense cytokine-mediated inflammation will ensue. Vascular engorgement, edema, and a fibrinopurulent exudate with tissue damage occur. Alveolar filling precludes gas exchange and, if extensive, can lead to respiratory failure. If sepsis occurs at the same time, shock and end-organ hypoperfusion may develop. Staphylococcal and group A streptococcal pneumonia can be particularly fulminant and necrotizing, with a high incidence of accompanying empyema, pneumatoceles, and sepsis. Empyema is increasingly associated with pneumococcal infections and antibiotic-resistant microorganisms.[132,133]

The clinical presentation of bacterial pneumonia, particularly pneumococcal, may include a preceding viral illness followed by fever with chills and rigors, shortness of breath, and an increasingly productive cough. Occasionally there is blood streaking of the sputum. Respiratory rate and oxygen saturation are important clinical indicators. Auscultation usually reveals such abnormalities as crackles or decreased breath sounds. Other less specific findings may include malaise, emesis, abdominal pain, and chest pain. Chest film will usually present with a lobar pattern in older children and adolescents but may appear patchier with a bronchopneumonic pattern in younger children.[134]

Atypical pneumonia ***(Mycoplasma pneumoniae, Chlamydophila pneumoniae)*** is the most common cause of CAP for school-age children (ages 5 and older) and young adults.[127] *Chlamydophila* pneumonia is clinically indistinguishable from and is typically grouped with *Mycoplasma* as "atypical pneumonia." Transmission is from person-to-person with a 2- to 3-week incubation period.

Mycoplasma is known to cause a wide spectrum of disease and has more extensive complications than previously recognized. Studies reveal that macrolide-resistant *Mycoplasma pneumoniae* is seen increasingly in infants and younger children.[135,136] Children experiencing recurrent respiratory tract

TABLE 36-2 COMMON TYPES OF PNEUMONIA IN CHILDREN

TYPE	CAUSAL AGENT	AGE	ONSET	SIGNS/SYMPTOMS	PATHOPHYSIOLOGY
Viral pneumonia	Respiratory syncytial virus (RSV), influenza (A and B), adenovirus, parainfluenza, human metapneumovirus (hMPV)	Infants for RSV All ages for others	Acute or gradual, winter and early spring	Mild to high fever, cough, rhinorrhea, malaise, rales, rhonchi, or wheezing; variable radiographic pattern	Edema, increased mucus, and interstitial pneumonia
Pneumococcal pneumonia	Pneumococci *(Streptococcus pneumoniae)*	1-4 yr	Acute, follows an upper respiratory tract infection, winter and early spring	High fever, productive cough, pleuritic pain, increased respiratory rate, decreased breath sounds in area of consolidation; lobar pattern or "round pneumonia" on radiograph	Inflammation of bronchial mucosa, alveolar exudate *Early:* red hepatization with WBCs, RBCs, and fibrin consolidation *Late:* gray hepatization with fibrin and neutrophils in alveoli *Resolution:* many phagocytic macrophages
Staphylococcal pneumonia	*Staphylococcus aureus* Methicillin-resistant *Staphylococcus aureus* (MRSA)	1 wk-2 yr	Acute, winter months	High fever, cough, respiratory distress, toxic appearance, sepsis, empyema, pneumatoceles are common; multilobar consolidation	Necrotizing patterns may occur in severe cases
Streptococcal pneumonia	Group A streptococci	All ages	Acute, any season	High fever, chills, respiratory distress, sepsis or shock; empyema, pneumatoceles	Tracheobronchitis, interstitial pneumonia with ulcers, exudate edema, and localized hemorrhage
Mycoplasma and *Chlamydophila pneumonia*	*M. pneumoniae* *C. pneumoniae*	School age and adolescents	Gradual	Low-grade fever; cough	Inflammation of bronchi with lymphocyte and chlamydia neutrophil recruitment

RBCs, Red blood cells; *WBCs,* white blood cells.

infections often have been found to be infected with atypical bacteria.

Mycoplasma microorganisms lack cell walls but have a limiting membrane and a specialized tip for attaching to ciliated respiratory epithelial cells. Local sloughing of cells occurs. Peribronchial lymphocytic infiltration develops, along with neutrophil recruitment to the airway lumen. The pattern resembles bronchitis or bronchopneumonia.

Onset of symptoms is usually gradual, resembling a typical upper respiratory tract infection with low-grade fever and prominent cough. There may be accompanying sore throat, myalgia, and headache. Cases are not usually clinically severe, and full recovery should be expected without complications. When complications do occur, they can include bronchopneumonia, parapneumonic effusions, and necrotizing pneumonitis.[137]

EVALUATION AND TREATMENT. Diagnosis of pneumonia is based on clinical, laboratory, and chest radiograph findings. Guidelines have been developed to improve and aid assessment and management of pediatric pneumonia.[138] Identifying etiologic pathogens can be very difficult in children, especially because there is often overlap between bacterial and viral pathogens. Biomarkers facilitate more rapid diagnosis and procalcitonin is most specific to bacterial infection and can guide antibiotic therapy. The highly sensitive C-reactive protein (hs-CRP) is less specific and elevated in both viral and bacterial infections.[139] Other laboratory tests that may be helpful include a white cell–granulocyte count or erythrocyte sedimentation rate (ESR) but do not indicate a specific etiology. Several microbiologic tests are available including polymerase chain reaction (PCR) and nucleic acid amplification tests (NAATs). On chest radiography, a bacterial pneumonia initially produces an alveolar infiltrate and later causes a segmental or lobar disease. A viral infection is more likely to be associated with an interstitial pattern.

Most pneumonias may be treated on an outpatient basis; however, some children require oxygen supplementation and, occasionally, assisted ventilation. This is particularly true with infants who have a viral interstitial pneumonia, such as RSV. In addition, adequate hydration, nutrition, and supportive pulmonary therapy are required to reduce the duration and severity of illness. Many hospitalized infants are markedly tachypneic and unable to coordinate their breathing with swallowing such that they may require enteral feeding. Aspiration is always a risk with infants in respiratory distress.

Appropriate antibiotic administration, whether oral or intravenous (IV), for bacterial pneumonias is dependent on age and severity assessment. Hospitalized children require antibiotic therapy.[140] Local patterns of drug resistance must be considered.[140] Both pneumococcal and mycoplasma pneumonia present some unique treatment obstacles and often need a multifaceted approach to care, including vaccine antigens, antibiotic

combinations, and immunoadjuvant therapies.[141] Children should be vaccinated against influenza and pneumococcus.[142]

Aspiration Pneumonitis

Aspiration pneumonitis is caused by a foreign substance, such as food, meconium, secretions (saliva or gastric secretions), or environmental compounds entering the lung and causing inflammation of lung tissue. The aspiration of meconium from amniotic fluid can occur at birth. Meconium contains bile salts from the fetal intestinal tract that cause inflammation. Neurologically compromised children or children with chronic lung disease may have chronic pulmonary aspiration (CPA) because of failure of protective reflexes. This can cause progressive lung disease, bronchiectasis, and respiratory failure and is the leading cause of death in children who are neurologically compromised.[143,144] Children undergoing sedation or anesthesia also may aspirate oral secretions contaminated with anaerobic bacteria or stomach contents, which may be acidic.

The severity of lung injury after an acute aspiration incident is determined by the volume of material aspirated, the pH of the aspirated material, and the presence of pathogenic bacteria. Very low pH or very high pH causes a significant inflammatory response. With hydrocarbon ingestions, lung injury is determined by the volatility and viscosity of the aspirated substance. A low-viscosity substance, such as gasoline or lighter fluid, is the most toxic; high-viscosity hydrocarbons, such as petroleum jelly or mineral oil, are much less likely to cause pneumonitis. Treatment for aspiration pneumonitis depends on the material aspirated but generally includes broad-spectrum antibiotic therapy. Children with CPA and a large amount of upper respiratory tract secretions may benefit from salivary gland injection with botulinum toxin A (BTX-A) to suppress secretion.[145]

Bronchiolitis Obliterans

Bronchiolitis obliterans (BO) is fibrotic obstruction of the respiratory bronchioles and alveolar ducts secondary to intense inflammation. It is relatively rare in children. Two types are noted in the literature—proliferative and constrictive—with the latter being the more common form. Most cases of BO in children are associated with viral pulmonary infections, such as adenovirus (most common), influenza, pertussis (whooping cough), measles, parainfluenza, RSV, human immunodeficiency virus (HIV), or *M. pneumoniae*. BO may occur after allograft transplantation (lung, heart-lung, and bone marrow) as a manifestation of graft-versus-host disease. It also is associated with collagen vascular disease, toxic fume inhalation, chronic hypersensitivity pneumonitis, Crohn disease, and Stevens-Johnson syndrome.[146,147] Initially, cough, respiratory distress, and cyanosis occur, followed by a brief period of improvement. The progression of disease is then reflected by tachypnea, sputum production, increased anterior/posterior diameter, crackles, wheezing, and hypoxemia.[148]

There is no specific treatment for BO and, because it is so rare, there have been no randomized clinical trials. Therapeutic options include inhaled corticosteroids, bronchodilators, antibiotics, and oxygen supplementation. Mechanical ventilation may contribute to the progression of the disease. Use of antiviral agents may be warranted in managing those with viral infection. For transplant recipients, augmentation of immunosuppressive therapies and treatment with anti-inflammatory agents are showing promise in reducing airway inflammation, thus improving pulmonary function.[149] Clinical progression can be quite variable depending on the predisposing condition. Some children experience partial recovery, whereas others follow a course of steady decline in lung function. Lung transplantation may be considered.[147]

Asthma

Asthma is a chronic inflammatory disease characterized by sensitization to allergens, bronchial hyperreactivity, and reversible airway obstruction. It is the most prevalent chronic disease in childhood, affecting about 10% of U.S. children between 5 and 17 years of age, with boys more often affected than girls. Asthma prevalence is increasing, especially among non-Hispanic blacks,[150] obese children,[151] and children from urban and low-income populations.[152] The overall asthma-related death rate is decreasing[153] and asthma-related deaths almost always occur outside the hospital setting.

The severity and persistence of asthma are influenced by age at disease onset, genetics, behavior, atopy, air pollution, level of allergen exposure, environmental tobacco smoke, gastroesophageal reflux, and respiratory tract infections.[154] Additional confounding variables that affect disparity in asthma morbidity and therapy are social stress in the home (e.g., violence and depressed housing conditions), lack of health insurance, poor access to asthma specialists, inappropriate utilization of health-care resources, and inadequate medical care.[153,155]

The wide spectrum of clinical disease in asthma and differential responses to standard treatment reflects a complex interaction between environmental factors and genetic susceptibility. *Environmental factors* include early exposure to allergens (e.g., air pollution, dust mites, cockroach antigen, cat exposure, tobacco smoke, and dietary factors); infections, particularly viral respiratory tract infections (e.g., rhinovirus and RSV); and stress.[156,157] Vitamin D insufficiency may be a risk factor for wheezing in children since vitamin D suppresses Th2-mediated allergic disease.[158] Environmental exposures interact with an individual's genetic vulnerabilities to induce the onset of clinical asthma and epigenetic mechanisms are being studied.[154,159,159a]

The *genetics of asthma* are complex. Genetic studies have led to the identification of many candidate genes or chromosomal regions that are associated with asthma.[160-163] Included in the long list of asthma-associated genes are those that code for increased levels of immune and inflammatory mediators (e.g., IL-4, IL-5, IL-13, IgE, and leukotrienes), adrenergic receptors, nitric oxide, and transmembrane proteins in the endoplasmic reticulum.[163,164] In addition, specific gene expression may impart associated phenotypes, such as bronchial hyperresponsiveness (BHR), inflammation, sensitization to allergens, airway fibroblasts, airway remodeling, and responsiveness to asthma therapies.[165] Linking specific genes to specific asthma phenotypes is leading to targeted therapies and personalized approaches to asthma treatment (see What's New? Asthma Phenotypes).

WHAT'S NEW?

Asthma Phenotypes

The severity and clinical course of asthma in children can vary from mild and transient to severe and lifelong. Research is now emerging that suggests genetically influenced differences in inflammatory and immune mechanisms may explain much of this variability. The majority of asthmatic children have the well-described allergic (type I hypersensitivity) form of asthma that is characterized by high levels of Th2 cytokines, IgE synthesis, and activation of eosinophils (therefore also called *eosinophilic asthma*), resulting in episodic bronchospasm that is responsive to inhaled bronchodilators and anti-inflammatory medications. Other mechanisms have been implicated in children whose asthma phenotype is characterized by more severe symptoms and relative unresponsiveness to treatment with inhaled steroids. One of these mechanisms is called *neutrophilic asthma* in which Th1 cytokines and activation of large numbers of polymorphonucleocytes appear to dominate lung injury. Neutrophilic asthma especially involves the cytokines TNF-α, interferon-gamma (IFN-γ), IL-17, and IL-27. Other genotypic changes can lead to diverse asthma phenotypes. For example, variability in the response to inhaled glucocorticoids may be related to the role of IL-13. Another example involves a specific polymorphism in the gene for the β-adrenergic receptor that is prevalent in black children and is associated with poor response to β-adrenergic inhaled medication. Variability of response to leukotriene receptor 1 antagonist is related to variation in leukotriene pathway candidate genes. Finally, genetic factors also have been identified that are important to the development of airway remodeling. Increased understanding of these asthma phenotypes is leading to new therapies that may provide significant improvements in personalized management of severe and drug-resistant asthma.

Data from Carolan BJ, Sutherland ER: *J Allergy Clin Immunol* 131(3):627-634, 2013; Corren J et al: *N Engl J Med* 365:1088–1098, 2011; Cowan K, Guilbert TW: *Curr Opin Pediatr* 24:344–351, 2012; Ducharme FM, Krajinovic M: *Pediatr Resp Rev* 12:170–176, 2011; Kotani H et al: *J Clin Pharm Ther* 37(1):112–116, 2012; Siroux V, Garcia-Aymerich J: *Curr Opin Allergy Clin Immunol* 11:393–399, 2012; Thomson NC, Patel M, Smith AD: *Biologics* 6:329–335, 2012; Wenzel S: *Nat Med* 18:716–725, 2012.

One hypothesis for the high prevalence of asthma in westernized cultures is called the "hygiene hypothesis." Allergen exposure shifts the immune system toward Th2-predominant phenotype with resultant increase in the production of antibodies, including IgE. This effect is normally balanced by exposure to numerous siblings, daycare, farming, endotoxin, and certain microorganisms (e.g., *Toxoplasma gondii*, hepatitis A virus, and *Helicobacter pylori*). It is proposed that children exposed to a highly hygienic environment and who receive vaccinations to prevent infections lack adequate exposure to common pathogens and therefore do not achieve a proper balance of their immune systems.[166,167] Asthma develops because the Th2 response (in which CD4 T-helper [Th] cells produce specific cytokines, such as IL-4, IL-5, and IL-13) promotes an atopic/allergic inflammatory response in the airways.[164] IL-4 and IL-13 are particularly important for B-cell switching to favor IgE production, and IL-5 is crucial for local differentiation and enhanced survival of eosinophils within the airways. This theory about the origins of asthma is consistent with many of the epidemiologic and pathophysiologic features of childhood asthma but is not yet proved.[168]

PATHOPHYSIOLOGY. The pathophysiology of asthma in children is similar to that for adults and is described in Chapter 35 (p. 1264). Asthma is initiated by a type I hypersensitivity reaction primarily mediated by IgE (see Figures 35-10, 35-11, and 35-12, pp. 1264-1265). As in adults, inflammation, bronchospasm, and mucus production in the airways lead to ventilation and perfusion mismatch with hypoxemia and expiratory airway obstruction with air trapping and increased work of breathing. In young children, airway obstruction can be more severe because of the smaller diameter of their airways.

CLINICAL MANIFESTATIONS. In a typical acute asthma attack in children, the major complaints are coughing, wheezing, and shortness of breath. About 70% to 80% of acute wheezing episodes are associated with viral respiratory tract infections. As a result, there may be signs of a preceding upper respiratory tract infection, such as rhinorrhea, or low-grade fever. In infants and toddlers younger than 2 years old, the most common of these is RSV.[169] In older children and adults, the major viral trigger is rhinovirus.[170]

There is expiratory wheezing that is often described as high pitched and musical, along with prolongation of the expiratory phase of the respiratory cycle. Breath sounds may become faint when air movement is poor. Sometimes hyperinflation (barrel chest) is visible. Respiratory and heart rates are elevated. Nasal flaring and accessory muscle use are evident, with retractions in the substernal, subcostal, intercostal, suprasternal, or sternocleidomastoid areas. Infants may appear to be "head bobbing" because of sternocleidomastoid muscle use. Pulsus paradoxus (decrease in systolic blood pressure of more than 10 mmHg during inspiration) may be present. The child may appear anxious or diaphoretic, important signs of respiratory compromise. The child may speak in clipped sentences or not at all because of dyspnea.

Findings in chronic asthma may include hyperinflation of the thorax (barrel chest) or pectus excavatum. Clubbing should not be seen in those with asthma and, if present, should trigger evaluation for other conditions, such as cystic fibrosis. Exercise intolerance may indicate underlying asthma.

EVALUATION AND TREATMENT. Asthma is often underdiagnosed and untreated, especially in preschool-age children because asthma symptoms overlap with other respiratory illness, such as bronchitis or upper respiratory tract infections. Diagnosis is based on symptom patterns (episodes of wheezing), presence of risk factors, and therapeutic responses. The major historical and physical factors that contribute to the diagnosis of asthma in children are parental history of asthma, physician-diagnosed atopic dermatitis, evidence of sensitization to aeroallergens, increased IgE and eosinophil levels, and reversible airflow obstruction on lung function.[171]

The modified asthma predictive index (API) can be used to help with asthma diagnosis and is recommended by the National Institutes of Health (NIH) guidelines.[171] Many children with less severe asthma outgrow the disease by adulthood.[172]

Confirmation of the diagnosis of asthma relies on pulmonary function testing using spirometry, which can be accomplished only after the child is 5 to 6 years of age. Characteristic abnormalities of spirometry would be reduced expiratory flow

rates that are reversible in response to an inhaled bronchodilator. For younger children, an empirical trial of asthma medications is commonly initiated.

The goal of asthma therapy is to achieve long-term control by reduction in impairment and risk.[154] Management of asthma medications in children is often difficult because fluctuations in severity of symptoms is common. Care providers must periodically assess asthma control in children to decide if a "step up" (increase) or "step down" (decrease) is indicated in their asthma therapy. Algorithms can help assess asthma control and offer information about how to adjust therapy accordingly. Before therapy is increased, care providers need to assess medication administration techniques, environmental controls, comorbidities, and educational needs. For a reduction in therapy, the child's asthma should be well controlled for a minimum of 3 months.[154] The pharmacologic treatment of asthma in children is essentially the same as that for adults and is initiated in a stepwise sequence based on asthma severity and response to treatment (see Chapter 35).

Acute Lung Injury/Acute Respiratory Distress Syndrome

Acute lung injury (ALI)/acute respiratory distress syndrome (ARDS) occurs in children of all ages. ALI precedes the development of ARDS and can result either from a direct or indirect injury, such as pneumonia, aspiration, near-drowning, and smoke inhalation, or from a systemic insult, such as sepsis, multiple trauma, or burns. ARDS is characterized by progressive respiratory distress, severe hypoxemia refractory to treatment with supplemental oxygen, decreased pulmonary compliance, bilateral infiltrates on chest x-ray, and no evidence of heart failure.[173]

The overall mortality in children is less than that experienced by the adult population but can be as high as 40%, depending on age and associated conditions and complications.[174] Children younger than 5 years appear to have diminished mortality compared with those older than 5 years of age. Children with underlying disease processes, such as Down syndrome[175] or systemic lupus erythematosus, and those who have undergone lung transplantation have decreased survival.

PATHOPHYSIOLOGY. The pathophysiology of ARDS in children is the same as that described for adults in Chapter 35 (see p. 1261 and Figure 35-8).

CLINICAL MANIFESTATIONS. ARDS develops acutely after the initial insult, usually within 24 hours (although occasionally it is delayed up to a few days). There is progressive respiratory distress and severe hypoxemia with poor response to oxygen supplementation. Initially, hyperventilation occurs, but CO_2 retention may ultimately develop because of inadequate functional air space, atelectasis, decreased pulmonary compliance, and respiratory muscle fatigue. Severity of the clinical course is modified by the cause of lung injury, comorbid factors (such as the presence of sepsis or multisystem organ failure), and the development of complications (such as nosocomial pneumonia). Some children who recover have residual pulmonary abnormalities.

EVALUATION AND TREATMENT. ARDS in older children and adolescents is similar to that in adults. However, infants have more compliant chest walls, lower hematocrit levels, higher baseline airway resistance, and lower functional residual capacity. The maturing lung may be at greater risk for ventilator-induced lung injury.[176,177] These factors have implications for management strategies that are different than those for older children and adolescents. There are few randomized controlled trials that have been completed to guide clinical management of ALI/ARDS in infants and very young children.

Treatment of ARDS remains supportive in nature and definitive studies related to infants and children are limited.[176,177] The goals of therapy are to preserve and restore oxygen delivery, minimize acute lung injury, and decrease morbidity and mortality by avoiding iatrogenic pulmonary complications. Most individuals with ARDS require oxygen administration with mechanical ventilation and relatively high levels of positive end-expiratory pressure to promote alveolar recruitment, stabilization, and redistribution of alveolar edema fluid into the interstitium. Lung-protective ventilation strategies may be used for ARDS, such as low tidal volumes, positive end-expiratory pressure (PEEP) ventilation, prone positioning, inverse inspiratory/expiratory ratio, high-frequency oscillatory ventilation, and airway pressure release ventilation.[178-180] Use of corticosteroids in children with ARDS is controversial and remains at the discretion of the clinician. There have been no randomized clinical trials regarding this treatment. Surfactant therapy appears to improve oxygenation and increase survival time in children 1 week to 21 years of age, particularly in cases of direct lung injury.[174,181] Extracorporeal membrane oxygenation (ECMO) has improved survival in some centers.[182,183]

Cystic Fibrosis

Cystic fibrosis (CF) is an autosomal recessive inherited disorder that is associated with defective epithelial chloride ion transport. The CF gene is located on chromosome 7. There are more than 1900 known mutations of this gene[184] divided into 6 classes with varying severity of disease expression. Classes 1 through 3 are associated with more severe disease and classes 4 through 6 with milder pulmonary disease (generally pancreatic sufficient). Death rates correlate respectively with the classes noted in the previous sentence.[185] CF affects primarily whites (approximately 1 in 3200) and is one of the most common lethal genetic diseases in this ethnic group. Approximately 30,000 individuals in the United States and 70,000 worldwide manifest the disease. The incidence in blacks is 1:15,000 and in Asian Americans is 1:31,000.[186] Estimated symptomless carrier frequency is higher, affecting 10 million or 1 in 29 whites in the United States. Approximately 1000 new cases of CF are diagnosed each year, and the median age at diagnosis is 6 months; 75% of cases are diagnosed by 1 year of age. Approximately 10% of cases are not diagnosed until after age 10; however, these cases usually have milder symptoms. The median age of survival in the United States is 37 years of age (2008 data).[186]

PATHOPHYSIOLOGY. CF is characterized by abnormal secretions that cause obstructive problems within the respiratory, digestive, and reproductive tracts. However, research suggests that

there may be additional CF-associated primary defects, such as an intrinsic proinflammatory state and abnormal local immune defenses in the lungs. The *cystic fibrosis transmembrane conductance regulator (CFTCR) gene* mutation results in the abnormal expression of **cystic fibrosis transmembrane conductance regulator (CFTCR) protein,** which is a cyclic adenosine monophosphate (cAMP)–activated chloride channel present on the surface of many types of epithelial cells, including those lining airways, bile ducts, the pancreas, sweat ducts, and the vas deferens. Despite knowing that chloride transport is a fundamental abnormality, the exact disease mechanisms in CF have still not been clearly defined at the cellular and end-organ levels.[187]

Although CF is a multiorgan disease, the lungs are the most critical site of involvement, and respiratory failure is almost always the cause of death. The typical features of CF lung disease are mucus plugging, chronic inflammation, and infection of the small airways.[188] The disease process causes progressive bronchiectasis that becomes widespread. Parenchymal involvement occurs much later and includes microabscess formation, patchy consolidation and pneumonia, peribronchial fibrosis, and cyst formation (Figure 36-14). The pathophysiology for these changes is outlined in Figure 36-15. Airway obstruction and weakening of the airway wall can lead to the development of peripheral bullae, which may rupture and cause pneumothorax. Hemoptysis, sometimes life threatening, may occur because of erosion of enlarged bronchial arteries that develop in response to the inflammation associated with bronchiectasis. Over a long period of time, pulmonary vascular remodeling occurs because of localized hypoxia and arteriolar vasoconstriction; pulmonary hypertension and cor pulmonale may develop with end-stage disease.

The mucus plugging seen in CF probably results from the combination of increased production of mucus, altered physicochemical properties of the mucus, and reduced mucociliary clearance.[189] Mucus-secreting airway cells (goblet cells and submucosal glands) are increased in number and size. It has been postulated that the CFTCR protein mutation results in dysregulation of the airway epithelial sodium channel (ENaC), although this relationship has recently been called into question.[190] What is clear is that abnormal chloride excretion and exaggerated sodium absorption with depletion of the airway surface liquid volume result in dehydration of airway mucus.[191] This facilitates adherence of mucus to the epithelium, subsequent impairment of ciliary mobility, and retention of bacteria that can then form biofilms. Finally, after secretion, CF mucus becomes even more viscous because of deoxyribonucleic acid (DNA) and filamentous (F) actin released from the high number of degraded neutrophils present in CF airways.

There are abnormal cytokine profiles in CF airway fluids, including deficient levels of IL-10 and excessive amounts of IL-1, IL-8, and TNF-α, all changes conducive to promoting inflammation. Neutrophils are present in great excess in CF airways and play a critical role in long-term damage[192] in large measure because of their release of damaging oxidants,

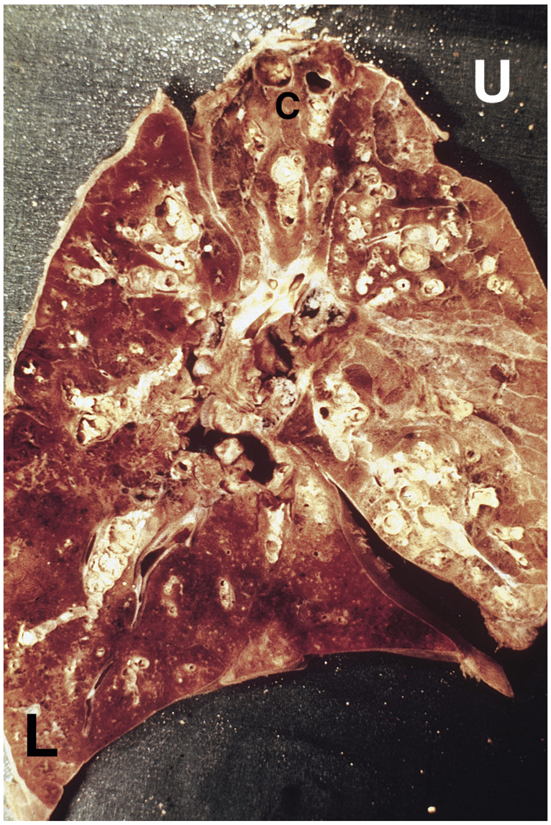

FIGURE 36-14 Pathology of the Lung in End-Stage Cystic Fibrosis. Key features are widespread mucous impaction of airways and bronchiectasis (especially in upper lobe, *U*), with hemorrhagic pneumonia in the lower lobe *(L)*. Small cysts *(C)* are present at the apex of the lung. (From Kleinerman J, Vauthy P: *Pathology of the lung in cystic fibrosis,* Atlanta, 1976, Cystic Fibrosis Foundation.)

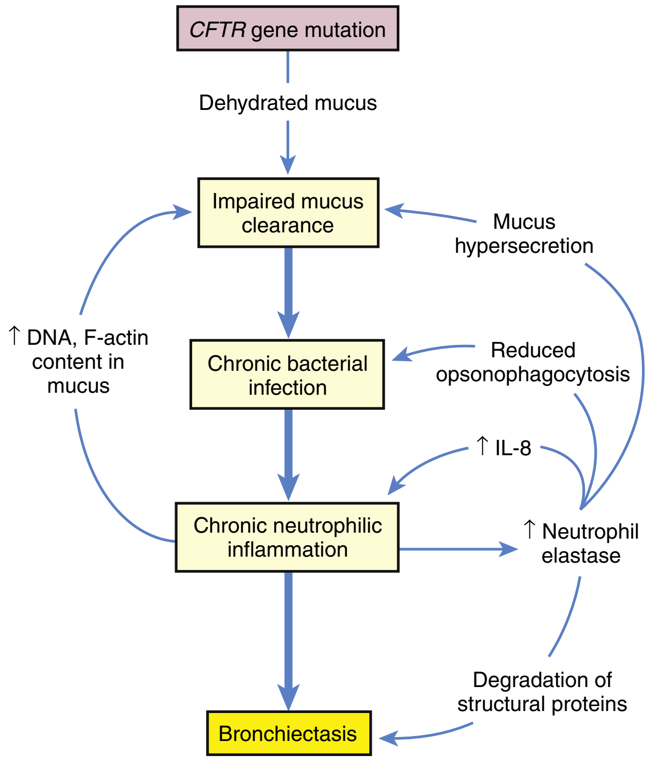

FIGURE 36-15 Pathogenesis of Cystic Fibrosis Lung Disease. *CFTR,* Cystic fibrosis transmembrane conductance regulator; *IL-8,* interleukin-8.

such as myeloperoxidase[193] and proteases, in massive amounts that overwhelm local antiprotease defenses. The mutant CFTR channel does not transport antioxidants to counteract neutrophil-associated oxidative stress.[194] One protease in particular, *neutrophil elastase,* has the following detrimental effects: (1) direct damage to lung structural proteins, such as elastin; (2) induction of airway cells to produce IL-8, a strong attractant for neutrophils and thus a means for augmenting a local "vicious cycle" of inflammation; (3) destruction of IgG and complement components important for opsonization and phagocytosis of pathogens; and (4) direct stimulation of mucus secretion by mucus-producing cells.

The majority of children with CF have chronic endobronchial infection. It is likely that local factors in the CF airway microenvironment favor bacterial colonization because no systemic immune defect has been found. Several bacteria colonize the CF lung including *Staphylococcus aureus* and *Burkholderia cepacia*.[195] However, *Pseudomonas aeruginosa* ultimately colonizes airways in 75% of children with CF. Infecting colonies of *Pseudomonas* adopt a mucoid phenotype and organize themselves into adherent biofilms, making it difficult for antibiotics and local defenses to reach them.[196] Their biofilm resists beta-lactam antibiotics and their rapid mutation makes them antibiotic resistant.[197] Persistence of infection incites chronic local inflammation, airway damage, bronchiectasis, microabscess formation, and foci of hemorrhagic pneumonia. There is progressive damage to the normal architecture of the lung with decline in pulmonary function.[198,199]

CLINICAL MANIFESTATIONS. The most common manifestations are respiratory and gastrointestinal (also see Chapter 42). Respiratory symptoms include persistent cough or wheeze, sputum production, and recurrent or severe pneumonia. More subtle respiratory tract presentations of CF include chronic sinusitis and nasal polyps. With appropriate treatment, cough, sputum production, and exercise limitation do not usually reach debilitating levels during childhood. Digital clubbing may appear quite early even in the absence of significant pulmonary impairment. Development of barrel chest or persistent crackles occurs much later in the course of the disease.

The overall severity of CF lung disease is highly variable. Even affected siblings may have disparate courses despite identical *CFTR* mutations, environment, and treatment strategy. We now know that some genetic variants significantly influence disease progression and survival among children with the same mutations.[200,201]

EVALUATION AND TREATMENT. Screening algorithms for cystic fibrosis include the immunoreactive trypsinogen (IRT) blood test, which is performed at birth (may be repeated) and is elevated in CF. This test can have false positives and negatives. Genotyping for *CFTR* mutations also is available as a supplemental diagnostic method.[202] The sweat test is a standard method of diagnosis and reveals sweat chloride concentration in excess of 60 mEq/L. There are more than 1900 specific mutations, but most standard laboratory panels include fewer than 100 mutations.[186] Newborn screening for CF is universal in the United States.[203] Genetic counseling of CF gene carriers is important so they understand risk assessment in relation to disease.[204]

Treatment is primarily focused on pulmonary health and nutrition. Because the pulmonary decline in CF is slow and insidious, and because of the early onset of chronic inflammation and infection, treatment strategies begin immediately at diagnosis and are modified over time as disease progresses. Pulmonary therapies include techniques to promote mucus clearance, such as chest physical therapy and related equipment (such as the high-frequency chest wall oscillation vest) and an assortment of handheld positive expiratory pressure (PEP) devices. Aerosol therapy includes antibiotics, bronchodilators, and nebulized deoxyribonuclease (DNase). DNase acts to liquefy mucus and may even have anti-inflammatory effects.[205,206]

Antibiotic practices vary, with prophylactic and treatment strategies being used. Increasing emphasis has been placed on delaying and controlling microbe colonization, particularly *Pseudomonas,* such as the maintenance use of inhaled antibiotics.[207] Inhaled hypertonic saline also has proven beneficial to improve airway surface water, thus improving mucus viscosity and airway clearance.[208] Azithromycin, ibuprofen, and corticosteroids can reduce airway inflammation and improve lung function.[209] Intravenous antibiotics are used to treat major exacerbations of pulmonary infection, which may be either subacute or acute. Individuals with end-stage lung disease may consider double lung transplant as a life-lengthening measure.[210]

Nutritional problems are extremely common in CF and poor nutrition is correlated with worse outcomes including progression of lung disease; onset of additional complications, such as decreased bone mineral density; and growth failure.[211,212] Elements of aggressive nutritional support include meticulous monitoring of growth parameters, controlling fat malabsorption, ensuring adequate caloric intake, and keeping overall health stable. Approximately 90% of children with CF have pancreatic insufficiency. This is the result of abnormal ion transport causing decreased fluid and bicarbonate secretion from the pancreatic acinar cells, which leads to thickened secretions plugging the smaller pancreatic ducts, and eventual autodigestion or atrophy of the acinar cells. Therefore, patients must take exogenous pancreatic enzymes with meals and snacks in order to absorb nutrients and control malabsorptive symptoms. Fat-soluble vitamins (A, D, E, and K) must be supplemented.[213] Caloric needs are high, especially with advancing lung disease, and high-calorie supplements or even gastrostomy feeding may be warranted (see Nutrition & Disease: Cystic Fibrosis [CF]).

Future treatments for CF in trial phases are aimed at improving inhaled antibiotic therapy, developing a vaccine against *Pseudomonas,* and incorporating growth hormone in the treatment regimen. Newer approaches to gene therapy are being developed, including mutation-specific diagnosis and treatment.[214]

There is a growing contingent of adults with CF living into their forties and fifties. Care for these individuals shifts away

NUTRITION & DISEASE

Cystic Fibrosis (CF)

Chronic inflammation, pancreatic enzyme deficiency, and undernutrition contribute to growth failure and poor clinical outcomes in CF. Energy needs to meet normal growth and weight gain in CF require a diet composed of 35% to 40% of calories from fat. Breast-feeding for the first 4 to 6 months has shown to be protective for the infant with CF, and then supplemental formula fortified with additional fat increases energy content. Oral pancreatic enzyme replacement is important in maintaining adequate nutritional status, particularly for fat absorption. The Food and Drug Administration now requires approval for the marketing of these products. Selection of dose and preparations is based on weight gain and individual response. High doses of lipase can be associated with fibrosing colonopathy and new products are being tested in clinical trials. Fecal pancreatic elastase-1 is a common diagnostic test for evaluating pancreatic insufficiency. Yearly monitoring of fat-soluble vitamins (A, D, E, and K) is recommended with supplementation as needed. Vitamin D supplements are needed to maintain serum concentrations at 30 ng/ml. Current recommendations are to follow the Cystic Fibrosis Foundation nutrition care guidelines available at www.cff.org/treatments/CFCareGuidelines/Nutrition/. The management of CF-related diabetes mellitus is a particular challenge and guidelines have been published by the American Diabetes Association. Nutritional counseling is a necessary component of care for all individuals with CF.

Data from Kalnins D, Wilschanski M: *Drug Des Dev Ther* 6:151–161, 2012; Moran A et al: *Diabetes Care* 33(12):2697–2708, 2010; Nakajima K et al: *Core Evid* 7:77–91, 2012; Tangpricha V et al: *J Clin Endocrinol Metab* 97(4):1082–1093, 2012; Wier HA, Kuhn RJ: *Curr Opin Pediatr* 23(5):541–544, 2011.

from a pediatric focus because their care needs are unique and often extremely complex.[215] Challenges noted in this specialty area are pregnancy and details about balancing disease management and adult life issues.[216]

SUDDEN INFANT DEATH SYNDROME

Sudden infant death syndrome (SIDS) remains a disease of unknown cause and is the most common cause of unexplained infant death in Western countries.[217,218] It is defined as "sudden death of an infant under 1 year of age which remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and review of the clinical history."[217]

The incidence of SIDS is low during the first month of life but sharply increases in the second month of life, peaks at 2 to 4 months of age, and is unusual after 6 months of age. The incidence of SIDS in the United States is 0.54 per 1000 live births.[219] It is more common in male infants (60%) than female (40%) infants and among American Indian/Alaskan Natives and blacks.[220] It almost always occurs during nighttime sleep, when infants are least likely to be observed. A seasonal variation has been noted, with higher frequencies during the winter months. This has been related to a higher rate of respiratory tract infection during those months, and such infections are often reported to have preceded the death.

Clinical risk groups include babies who were preterm or low birth weight, multiple births, and siblings of prior SIDS victims (fourfold to sixfold increased risk). SIDS is more prevalent among infants of low or adverse socioeconomic status and occurs more frequently when family size is larger.[221] Nevertheless, about 75% of all SIDS victims have no known predisposing clinical risk factor. Maternal factors that predict increased SIDS risk are maternal smoking, young maternal age (younger than 20 years), unmarried mother, less prenatal care, poverty, and illicit drug use or binge-drinking.[222] Avoidable risk factors that relate to the baby's sleeping situation are prone positioning (and to a lesser extent, side sleeping), sleeping on soft bedding, overheating (environmental or overwrapping), and bed sharing with an adult (particularly one who smokes).[223] Epidemiologic studies have shown that SIDS rates decreased where massive public campaigns warned against prone sleeping for infants (e.g., the Back-to-Sleep campaign).[224]

The etiology of SIDS remains unknown, but probably involves a combination of predisposing factors including a vulnerable infant, environmental stressors, a critical developmental period for homeostatic control, and altered cardiorespiratory, circulatory, and arousal characteristics.[225,226] There has been long-standing interest in hypotheses involving impaired autonomic regulation and failure of cardiovascular, ventilatory, and arousal responses (particularly those regulated by the hypoglossal nucleus [HGN]) to hypoxemia or hypercarbia.[227] Alternative theories involve airway obstruction events, such as control of tongue movements related to inspiratory activity; increased vagal tone; sudden intrapulmonary shunting because of abnormalities of surfactant or pulmonary vessels; or exaggerated inflammation, eosinophil degranulation, and massive cytokine release causing pulmonary edema in response to either bacterial pathogens from the nasopharynx or viral respiratory tract infections.[228,229]

Finally, there is growing evidence that genetic factors may predispose certain individuals to SIDS. The most important risk factor genes include those involved in the regulation of the immune system, cardiac function, and the serotonergic network related to brainstem function.[230,231] It is estimated that 10% to 20% of SIDS cases may be caused by genetic variation in either ion channel or ion channel–associated proteins associated with primary electrical heart disease (e.g., long-QT and short-QT syndrome).[232]

Currently, the best strategy to reduce SIDS is avoidance of all the controllable risk factors. Recommendations include supine positioning; use of a firm sleep surface; room-sharing without bed-sharing; routine immunization; consideration of a pacifier; and avoidance of soft bedding, overheating, and exposure to tobacco smoke, alcohol, and illicit drugs.[233] Breast-feeding has been identified as a specific risk reduction measure.[234] Parents of infants with clinical risk should be taught cardiopulmonary resuscitation as a precaution. Home monitoring has not been proven to decrease the incidence of SIDS and more research is needed.[235] Some at-risk infants may warrant cardiorespiratory monitoring after careful consideration of the individual situation.

SUMMARY REVIEW

Structure and Function

1. The airways of infants and children are narrower than those of adults, thus making them more prone to obstruction.
2. Infants and young children continue to form new alveoli for several years after birth.
3. Surfactant production is an important marker of developmental maturity of the fetal lung and is secreted into the airways by 30 weeks of gestation.
4. The immature chest wall is soft and compliant, contributing to inefficient mechanisms of breathing.
5. Children have greater oxygen consumption than adults per unit of body weight.
6. Immune mechanisms are not fully developed at birth, making young infants more susceptible to infection.
7. Physiologic control of breathing may be impaired during the first few weeks of life.

Pulmonary Disorders

1. Physical examination can provide important clues in assessing the location and nature of UAO.
2. Upper airway infections can pose serious threats because of inflammatory edema and airway obstruction, including bacterial tracheitis, retropharyngeal abscess, and peritonsillar infections. Recognition and rapid evaluation are crucial.
3. Viral croup (laryngotracheobronchitis) is the most common cause of acute upper airway obstruction in children and usually affects children ages 6 months to 5 years. Subglottic edema may be mild to severe. Parainfluenza is the most common cause.
4. Acute epiglottitis is a life-threatening emergency that is now rarely seen because of vaccination against *H. influenzae,* which had been the primary causative microorganism. Current cases usually represent vaccine failure or are caused by other bacteria, such as group A streptococci.
5. Aspiration of a foreign body should be considered whenever there is a sudden onset of stridor, coughing, wheezing, or hoarseness. This usually occurs in 1- to 3-year-olds. Occasionally diagnosis is delayed and symptoms may be attributed to asthma, bronchitis, or pneumonia without recognition of the underlying cause.
6. Chronic UAO may be manifested by stridor, abnormal cry, wheezing, or dyspnea. The most common cause of stridor in infants is laryngomalacia. Other causes include subglottic stenosis, vocal cord paralysis, and vascular rings.
7. Obstructive sleep apnea usually occurs in older children rather than infants and is underdiagnosed. Typical symptoms are snoring, gasping, and restless sleep. The most common cause in children is adenotonsillar hypertrophy.
8. RDS of the newborn usually occurs in premature infants who are born before surfactant production and alveolocapillary development are complete. Atelectasis and hypoventilation cause shunting, hypoxemia, and hypercapnia.
9. BPD is a chronic lung disease of infancy that is usually the consequence of acute respiratory disease in premature infants who required oxygen and positive pressure ventilatory support. Contributing factors include structural immaturity, inflammation, and disordered lung repair processes.
10. Bronchiolitis occurs in infants and toddlers, usually in the winter and early spring. It is caused by viruses, most commonly RSV. There is extensive edema, inflammation, and damage to the bronchiolar epithelium. Injections of monoclonal antibody against RSV are recommended as a preventive measure for high-risk infants.
11. Childhood pneumonia can be caused by viruses (most common), bacteria, or *Mycoplasma.* Lobar pneumonia is usually bacterial. Certain bacteria, such as *S. aureus* and group A streptococci, can cause particularly fulminant disease, as well as abscesses and empyema.
12. Aspiration pneumonitis can occur because of lung inflammation from entry of any foreign substance, including food, drink, or chemicals. Aspiration of oropharyngeal bacteria can occur because of loss of protective reflexes in neurologically impaired children, or during induction of anesthesia.
13. Asthma is an obstructive airway disease with episodes of acute respiratory symptoms (cough, wheeze, dyspnea) and intermittent or chronic subacute symptoms. It is the most common chronic condition in children. It is a disease of local airway inflammation, with exacerbation in response to triggers, such as infections or allergens. Inflammatory cell infiltration, mucosal edema, mucus plugging of airways, and epithelial damage cause obstruction to airflow, and there is evidence of long-term remodeling of airways.
14. ARDS is an acute life-threatening condition characterized by severe hypoxemia, poor lung compliance, and diffuse densities on chest radiograph. It can be triggered by acute pulmonary insults or major systemic illness (e.g., sepsis) or trauma. High-level ventilatory support is required, and mortality is significant.
15. CF is an autosomal recessive disease characterized by thick, tenacious mucus, plugging of airways, chronic pulmonary infection, and bronchiectasis related to airway epithelial chloride and sodium transport. The other major manifestations are digestive and nutritional, related to pancreatic insufficiency. Median survival is currently 37 years, with mortality primarily related to lung disease.

Sudden Infant Death Syndrome

1. SIDS is a diagnosis of exclusion after thorough investigation and autopsy following sudden death of an infant less than 6 months of age. Usually the event occurs during nighttime sleep.
2. The cause is unknown. However, some known risk factors are avoidable, such as maternal smoking, prone sleeping, soft bedding surfaces, and overheating. The incidence of SIDS has decreased significantly since public health campaigns have encouraged the supine sleeping position for babies.

- Review Questions and Answers

CHAPTER OUTLINE

The primary function of the kidney is to maintain a stable internal environment for optimal cell and tissue metabolism. The kidneys accomplish these life-sustaining tasks by balancing solute and water transport, excreting metabolic waste products, conserving nutrients, and regulating acids and bases. The kidney also has an endocrine function, secreting the hormones renin, erythropoietin, and 1,25-dihydroxy-vitamin D_3 for regulation of blood pressure, erythrocyte production, and calcium metabolism, respectively. The kidney also can synthesize glucose from amino acids, performing the process of gluconeogenesis (see What's New? The Kidney and Glucose Regulation). The formation of urine is achieved through the processes of filtration, reabsorption, and secretion by the glomeruli and tubules within the kidney. The bladder stores the urine that it receives from the kidney by way of the ureters. Urine is then removed from the body through the urethra.

STRUCTURES OF THE RENAL SYSTEM

Structures of the Kidney

The **kidneys** are paired organs located in the posterior region of the abdominal cavity behind the peritoneum (Figure 37-1). They lie on either side of the vertebral column with their upper and lower poles extending from approximately the twelfth thoracic to the third lumbar vertebrae. The right kidney is slightly lower than the left and is displaced downward by the overlying liver. Each kidney is approximately 11 cm long, 5 to 6 cm wide, and 3 to 4 cm thick. A tightly adhering capsule (the **renal capsule**) surrounds each kidney, and the kidney then is embedded in a mass of fat. The capsule and fatty layer are covered with a double layer of **renal fascia,** fibrous tissue that attaches the kidney to the posterior abdominal wall.

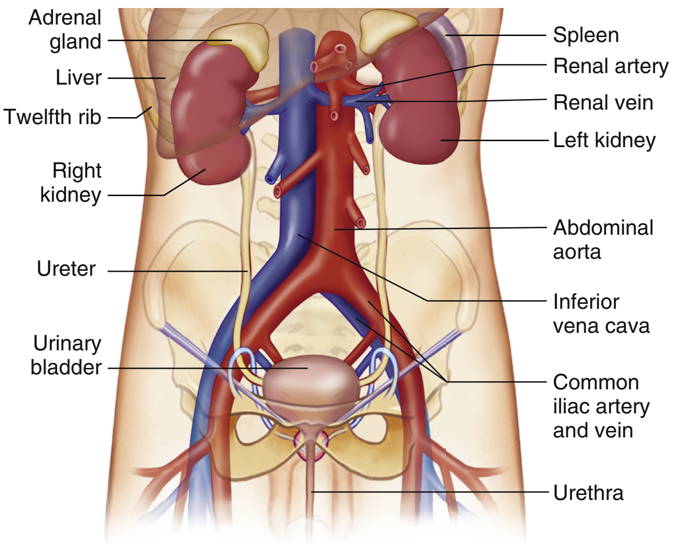

FIGURE 37-1 Organs of the Urinary System. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

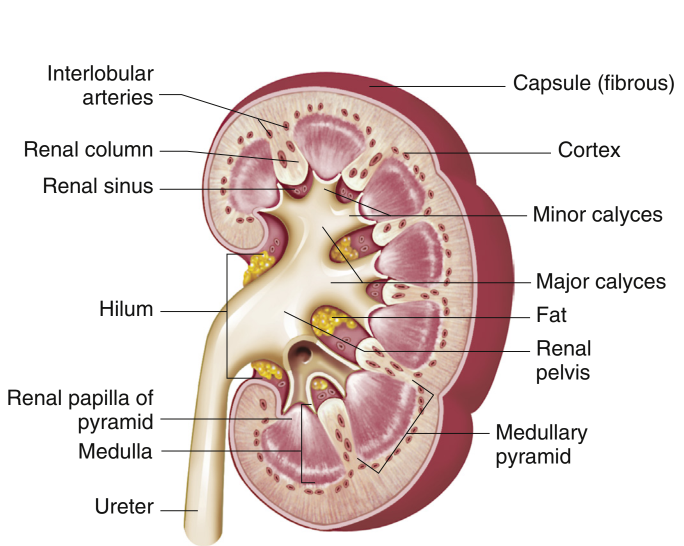

FIGURE 37-2 Kidney Structure. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

WHAT'S NEW?

The Kidney and Glucose Regulation

The human kidney contributes to the regulation of glucose concentration by making glucose through gluconeogenesis, by taking up glucose from the circulation, and by reabsorbing glucose from the glomerular filtrate. The human liver and kidneys release approximately equal amounts of glucose through gluconeogenesis in the postabsorptive state (4 to 12 hours after meal ingestion). Other tissues lack the enzyme necessary for gluconeogenesis (glucose-6-phosphatase) and cannot participate in gluconeogenesis. In the postprandial state (up to 4 hours after meal ingestion), although overall endogenous glucose release decreases substantially, renal gluconeogenesis increases by approximately twofold.

About 180 grams of glucose are normally filtered each day by the kidneys. Almost all of this is actively reabsorbed by means of sodium-glucose cotransporter 2 (SGLT2), a transmembrane protein expressed in the luminal border of the proximal tubule. This ensures sufficient energy is available during fasting periods. When plasma glucose concentrations exceed a threshold, the SGLT2 becomes saturated and glucose appears in the urine. Individuals with diabetes mellitus have an increased transport maximum (T_M) for glucose from enhanced expression of SGLT2 and this contributes to hyperglycemia when there is poor glucose control. SGLT2 inhibitors are being evaluated for reducing hyperglycemia associated with diabetes mellitus.

Renal glucose release is stimulated by epinephrine and is inhibited by insulin. Insulin suppresses glucose release in both the liver and the kidney. The kidneys do not synthesize glycogen and, therefore, do not release glucose through glycogenolysis. In the postabsorptive state, the kidneys utilize about 10% of all glucose used by the body. When there is hypoglycemia, the liver initially releases glucose through glycogenolysis and then increases gluconeogenesis. The kidney also counter-regulates hypoglycemia through gluconeogenesis, which may explain in part why individuals with renal failure tend to develop hypoglycemia.

Data from DeFronzo RA, Davidson JA, Del Prato S: *Diabetes Obes Metab* 14(1):5–14, 2012; Gerich JE: *Diabet Med* 27(2):136–142, 2010; Mather A, Pollock C: *Kidney Int Suppl* (120):S1–S6, 2011; Mitrakou A: *Diabetes Res Clin Pract* 93(Suppl 1):S66–S72, 2011.

The cushion of fat and the position of the kidney between the abdominal organs and muscles of the back protect it from trauma. A medial indentation (the **hilum**) is where the renal blood vessels, nerves, lymphatic vessels, and ureter enter and exit the kidney.

The structures of the kidney are summarized in Figure 37-2. The outer layer of the kidney is called the **cortex** and contains all of the glomeruli, most of the proximal tubules, and some segments of the distal tubule. The **medulla** forms the inner part of the kidney and consists of regions called the **pyramids. Renal columns** extend from the cortex down between the renal pyramids. The apexes of the pyramids project into **minor calyces** (cup-shaped cavities) that unite to form **major calyces.** The minor calyces receive urine from the collecting ducts through the renal papilla. The major calyces join to form the **renal pelvis,** which connects with the proximal end of the ureter. The walls of the calyces, pelvis, and ureter are lined with epithelial cells and contain smooth muscle cells that contract to move urine to the bladder.

The structural unit of the kidney is the lobe. Each lobe is composed of a pyramid and the overlying cortex. On average, there are 14 lobes in each kidney.

Nephron

The **nephron** is the functional unit of the kidney. Each kidney contains approximately 1.2 million nephrons. The nephron is a tubular structure with subunits that include the renal corpuscle, proximal convoluted tubule, loop of Henle (nephron ansa), distal convoluted tubule, and collecting duct, all of which contribute to the formation of urine (Figure 37-3). The different epithelial cells lining various segments of the tubule facilitate the special functions of reabsorption and secretion (Figure 37-4).

The kidney has three kinds of nephrons: (1) **superficial cortical nephrons** (85% of all nephrons), which extend partially into the medulla; (2) **midcortical nephrons** with short or long loops; and (3) **juxtamedullary nephrons,** which lie close to and extend deep into the medulla and are important for the process

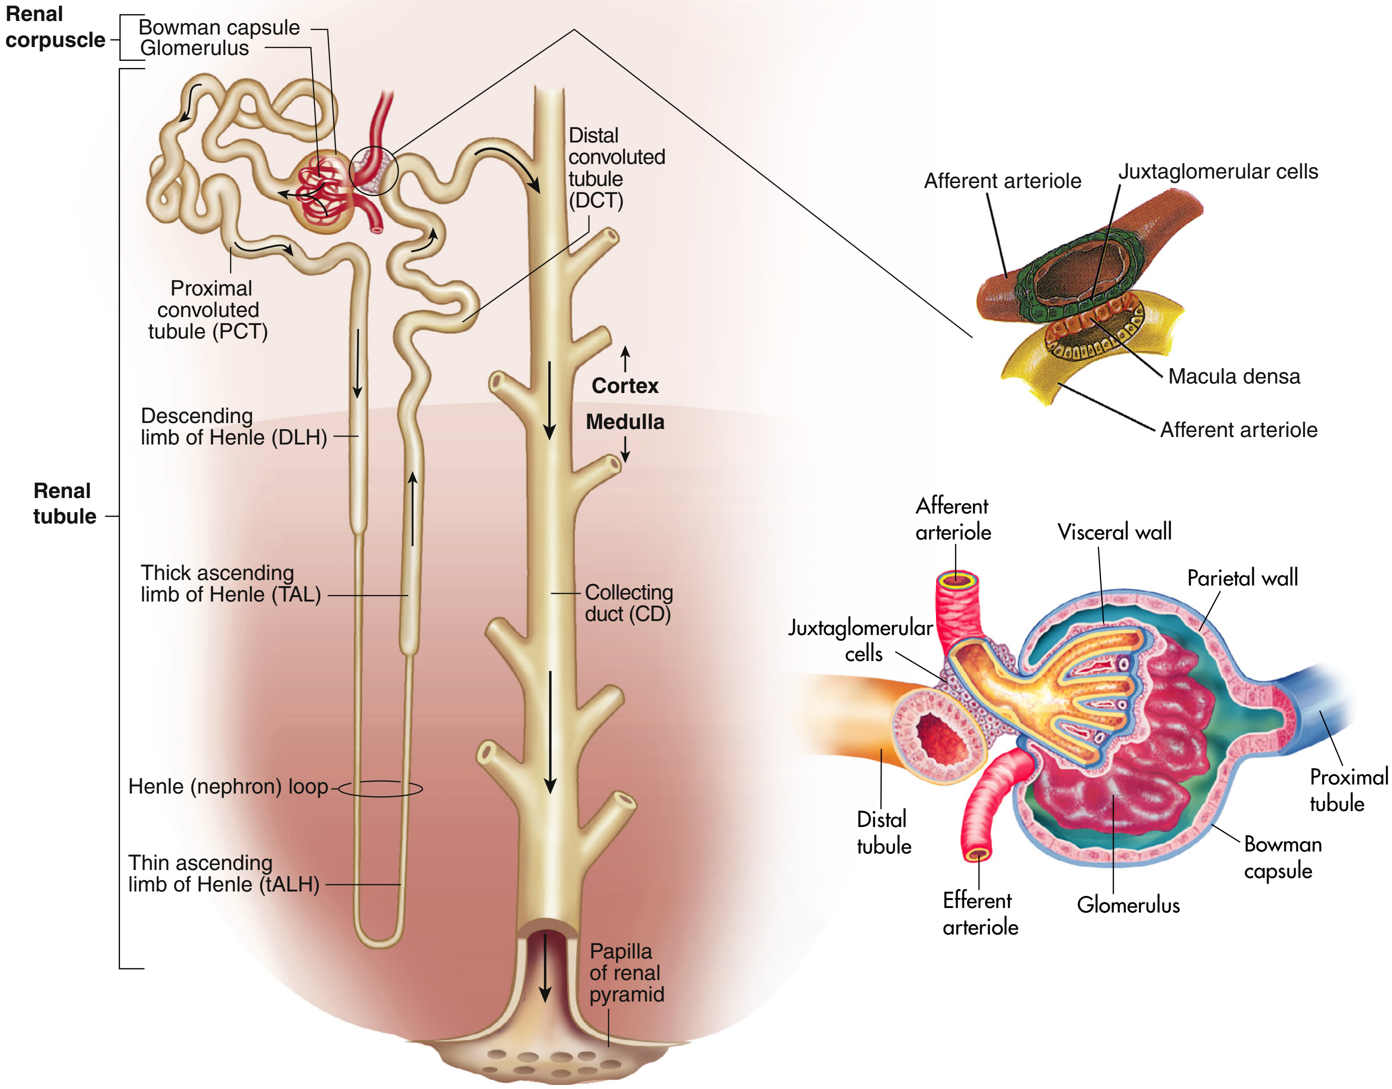

FIGURE 37-3 **Components of the Nephron.** (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby; Damjanov I: *Pathology for health professions,* ed 4, St Louis, 2012, Mosby.)

of concentrating urine (Figure 37-5). The **glomerulus** (Figure 37-6; see also Figure 37-3) is a tuft of capillaries that loop into the circular **Bowman glomerular capsule (Bowman space),** like fingers pushed into bread dough. **Mesangial cells** and the **mesangial matrix,** secreted by mesangial cells, lie between and support the glomerular capillaries. Different mesangial cells contract like smooth muscle cells to regulate glomerular capillary blood flow. They also have phagocytic properties similar to monocytes and release inflammatory cytokines and growth factors.[1] Together, the glomerulus, Bowman capsule, and mesangial cells are called the **renal corpuscle.**

The **glomerular filtration membrane** filters selected blood components through its three layers: (1) the inner layer is the glomerular endothelium, (2) the middle layer is the glomerular basement membrane (GBM), and (3) the outer layer is the visceral epithelium, which forms the inner layer of Bowman capsule. Each layer has unique structural properties that allow all components of the blood to be filtered, with the exception of blood cells and plasma proteins with a molecular weight greater than 70,000 (Figure 37-7; see also Figure 37-6).

Glomerular endothelial cells synthesize nitric oxide (a vasodilator) and endothelin-1 (a vasoconstrictor) that help regulate glomerular blood flow. The **glomerular endothelium** is perforated by many small openings or windows, called *fenestrae.* The fenestrae are maintained by vascular epithelial growth factor (VEGF) produced by the visceral epithelium. The middle basement membrane is composed of a selectively permeable network of proteoglycans (type IV collagen) secreted and maintained by the epithelial cells.[2] The **visceral epithelium** of the Bowman capsule is composed of cells called **podocytes** (foot-like processes)[3]

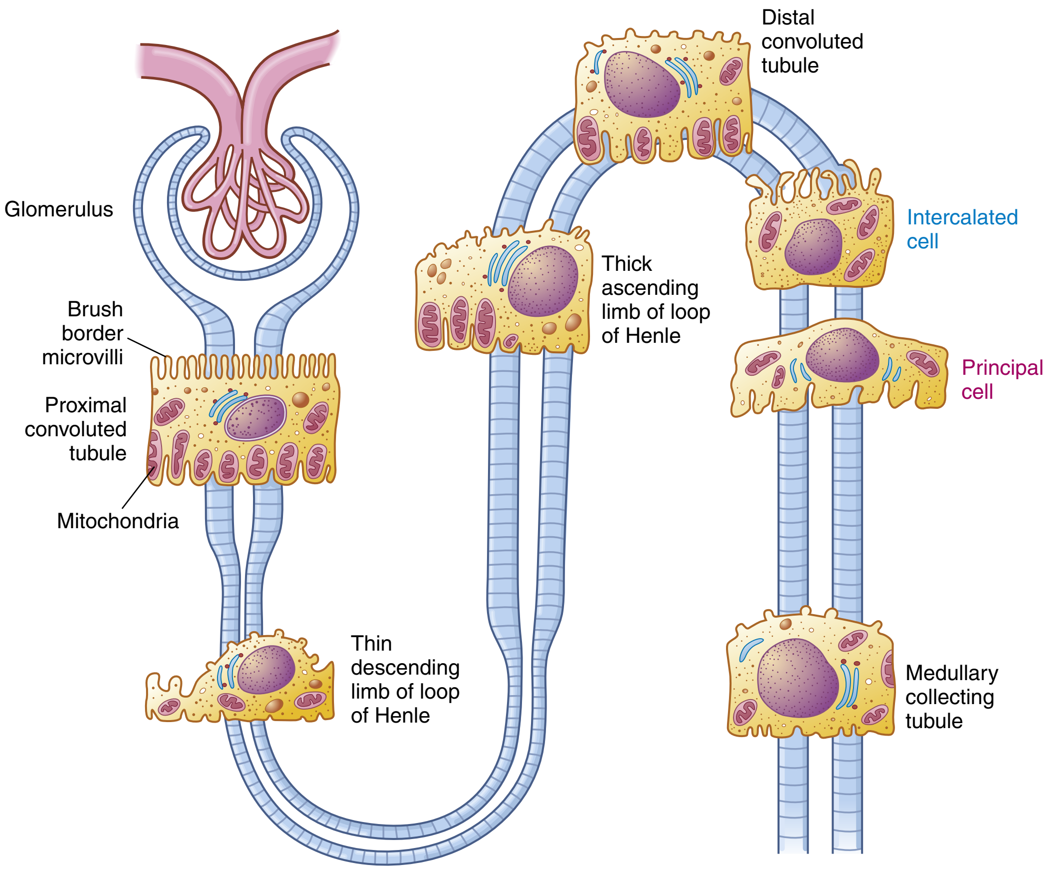

FIGURE 37-4 **Epithelial Cells of the Various Segments of Nephron Tubules.** The brush border and high number of mitochondria in the cells of the proximal convoluted tubule permit reabsorption of 60% of the glomerular filtrate. *Intercalated cells (blue text)* secrete either H^+ (reabsorb HCO_3^-) or HCO_3^- and reabsorb K^+. *Principal cells (magenta text)* reabsorb Na^+ and water and secrete K^+.

that radiate and adhere to the basement membrane covering the glomerular capillaries. The foot processes of one podocyte interlock with the foot processes of adjacent podocytes, forming an elaborate network of intercellular clefts. These clefts are called **filtration slits** (see Figure 37-7) and modulate filtration. *Nephrin, podocin, CD2-associated protein,* and other protein molecules ensure proper function of the fenestrae.[4]

The podocytes are endocytic, which allow molecules to enter the cell without passing through the cell membrane, and they prevent leakage of proteins into the urine. The visceral epithelium is reflected back at the vascular pole to become the **parietal epithelium.** The space between the visceral and parietal epithelia is the **Bowman (urinary) space,** which is continuous with the lumen of the renal tubules.

Glomerular filtration occurs when plasma filtrate from the glomerulus passes through the three layers of the glomerular membrane into Bowman space to form the primary urine. The endothelium, basement membrane, and podocytes are covered with protein molecules bearing anionic (negative) charges that retard the filtration of anionic proteins and prevent proteinuria.

The glomerulus is supplied by the afferent arteriole and drained by the efferent arteriole. A group of specialized cells known as **juxtaglomerular cells** are located around the afferent arteriole where it enters the glomerulus (see Figures 37-3 and 37-6). Between the afferent and efferent arterioles is a portion of the distal convoluted tubule with specialized sodium- and chloride-sensing cells known as the **macula densa.** Together the juxtaglomerular cells and macula densa cells form the **juxtaglomerular apparatus (JGA)** (see Figure 37-6). Control of renal blood flow, glomerular filtration, and renin secretion occurs at this site.

The **proximal convoluted tubule** continues from the Bowman capsule and has an initial convoluted segment (pars convoluta) and then a straight segment (pars recta) that descends toward the medulla (see Figure 37-3). The wall of the tubule consists of one layer of cuboidal epithelial cells with a surface layer of microvilli (a brush border) that increases reabsorptive surface area. This is the only surface inside the nephron where the cells are covered with microvilli (see Figure 37-4). The proximal convoluted tubule joins the hairpin-shaped **loop of Henle.** The loop is composed of a thin descending segment, thin ascending segment and a thick ascending segment. The thin descending segment is composed of squamous cells, and is highly permeable to water but less permeable to ions. It has no active transport functions. The thin ascending segment is permeable to ions but not to water. The thick ascending segment actively transports ions into the interstitium and passes urine into the distal convoluted tubule (see Figure 37-14).

The more numerous cortical nephrons have glomeruli originating close to the surface of the cortex or in the midcortex, unlike the juxtamedullary nephrons, whose glomeruli are

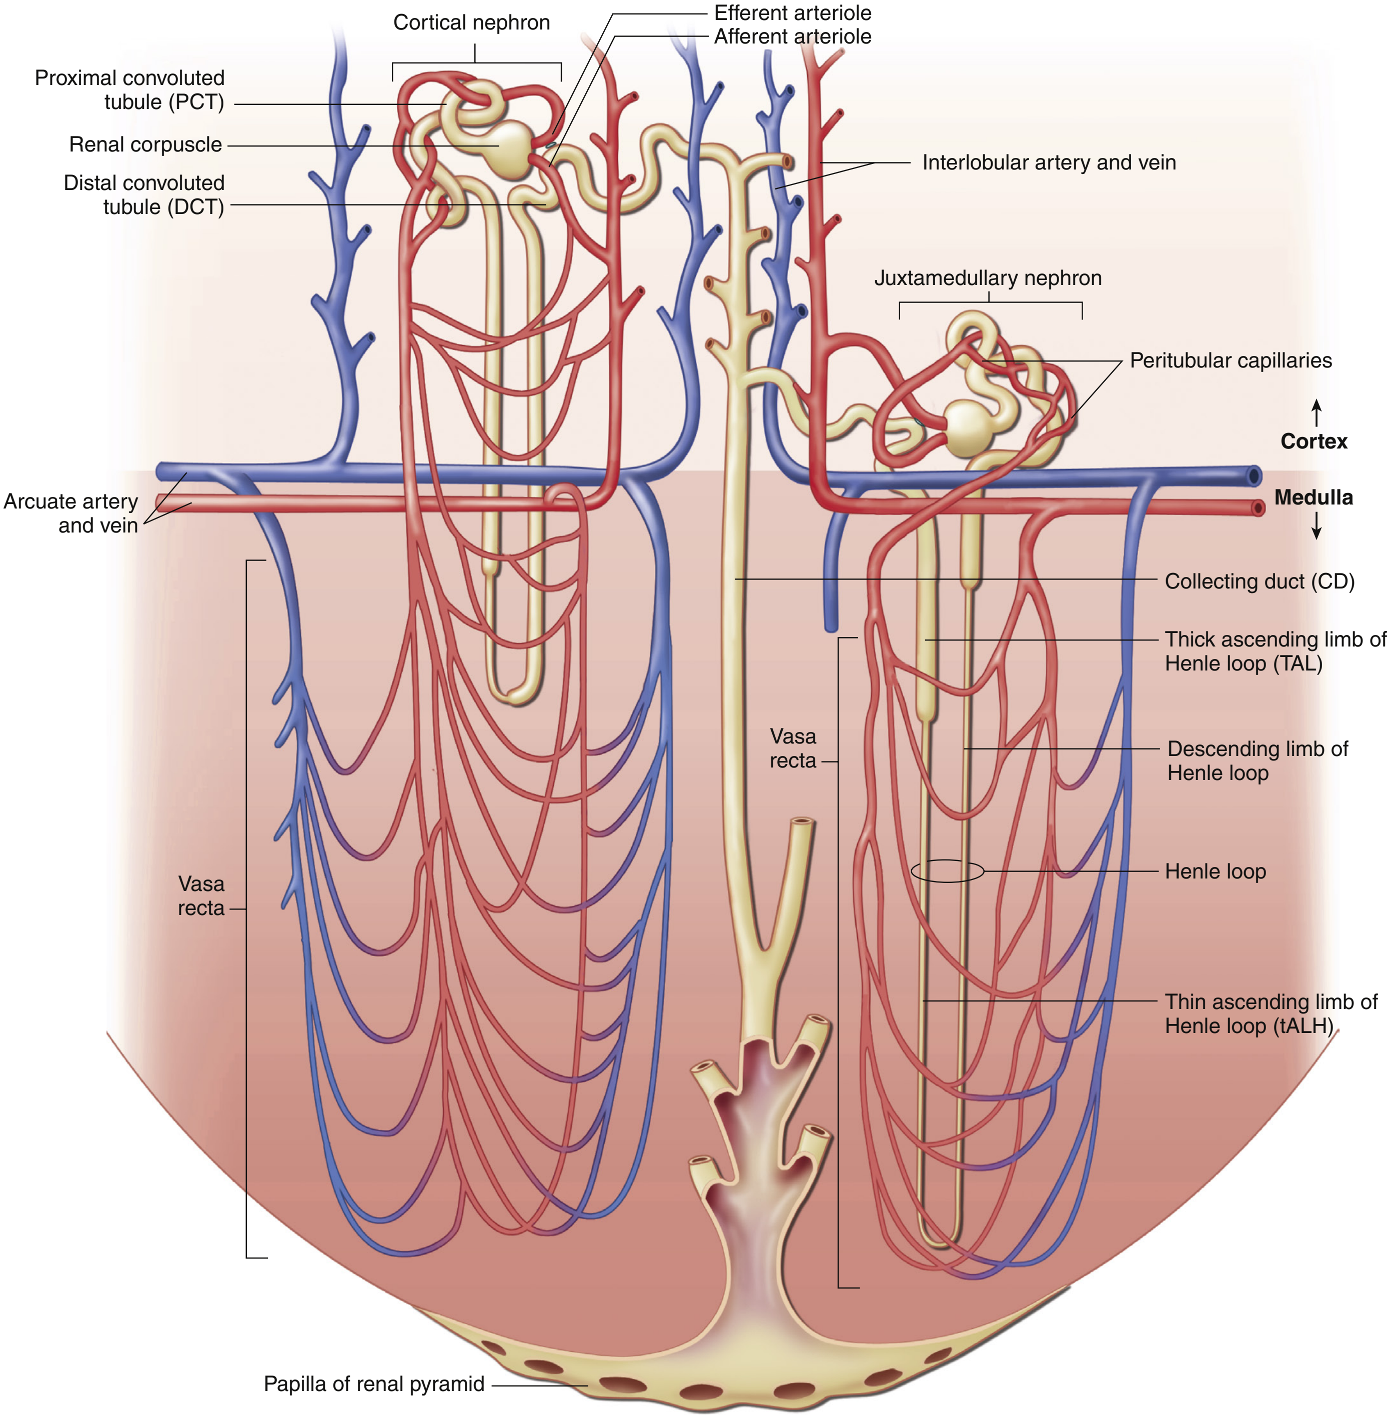

FIGURE 37-5 The Nephron Unit with Its Blood Vessels. Blood flows through nephron vessels as follows: interlobular artery, afferent arteriole, glomerulus, efferent arteriole, peritubular capillaries (around the tubules), venules, interlobular vein. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

located deep in the cortex close to the medulla. The major structural difference between the glomeruli in the two types of nephrons is the length of the loop of Henle. In cortical nephrons the loop is short and may not extend into the medulla. The loop of Henle for the juxtamedullary nephrons, however, may extend the whole length of the medulla (40 mm). Juxtamedullary nephrons represent about 12% of the total number of nephrons and are important for the concentration and dilution of urine.

The **distal convoluted tubule** extends from the distal portion of the loop of Henley to the **collecting duct.** The collecting duct is a large tubule that descends down the cortex through the renal pyramids of the inner and outer medullae, draining urine into the minor calyx. The collecting duct is composed of two epithelial cell types: **principal cells** that reabsorb sodium and water and secrete potassium, and **intercalated cells** that secrete hydrogen and reabsorb potassium (see Figure 34-4).

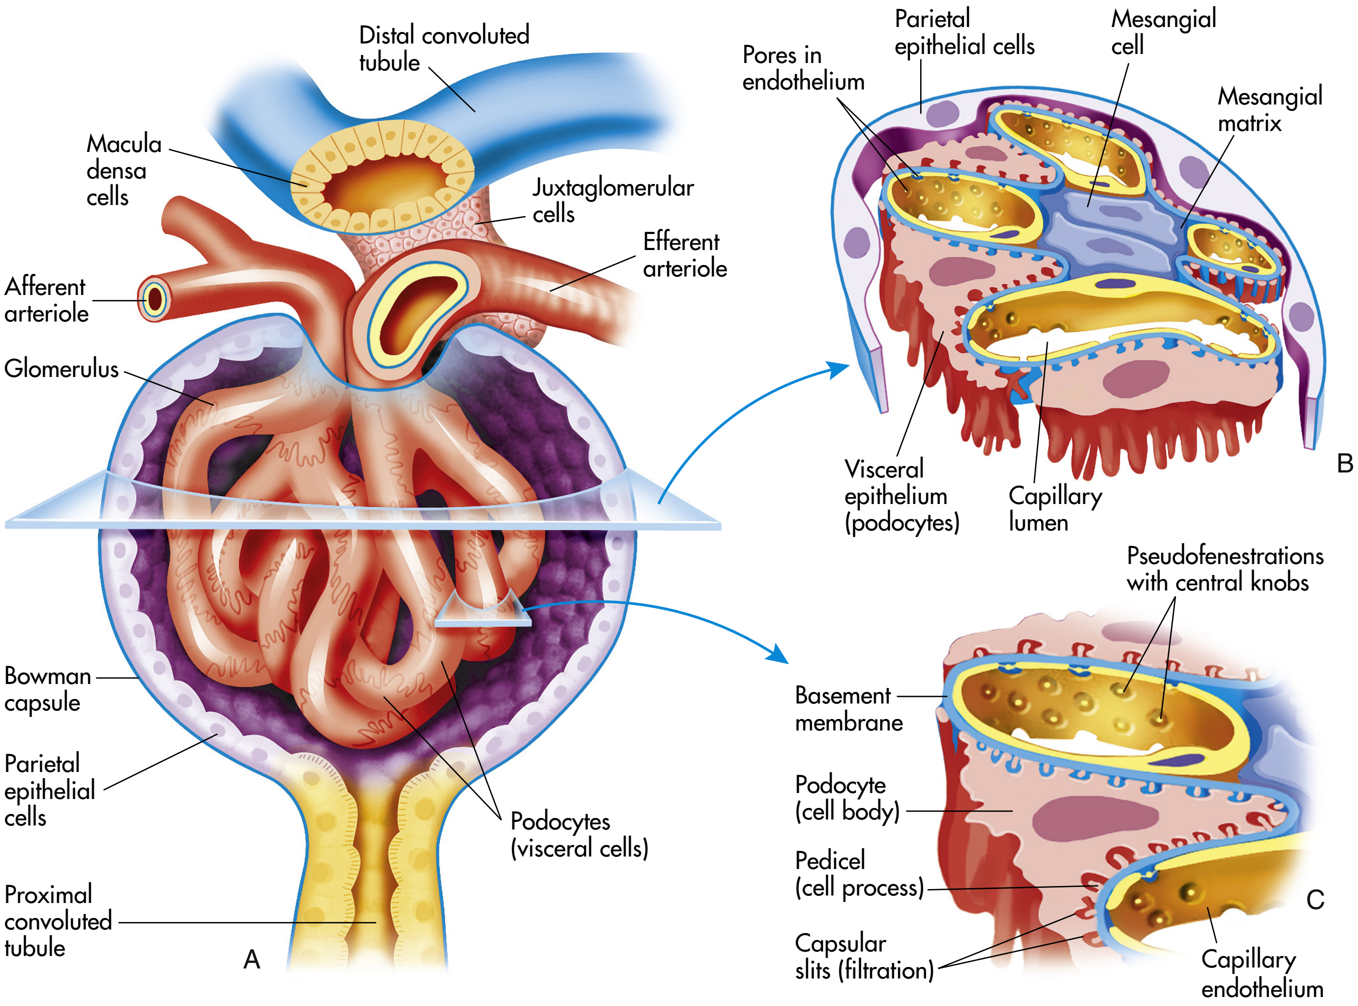

FIGURE 37-6 **Anatomy of the Glomerulus and Juxtaglomerular Apparatus. A,** Longitudinal cross section of glomerulus and juxtaglomerular apparatus. **B,** Horizontal cross section of glomerulus. **C,** Enlargement of glomerular capillary filtration membrane.

Black arrow indicates direction of urine flow. (From Kissane JM, editor: *Anderson's pathology,* ed 9, St Louis, 1990, Mosby.)

Blood Vessels

The blood vessels of the kidney closely parallel nephron structure. The **renal arteries** arise from the abdominal aorta at the first lumbar vertebra and supply approximately 20% of the cardiac output to the kidneys. At the renal hilum they divide into anterior and posterior branches and then subdivide into lobar arteries that supply blood to the lower, middle, and upper portions of the kidney. The **interlobar arteries** are further subdivisions that travel down the renal columns and between the pyramids. At the cortical-medullary junction, interlobar arteries branch into the **arcuate arteries** that arch over the base of the pyramids and run parallel to the surface of the kidney. The interlobular arteries arise from the arcuate arteries and extend through the cortex toward the periphery of the kidney and supply the afferent glomerular arterioles (see Figure 37-5).

The afferent arterioles subdivide into the glomerulus, a fistlike structure of four to eight **glomerular capillaries** (see Figure 37-6). The glomerular capillaries feed into the efferent arteriole, which conveys blood to a second capillary bed, the peritubular capillaries. This is the only place in the body where an arteriole is positioned between two capillary beds. Increases or decreases in the resistance of the afferent and efferent arterioles increase or decrease glomerular filtration. The **peritubular capillaries** surround the the proximal and distal convoluted tubules and the loop of Henle (see Figure 37-5). The peritubular capillaries are adapted differently for the cortical and juxtamedullary nephrons. The peritubular capillaries surrounding the tubules of the cortical nephrons are similar to capillaries in other tissues. For the juxtamedullary nephrons a network of capillaries called the **vasa recta** forms loops and closely follows the loops of Henle. The capillaries of the vasa recta are the only blood supply to the medulla. They influence the osmolar concentration of the medullary extracellular fluid, which is important to the formation of concentrated urine. All capillaries then drain into the venous system. The renal veins follow the arterial path in a reverse direction and have the same names as the arteries. The renal vein empties into the inferior vena cava. The lymphatic vessels tend also to follow the distribution of the blood vessels.

Urinary Structures

Ureters

The urine formed by the nephrons flows from the distal tubules and collecting ducts through the duct of Bellini and the **renal papillae** (projections of the ducts) into the calyces, where it is collected in the renal pelvis (see Figure 37-2) and then funneled into the **ureters.** Each adult ureter is approximately 30 cm long and is composed of long, intertwining smooth muscle bundles. The lower ends of the ureters pass obliquely through the posterior aspect of the bladder wall. The close approximation of smooth muscle cells permits the direct transmission of electrical stimulation from one cell to another. The resulting downward peristaltic activity propels urine into the bladder. Contraction of the bladder during **micturition** (urination) compresses the lower end of the ureter, preventing reflux. Peristalsis is maintained even when the ureter is denervated, so ureters can be transplanted.

Sensory innervation for the upper part of the ureter arises from the tenth thoracic nerve roots, with referred pain to the umbilicus. The innervation of lower segments arises from the sacral nerves with referred pain to the vulva or penis. The ureters have a rich blood supply. The primary arteries come from the kidney with contributions from the lumbar and superior vesical arteries.

Bladder and Urethra

The **bladder** is a bag composed of a basket weave of smooth muscle fibers that forms the **detrusor muscle** and its smooth lining of **transitional epithelium (uroepithelium).** As the bladder fills with urine, it distends and the layers of transitional epithelial cells within the lining slide past each other and become thinner as the volume of the bladder increases. The transitional epithelium forms the interface between the urinary space and underlying vasculature, connective, nervous, and muscle tissue. It senses and transduces information about luminal pressure and urine composition within the urinary tract.[5] The **trigone** is a smooth triangular area lying between the openings of the two ureters and the urethra (Figure 37-8). The position of the bladder varies with age and gender. In infants and young children the bladder rises above the symphysis pubis, providing easy access for percutaneous aspiration. In adults it lies in the true pelvis, in front of the rectum and in front of the uterus in women. Inferiorly, the bladder sits on the prostate in men and on the anterior vagina in women. The bladder has a profuse blood supply, accounting for the bleeding that readily occurs with trauma, surgery, or inflammation.

The **urethra** extends from the inferior side of the bladder to the outside of the body. Two muscles called *sphincters* control excretion of urine from the bladder through the urethra. A ring of smooth muscle forms the **internal urethral sphincter** at the junction of the urethra and bladder. The **external urethral sphincter** is composed of striated skeletal muscle and is under voluntary control. The entire urethra is lined with mucus-secreting glands. The female urethra is short (3 to 4 cm). The male urethra is long (18 to 20 cm) and has three main segments: prostatic, membranous, and penile. The prostatic urethra is

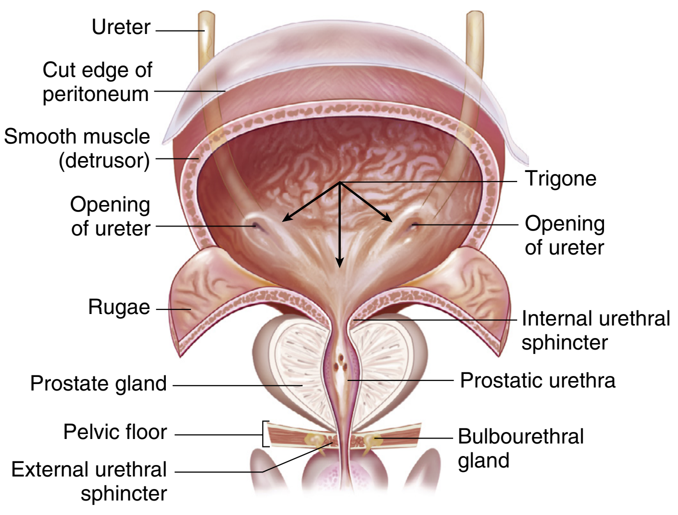

FIGURE 37-8 **Structure and Location of the Urinary Bladder.** Frontal view of a dissected urinary bladder (male) in a fully distended position. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

closest to the bladder. It passes through the prostate gland and contains the openings of the ejaculatory ducts. The membranous urethra is the segment that passes through the floor of the pelvis. The penile segment forms the remainder of the tube. The penile segment is surrounded by the corpus spongiosum erectile tissue and contains the openings of the bulbourethral glands.

The innervation of the bladder and internal urethral sphincter is supplied by parasympathetic fibers of the autonomic nervous system that arise from the sacral levels of the spinal cord (S2 to S4). Sensory fibers from the bladder and urethra may extend as high as the T6 portion of the spinal cord. Skeletal motor neurons in the pudendal nerve innervate the external urethral sphincter. The reflex arc required for micturition is stimulated by mechanoreceptors that respond to stretching of tissue. The mechanoreceptors sense bladder fullness and send impulses to the sacral level of the spinal cord with bladder filling. When the bladder accumulates 250 to 300 ml of urine, the bladder contracts and the internal urethral sphincter relaxes through activation of the spinal reflex arc (known as the *micturition reflex*). At this time a person feels the urge to void. In older children and adults, the reflex can be inhibited or facilitated by impulses coming from the brain, resulting in voluntary control of micturition.

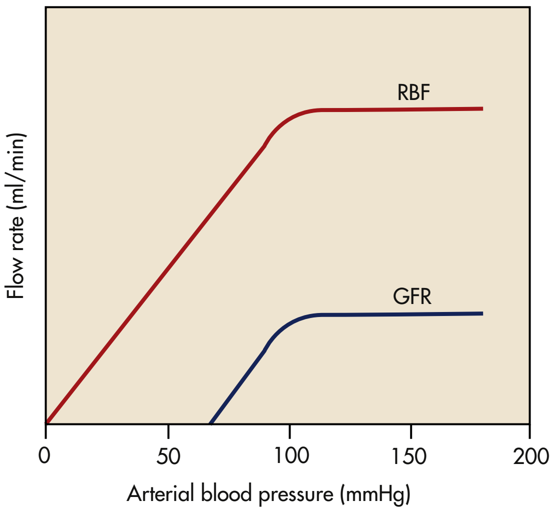

FIGURE 37-9 **Autoregulation of Renal Blood Flow.** Blood flow and glomerular filtration rate are stabilized with changes in mean arterial pressure between about 80 and 180 mmHg. (From Berne RM, Levy MN, editors: *Principles of physiology,* ed 4, St Louis, 2006, Mosby.) *GFR*, Glomerular filtration rate; *RBF*, renal blood flow.

RENAL BLOOD FLOW

The kidneys are highly vascular organs and receive about 20% to 25% of the cardiac output, which in adults is equivalent to 1000 to 1200 ml of blood per minute. With a normal hematocrit of 45%, about 600 to 700 ml of blood flowing through the kidney per minute is plasma. From the renal plasma flow (RPF), 20% (approximately 120 to 140 ml/minute) is filtered at the glomerulus and passes into the Bowman capsule. The filtration of the plasma per unit of time is known as the **glomerular filtration rate (GFR),** which is directly related to the perfusion pressure in the glomerular capillaries.

The remaining 80% (about 480 ml/minute) of plasma flows through the efferent arterioles to the peritubular capillaries. The ratio of glomerular filtrate to RPF per minute (120/600 = 0.20) is called the *filtration fraction.* Normally all but 1 to 2 ml per minute of the glomerular filtrate is reabsorbed and returned to the circulation by the peritubular capillaries.

The GFR is directly related to renal blood flow (RBF), which is regulated by intrinsic autoregulatory mechanisms, neural regulation, and hormonal regulation. In general, blood flow to any organ is determined by the arteriovenous pressure differences across the vascular bed. If mean arterial pressure decreases or vascular resistance increases, renal blood flow decreases.

Autoregulation of Renal Blood Flow

In the kidney a local mechanism of **autoregulation** tends to keep the rate of glomerular perfusion and therefore the GFR fairly constant over a range of arterial pressures between 80 and 180 mmHg (Figure 37-9). This means that changes in afferent arteriolar pressure and resistance occur in the same direction. For example, as systemic blood pressure increases, the afferent arterioles constrict, preventing an increase in filtration pressure. Opposite processes occur with a decrease in systemic blood pressure. Therefore, renal blood flow and GFR are relatively constant. The purpose of renal autoregulation is to prevent wide fluctuations in systemic arterial pressure from being transmitted to the glomerular capillaries. In this way, large fluctuations in GFR are prevented and solute and water excretion is constantly maintained despite arterial pressure changes.[6] Autoregulation may also protect the kidney from damage by hypertension.

One mechanism responsible for the autoregulatory response in the kidney is a **myogenic mechanism.** As arterial pressure declines, the stretch on the afferent arteriolar smooth muscle decreases and the arteriole relaxes, causing an increase in glomerular perfusion; an increase in arteriolar pressure causes the arteriole smooth muscle to contract and decreases glomerular perfusion. **Tubuloglomerular feedback** is a second mechanism for keeping renal blood flow and GFR constant and stable. As the GFR in an individual nephron increases or decreases, the macula densa cells in the distal tubule sense the increasing or decreasing amounts of filtered sodium. When sodium filtration increases, the macula densa cells stimulate afferent arteriolar vasoconstriction to decrease GFR. The opposite occurs with decreases in sodium filtration at the macula densa.[7] A third unknown mechanism also contributes to autoregulation.[8]

Neural Regulation

The blood vessels of the kidney are innervated by sympathetic adrenergic/noradrenergic fibers that cause arteriolar vasoconstriction to reduce renal blood flow. The innervation of the kidney comes primarily from the celiac ganglion and greater splanchnic nerve (see Figure 15-25). The afferent and efferent arterioles are richly innervated, but nerves have not been observed in the glomerular capillaries.

Renal blood flow is reflexively related to the systemic arterial pressure. When systemic arterial pressure decreases, increased

sympathetic nerve activity is mediated reflexively through feedback from the baroreceptors of the carotid sinus and aortic arch. This is achieved through the baroreceptor reflex, which stimulates vasoconstriction of the afferent arterioles with activation of α_1-adrenoreceptors. This decreases glomerular perfusion and GFR, although autoregulatory processes dampen the response. Decreased GFR diminishes excretion of sodium and water, promoting an increase in blood volume and thus an increase in blood pressure.

Exercise, body position, and hypoxia also influence renal blood flow. Exercise and change of body position activate renal sympathetic neurons and cause mild vasoconstriction. Severe hypoxia stimulates the chemoreceptors of the carotid and aortic bodies and decreases renal blood flow by means of sympathetic stimulation.

Hormones and Other Factors

Hormonal factors and many mediators can alter the resistance of the renal vasculature by stimulating vasodilation or vasoconstriction. A major hormonal regulator of renal blood flow is the renin-angiotensin-aldosterone system (RAAS), which can increase systemic arterial pressure and increase sodium reabsorption. Renin is an enzyme formed and stored in granular cells of the afferent arterioles of the JGA (see Figure 37-3). The release of renin is principally triggered by decreased blood pressure in the afferent arterioles, which reduces stretch of the juxtaglomerular cells; decreased sodium chloride concentrations in the distal convoluted tubule; sympathetic nerve stimulation of β-adrenergic receptors on the juxtaglomerular cells; and release of prostaglandins.[9]

When renin is released, it cleaves an α-globulin (angiotensinogen produced by liver hepatocytes) in the plasma to form angiotensin I, which is physiologically inactive. In the presence of angiotensin-converting enzyme (ACE) produced from the pulmonary and renal endothelium, angiotensin I is converted to angiotensin II. **Angiotensin II** stimulates secretion of aldosterone by the adrenal cortex (see Chapter 21), is a potent vasoconstrictor, and stimulates antidiuretic hormone (ADH) secretion and thirst. Vitamin D_3 is a potent negative endocrine regulator of renin gene expression.[10] Numerous physiologic effects of the RAAS serve the purpose of stabilizing systemic blood pressure and preserving the extracellular fluid volume during hypotension or hypovolemia, including sodium reabsorption, potassium excretion, systemic vasoconstriction, sympathetic nerve stimulation, thirst stimulation, and drinking. (The combined effects of the RAAS are summarized in Figure 37-10.) ACE inhibitors are a class of drugs that reduce blood pressure by inhibiting the formation of angiotensin II and aldosterone.

Natriuretic peptides are a group of peptide hormones, including **atrial natriuretic peptide (ANP),** secreted from myocardial cells in the atria and **brain natriuretic peptide (BNP)** secreted from myocardial cells in the cardiac ventricles. When the heart dilates during volume expansion or heart failure, ANP and BNP inhibit sodium and water absorption by kidney tubules, inhibit secretion of renin and aldosterone, vasodilate the afferent arterioles, and constrict the efferent arterioles. The result is increased urine formation leading to decreased blood volume and blood pressure.[11] **C-type natriuretic peptide** is secreted from vascular endothelium and in the nephron and causes vasodilation.[12] **Urodilatin** is secreted by the distal convoluted tubules and collecting ducts and causes vasodilation and natriuretic and diuretic effects. Other hormones and mediators that influence renal blood flow are summarized in Table 37-1.

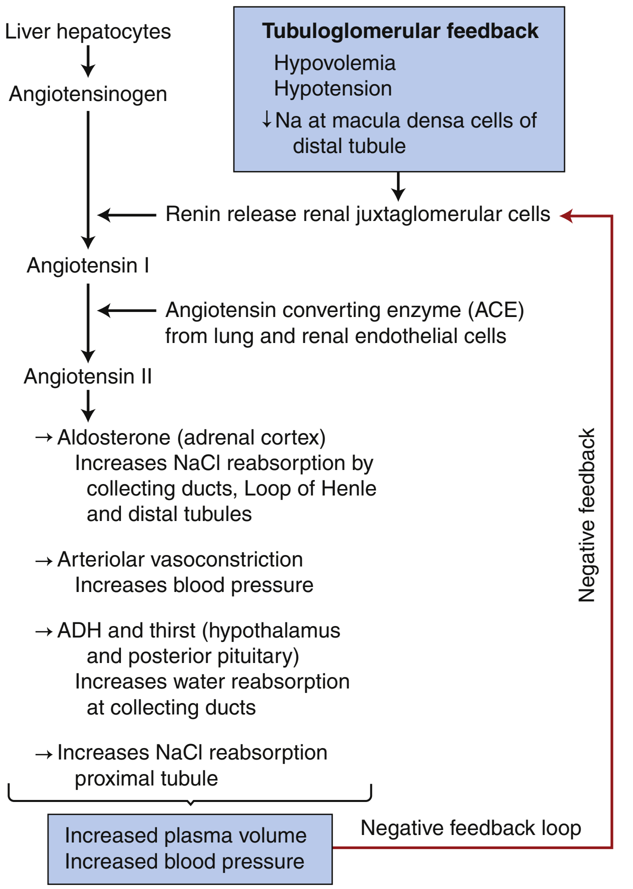

FIGURE 37-10 Renin-Angiotensin-Aldosterone System. Activation of tubuloglomerular feedback mechanisms stimulates the release of renin with activation of the renin-angiotensin-aldosterone system. Plasma volume and blood pressure are increased with the reabsorption of sodium chloride and water from the renal tubules. The restoration of plasma volume and blood pressure then decrease the release of renin, forming a negative feedback loop. *ADH,* Antidiuretic hormone.

KIDNEY FUNCTION

The major function of the kidney is urine formation and involves the processes of filtration, reabsorption, and secretion. These processes are the function of the nephrons. Fluid is filtered at the glomerulus. Substances are reabsorbed from the filtrate or secreted into the filtrate by the renal tubules. The final urine flows into the minor and major calyces, and then is propelled by the ureters to the bladder for storage and elimination.

Nephron Function

The nephron can perform many functions simultaneously. It filters the plasma at the glomerulus and reabsorbs and secretes different substances at various parts of its tubular structure (Figure 37-11). The function of the nephron is to form a filtrate

TABLE 37-1 HORMONES, MEDIATORS, AND RENAL BLOOD FLOW

HORMONE OR MEDIATOR	EFFECT ON RENAL BLOOD FLOW
Adenosine	Produced within kidney; causes vasoconstriction of afferent arteriole; decreases RBF and GFR
Angiotensin II	Produced systemically and within kidneys; constricts afferent and efferent arterioles; decreases RBF and GFR
Atrial and brain natriuretic peptides	Produced by atria and ventricles of the heart with hypertension and increased blood volume; causes vasodilation of afferent arteriole and vasoconstriction of efferent arteriole; modest increase in GFR with little change in RBF
Bradykinin	Produced in kidney from kininogen and causes vasodilation by release of nitric oxide and prostaglandins; increases RBF and GFR
Dopamine	Produced by the proximal tubule; increases RBF; inhibits renin secretion
Endothelin	Produced by renal vessel endothelial cells, mesangial cells, and distal tubule cells in response to bradykinin, angiotensin II, epinephrine, and stretch; most active with renal disease; profound vasoconstriction of afferent and efferent arterioles; decreases RBF and GFR
Histamine	Produced locally within the kidney; modulates RBF in basal state and during inflammation; increases RBF by decreasing afferent and efferent arteriolar resistance and does not decrease GFR
Nitric oxide	Produced by renal vessel endothelial cells with increased stretch and by stimulation of acetylcholine, histamine, bradykinin, ATP; increases vasodilation of afferent and efferent arterioles
Prostaglandins, PGI_2, PGE_2	Produced locally within kidney with decreased RBF; dampen vasoconstriction caused by sympathetic nerves and angiotensin II; prevent harmful vasoconstriction and renal ischemia
Urodilatin (a natriuretic peptide)	Produced by distal tubule and collecting duct when there is increased circulating volume and increased blood pressure; inhibits sodium and water reabsorption from medullary part of collecting duct, thereby producing diuresis

GFR, Glomerular filtration rate; *RBF,* renal blood flow.

of protein-free plasma. This process, known as **ultrafiltration,** occurs across the glomerular membrane. The nephron then regulates the filtrate to maintain body fluid volume, electrolyte composition, and pH within narrow limits.

Regulation of the filtrate occurs through two processes: tubular reabsorption and tubular secretion. **Tubular reabsorption** is the movement of fluids and solutes from the tubular lumen to the peritubular capillary plasma. Transfer of substances from the plasma of the peritubular capillary to the tubular lumen is **tubular secretion.** The mechanisms involve active as well as passive transport. **Excretion** is the elimination of a substance in the final urine (Figure 37-12).

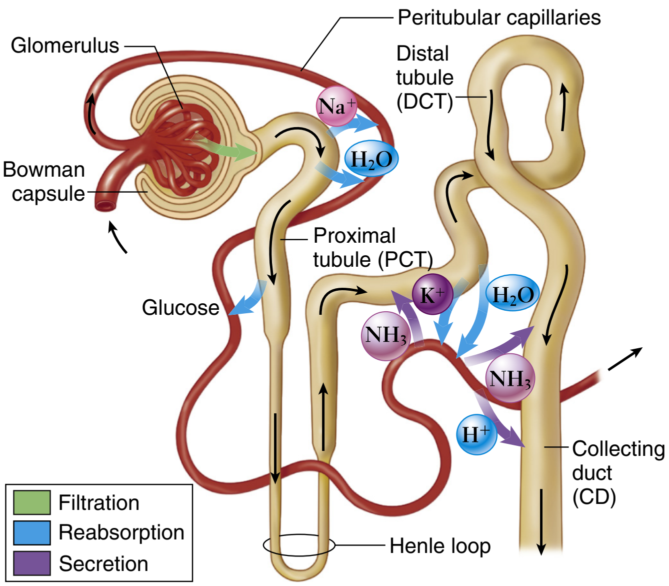

FIGURE 37-12 Urine Formation: Glomerular Filtration, Tubular Reabsorption, and Tubular Secretion. The three processes by which the kidneys excrete urine. Water, electrolytes, glucose, and organic molecules are filtered at the glomerulus. Sodium and glucose are reabsorbed into peritubular capillaries by active transport from the proximal convoluted tubules and water reabsorption follows by osmosis. Sodium is reabsorbed by active transport from distal convoluted tubules; more sodium is conserved when aldosterone is secreted. Osmotic reabsorption of water from them occurs when ADH is present. Secretion of ammonia (NH_3), hydrogen, and potassium occurs from peritubular capillaries into distal tubules by active transport. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

Glomerular Filtration

The fluid filtered by the glomerular capillary filtration membrane is protein free but contains electrolytes such as sodium, chloride, and potassium and organic molecules such as creatinine, urea, and glucose in the same concentrations as in plasma. Like other capillary membranes, the glomerulus is freely permeable to water and relatively impermeable to large colloids such as plasma proteins. The size of the molecules and their electrical charge are important factors affecting the permeability of substances crossing the glomerulus. The small size of the filtration slits in the glomerular epithelium restricts the passage of proteins and other macromolecules. The negative charge along the filtration membrane further impedes the passage of negatively charged macromolecules (because like forces repel each other). Positively charged macromolecules therefore permeate the membrane more readily than neutrally charged particles.

Capillary pressures also affect glomerular filtration. The hydrostatic pressure within the capillary is the major force for inducing water and solute movement across the filtration membrane into Bowman capsule. This pressure is determined by the systemic arterial pressure and the resistances to blood flow in the afferent and efferent arterioles. Two forces oppose the filtration effects of the glomerular capillary hydrostatic pressure (P_{GC}): (1) the hydrostatic pressure in Bowman space (P_{BC}), and (2) the effective oncotic pressure of the glomerular capillary blood (π_{GC}). (As explained in Chapter 3, hydrostatic pressure is a pushing force in relation to water, and oncotic pressure is a pulling force.) Because the fluid in Bowman space normally contains only minute amounts of protein, it usually does not have an oncotic influence on the plasma of the glomerular capillary (Figure 37-13).

The combined effect of forces favoring and forces opposing filtration determines the filtration pressure. The **net filtration pressure (NFP)** is the sum of forces favoring and opposing filtration and is expressed by the following equation:

$$\text{NFP} = (P_{GC} + \pi_{BC})\ \text{(forces favoring filtration)} - (P_{BC} + \pi_{GC})\ \text{(forces opposing filtration)}$$

The estimated values contributing to the forces of net filtration are presented in Figure 37-13.

As the protein-free fluid is filtered into Bowman capsule, the plasma oncotic pressure increases and the hydrostatic pressure decreases. The increase in glomerular capillary oncotic pressure is great enough to reduce the net filtration pressure to zero at the efferent end of the capillary and to stop the filtration process effectively. The low hydrostatic pressure and increased oncotic pressure in the efferent arteriole then are transferred to the peritubular capillaries and facilitate reabsorption of fluid from the proximal convoluted tubules.

Filtration Rate. The total volume of fluid filtered by the glomeruli averages 180 L/day, or approximately 120 ml/minute, a phenomenal amount considering the size of the kidneys. Because only 1 to 2 L of urine is excreted per day, 99% of the filtrate is reabsorbed into the peritubular capillaries and thus is returned to the blood. The factors determining the GFR are directly related to the pressures that favor or oppose filtration. Any changes in afferent or efferent arteriolar resistance will alter glomerular capillary hydrostatic pressure and GFR. Vasoconstriction of one or the other of these two arterioles produces opposite effects on glomerular pressure. For example, if the afferent arteriole constricts, blood flow decreases, with a corresponding drop in glomerular pressure. The GFR then decreases, and body fluids are conserved. Conversely, constriction of the efferent arteriole increases the net filtration pressure, and the GFR increases. When both afferent and efferent arterioles constrict, little change occurs in filtration pressure, but renal blood flow is reduced and so is the GFR.

Obstruction to the outflow of urine (caused by strictures, stones, or tumors along the urinary tract) can cause a retrograde increase in pressure at Bowman capsule and a decrease in GFR. Low levels of plasma protein in the blood from severe malnutrition or liver disease result in a decrease in π_{GC}, which increases GFR. Excessive loss of protein-free fluid from vomiting, diarrhea, use of diuretics, or excessive sweating can increase glomerular capillary oncotic pressure and decrease the GFR. Renal disease also can cause changes in pressure relationships by altering capillary permeability and the surface area available for filtration (see Chapter 38).

Tubular Transport. By the time the filtrate reaches the end of the proximal convoluted tubule, approximately 60% to 70% of filtered sodium and water and about 50% of urea have been reabsorbed, along with 90% or more of potassium, glucose, bicarbonate, calcium, phosphate, amino acids, and uric acid. All this occurs by active transport. Chloride, water, and urea are reabsorbed passively but are linked to the active transport of

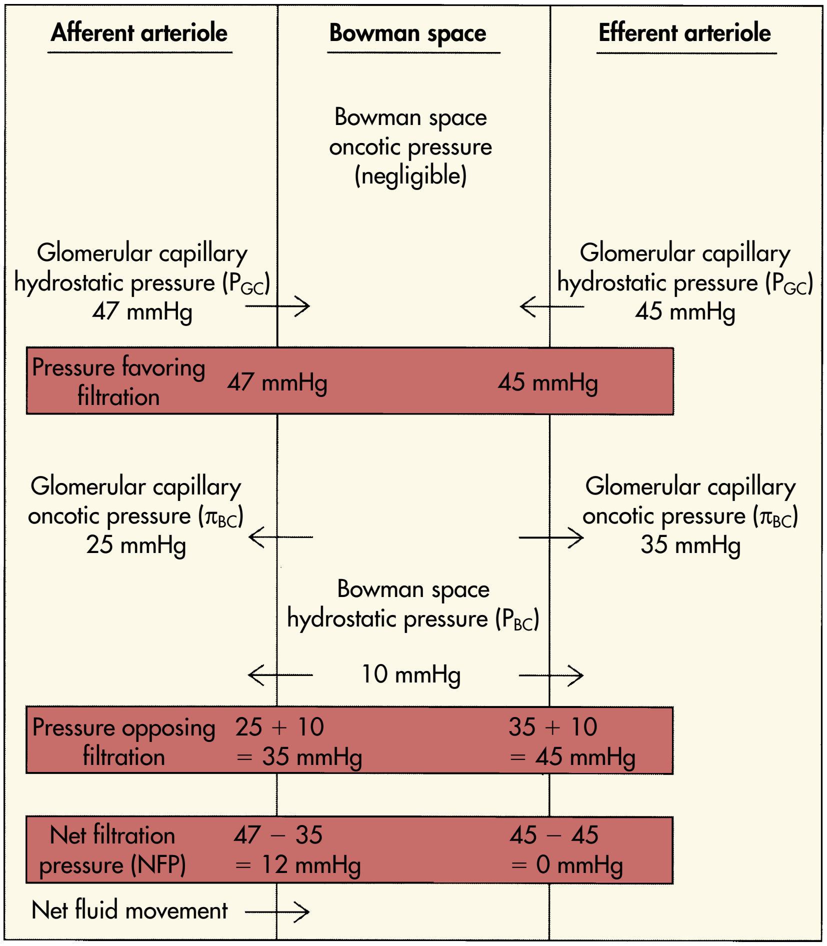

FIGURE 37-13 Glomerular Filtration Pressures.

sodium (a cotransport mechanism). For some molecules, active transport in the renal tubules is limited as carrier molecules become saturated, a phenomenon known as **transport maximum (T_m).** The reabsorption of glucose is an important example. Glucose reabsorption in the proximal convoluted tubule is coupled to sodium transport and has a maximal transport capacity, or renal threshold. This means that when the carrier molecules for glucose become saturated, what is not reabsorbed is excreted in the urine. Normally the plasma level and filtered glucose load are not high enough to saturate the carrier mechanism. When the plasma glucose concentration reaches 180 mg/dl, however, as occurs in the individual with uncontrolled diabetes mellitus, the renal threshold for glucose is achieved. Any further increase in the plasma level causes loss of glucose in the urine.

Proximal Convoluted Tubule. Active reabsorption of sodium is the primary function of the proximal convoluted tubule. Water, most other electrolytes, and organic substances are cotransported with sodium. The osmotic force generated by active sodium transport promotes the passive diffusion of water out of the tubular lumen and into the peritubular capillaries. Passive transport of water is further enhanced by the elevated oncotic pressure of the blood in the peritubular capillaries. The reabsorption of water leaves an increased concentration of urea within the tubular lumen, creating a gradient for its passive diffusion to the peritubular plasma.

As the positively charged sodium ions leave the tubular lumen, negatively charged chloride ions passively follow to maintain electroneutrality. Because the inner membrane of the proximal tubular cell has a limited permeability to chloride, chloride reabsorption lags behind sodium.

Hydrogen ions are actively exchanged for sodium ions in the tubular lumen. The hydrogen ions (H^+) then combine with bicarbonate (HCO_3^-) in the tubular lumen to form carbonic acid (H_2CO_3). The carbonic acid rapidly breaks down, or dissociates, to carbon dioxide (CO_2) and water (H_2O), which then diffuse into the tubular cell where carbonic anhydrase catalyzes the reaction between CO_2 and H_2O to form HCO_3^- and H^+. HCO_3^- combines with sodium and is transported (reabsorbed) to the peritubular capillary blood. The H^+ is not excreted but is again exchanged for sodium and reenters the lumen to recombine with HCO_3^-. Thus, in the proximal convoluted tubule, for every H^+ ion secreted into the tubular lumen, a HCO_3^- ion enters the blood (see Figure 3-13, p. 126).

Bicarbonate is freely filtered at the glomerulus, but is not readily reabsorbed because the peritubular capillary membrane is not highly permeable to the molecule. As described previously, HCO_3^- combines with H^+ in the tubular cell and is eventually reabsorbed as CO_2 and H_2O. One of the unusual aspects of this process is that the bicarbonate molecule filtered at the glomerulus is not the same molecule that is reabsorbed

BOX 37-1 SUBSTANCES TRANSPORTED BY RENAL TUBULES

REABSORPTION	SECRETION
Albumin	Choline
Ascorbate	Creatinine
Fructose	Histamine
Galactose	Methyl guanidine
Glucose	*para*-Aminohippurate
Glutamate	Penicillin
Phosphate	Steroid glucuronides
Sulfate	Thiamine
Xylose	

(because it dissociates) and the hydrogen ion secreted by the proximal tubule is not excreted in the urine. Bicarbonate is thus conserved, and in this exchange, bicarbonate and hydrogen normally do not contribute to the urinary excretion of acid or the addition of acid to the blood. In the form of CO_2 and H_2O, approximately 90% of filtered bicarbonate is reabsorbed by the proximal tubules.

In addition to the proximal tubular secretion of hydrogen ions, secretory transport maximums (T_m) exist for creatinine, other organic bases, and endogenous and exogenous organic acids, including *para*-aminohippurate (PAH) and penicillin (Box 37-1). These secretory mechanisms are important for eliminating drugs and other exogenous chemical products from the body. Frequently, exogenous substances are conjugated with sulfate and glucuronic acid by the liver and then actively secreted by the renal tubules. This has important clinical implications because many drugs and their metabolites are eliminated from the body in this way. When the renal tubules are damaged, metabolic byproducts and drugs may accumulate, causing toxic levels in the body.

Loop of Henle and Distal Convoluted Tubule. The filtrate entering and leaving the proximal convoluted tubule is essentially isosmotic with the plasma and has a concentration of about 285 mOsm. Although approximately 65% of salt and water is reabsorbed along the proximal tubule, they are reabsorbed in equal amounts, causing only minor changes in the osmotic and electrolyte concentrations of the fluid flowing into the loop of Henle. Therefore, any concentration or dilution of urine occurs at more distal sites of the nephron, principally in the medullary loop of Henle and collecting ducts. Near the top of the renal pyramids, the interstitial osmolality reaches 1200 mOsm/L.

These quantitative changes taking place in the loop of Henle are related to the length of the loop and its depth of penetration into the medulla. The structural features of the medullary hairpin loops provide the kidney with the ability to concentrate urine and conserve water for the body. The transition of the filtrate into urine is a function of the concentrating ability of the loops and final adjustments in urine composition made by the distal tubule and collecting duct.

The primary function of the loop of Henle is to establish a hyperosmotic state within the medullary interstitial fluid. This is achieved by reabsorbing more solute than water into the interstitium. The fluid leaving the ascending limb of the loop is therefore hypoosmotic, or more dilute than the fluid that entered. This dilution allows the distal tubule and collecting duct to make final adjustments in the concentration or dilution of the excreted urine according to body needs. The vasa recta act to maintain the high osmotic gradient established by the loop of Henle (see Figure 37-14, p. 1332).

Different transport or permeability functions of the loop of Henle are important for dilution and concentration of urine. The thin, descending segment of the loop of Henle is highly permeable to water and moderately permeable to sodium, urea, and other solutes. The thin, ascending segment is more permeable to solutes and almost impermeable to water. The thick portion of the ascending segment is highly permeable to sodium, potassium, and chloride and significantly less permeable to water and urea. *Tamm-Horsfall glycoprotein,* also known as uromodulin, is formed on the epithelial surface of the thick ascending segment and the first segment of the distal tubule. It is the most abundant urinary protein and protects against bacterial adhesion and urolithiasis, and is a ligand for lymphokines.[13]

The convoluted portion of the distal tubule has limited permeability to water but readily absorbs ions and contributes to the dilution of the tubular fluid. The later, straight segment of the distal tubule and the collecting duct are permeable to water as controlled by ADH. Sodium is readily absorbed by the later segment of the distal tubule and collecting duct under the regulation of the hormone aldosterone (see Chapter 21). Potassium is actively secreted by principal cells and is reabsorbed in lesser amounts by intercalated cells in these segments. Potassium secretion is controlled by aldosterone and other factors related to the concentration of potassium in body fluids.[14]

Hydrogen is also secreted by the distal tubule and combines with non–bicarbonate buffers (ammonium and phosphate) for the elimination of excess acids in the urine. The distal tubule thus contributes to the regulation of acid-base balance by excreting hydrogen ions into the urine and by adding new bicarbonate to the plasma (see Figure 3-13, p. 126). The mechanism is similar to the conservation of bicarbonate by the proximal tubule, except that the hydrogen ion is excreted in the urine. (The specific mechanisms of acid-base balance and acid excretion are described in Chapter 3.)

Glomerulotubular Balance. Normally, 99% of the glomerular filtrate is reabsorbed. When the GFR spontaneously decreases or increases, the renal tubules and, primarily the proximal tubules, automatically adjust their rate of reabsorption of sodium and water to balance the change in GFR. Thus a constant fraction of filtered sodium and water is reabsorbed from the proximal tubule. This prevents wide fluctuations in sodium and water excretion into the urine and maintains sodium and water balance.[15]

Concentration and Dilution of Urine

The production of concentrated urine involves a **countercurrent exchange system,** in which fluid flows in opposite directions through parallel tubes. A concentration gradient causes fluid to be exchanged across the parallel pathways. In the nephron the fluid moves up and down the parallel sides of the hairpin loop of Henle in the medulla. The longer the loop, the greater the concentration gradient because the concentration gradient increases from the cortex to the tip of the medulla. The loops of Henle therefore serve as multipliers of the concentration

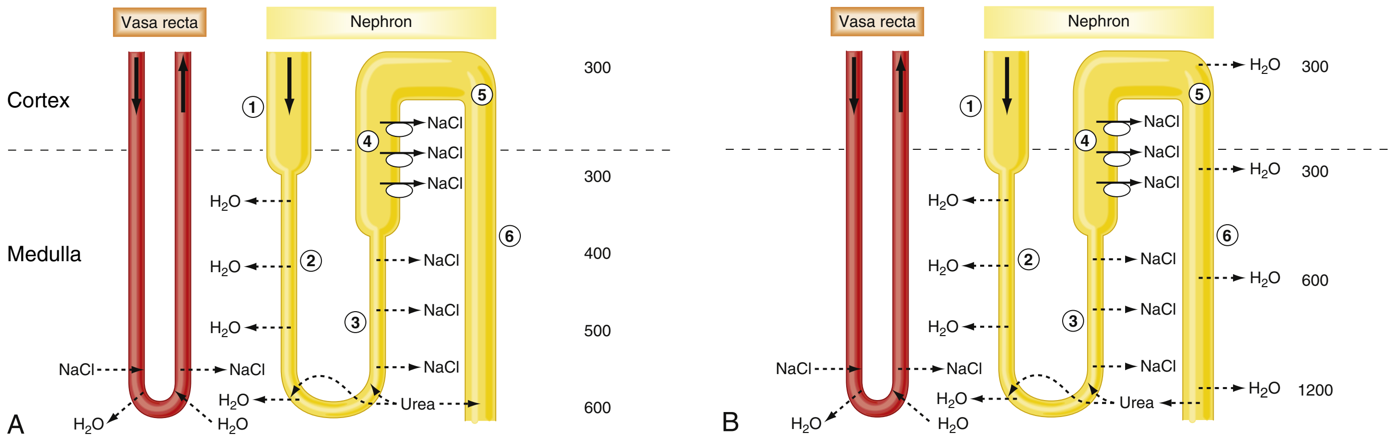

FIGURE 37-14 Countercurrent Mechanism for Concentrating and Diluting Urine. **A,** Urine dilution; **B,** urine concentration. **1,** Filtrate isotonic to plasma. **2,** Descending thin limb permeable to water. **3,** Ascending thin limb impermeable to water; permeable to ions. **4,** Ascending thick limb actively transports NaCl; impermeable to water and urea. **5,** DT actively resorbs NaCl; resorbs water in presence of ADH. **6,** Medullary CD actively resorbs NaCl, and slightly permeable to water and urea. See text for details.

gradient, and the vasa recta act as a countercurrent exchanger for maintaining the gradient.[16]

Water, Sodium, and Chloride

The process is initiated in the thick ascending limb of the loop of Henle with the active transport of sodium chloride out of the tubular lumen and into the medullary interstitium (Figure 37-14). Because the lumen of the ascending limb is impermeable to water, water cannot follow the sodium/chloride transport. This lack of luminal permeability causes the ascending tubular fluid to become hypoosmotic and the medullary interstitium to become hyperosmotic. The descending thin limb of the loop, which receives fluid from the proximal tubule, is highly permeable to water, but it is the only place in the nephron that does not actively transport either sodium or chloride. Sodium and chloride may, however, diffuse into the descending tubule from the interstitium. The hyperosmotic interstitium causes water to move out of the descending thin limb, and the remaining fluid in the descending tubule becomes increasingly concentrated as it flows toward the tip of the medulla. As the tubular fluid rounds the loop and enters the ascending thin limb, sodium and chloride are removed and water is retained. The fluid then becomes more and more dilute as it encounters the distal tubule. The data tubule resorbs water in the presence of antidiuretic hormone.

The slow rate of blood flow and the hairpin structure of the vasa recta allow blood to flow through the medullary tissue without disturbing the osmotic gradient. As blood flows into the descending limb of the vasa recta, it encounters the increasing osmotic concentration gradient of the medullary interstitium. Water moves out, and sodium and chloride diffuse into the descending vasa recta. The plasma becomes increasingly concentrated as it flows toward the tip of the medulla.

As the blood flow passes into the ascending limb and back toward the cortex, the surrounding interstitial fluid becomes comparatively more dilute. Water then moves back into the vasa recta, and sodium and chloride diffuse out. The net result is a preservation of the medullary osmotic gradient. If blood were to flow rapidly through the vasa recta, as occurs in some renal diseases, the medullary concentration gradient would be washed away and the ability to concentrate urine and conserve water would be lost. The efficiency of water conservation is related to the length of the loops: the longer the loops, the greater the ability to concentrate the urine. Many desert animals have very long loops and can reabsorb water so efficiently that they rarely need to drink.

Urea

Urea is an end product of protein metabolism and is the major constituent of urine along with water. The glomerulus freely filters urea. Tubular reabsorption depends on urine flow rate with less reabsorption occurring at higher flow rates. Approximately 50% of urea is excreted in the urine, and 50% is recycled within the kidney. The recycling of urea from the tubules and collecting ducts contributes to the osmotic gradient within the medulla and is necessary for the concentration and dilution of urine. Because urea is an end product of protein metabolism, individuals with protein deprivation cannot maximally concentrate their urine.

Catecholamines

In response to hemorrhage or extracellular fluid depletion, sympathetic neurons release norepinephrine, and the adrenal medulla releases epinephrine and norepinephrine. Norepinephrine and epinephrine promote afferent arteriolar vasoconstriction and decrease GFR and RBF. **Renalase** is a hormone produced by the kidney that degrades catecholamines and regulates blood pressure.[17]

Antidiuretic Hormone

The distal tubule in the cortex receives the hypoosmotic urine from the ascending limb of the loop of Henle. The concentration

TABLE 37-2 **ACTION OF DIURETICS**

DIURETIC	SITE OF ACTION	ACTION	SIDE EFFECTS
Osmotic Diuretic			
Mannitol Glycerol Urea	Proximal tubule	Freely filtered but not reabsorbed; osmotically attracts water and diminishes sodium reabsorption	Hypokalemia, dehydration
Carbonic Anhydrase Inhibitors			
Acetazolamide	Proximal tubule	Inhibits carbonic anhydrase; blocks hydrogen ion secretion and reabsorption of sodium and bicarbonate	Hypokalemia, systemic acidosis, alkaline urine
Inhibitors of Sodium/Chloride Reabsorption			
Thiazides	Between end of ascending loop and beginning of distal tubule	Blocks sodium and chloride reabsorption; mildly suppresses carbonic anhydrase	Hypokalemia, metabolic alkalosis
Furosemide Ethacrynic acid Torsemide	Thick ascending limb of Henle loop	Blocks active transport of chloride, sodium, and potassium	Hypokalemia, uric acid retention
Bumetanide	Cortical vasodilation	Increased rate of urine formation	Hypokalemia, uric acid retention
Potassium Sparing			
Spironolactone Eplerenone	Distal tubule	Inhibits aldosterone, blocks sodium reabsorption, and results in potassium retention	Hyperkalemia, nausea, confusion, gynecomastia
Triamterene Amiloride	Distal tubule	Blocks sodium reabsorption and inhibits potassium excretion	Nausea, vomiting, headache, and amiloride granulocytopenia, skin rash
Aquaretics			
Vasopressin (V2 receptor) blockers (i.e., conivaptan)	Distal tubule and collecting ducts	Blocks action of antidiuretic hormone	Dehydration

of the final urine is controlled by **antidiuretic hormone (ADH),** which is secreted from the posterior pituitary, or neurohypophysis. ADH increases water permeability in the last segment of the distal tubule and along the entire length of the collecting ducts, which pass through the inner and outer zones of the medulla.

In the presence of ADH, water reabsorption is high. Most of the water is reabsorbed in the medullary collecting ducts because of the high osmotic gradient in the medullary interstitium. The water diffuses into the ascending limb of the vasa recta and returns to the systemic circulation. The excreted urine can have a high osmotic concentration, up to 1400 mOsm. The volume is normally reduced to about 1% of the amount that was filtered at the glomerulus.

Excess ADH secretion is therefore one cause of **oliguria,** or diminished excretion of urine, clinically defined as less than 400 ml/day or 30 ml/hr. The syndrome of inappropriate secretion of ADH occurs when the posterior pituitary hypersecretes ADH, resulting in excess water reabsorption and water excess in the plasma (see Chapters 3 and 22).

Inadequate secretion of ADH occurs in diabetes insipidus, and causes the distal tubules and collecting ducts to become impermeable to water. Water remains in the tubular lumen and is excreted as a dilute and large volume of urine. (The mechanism for the regulation of ADH and plasma osmolality is described in Chapter 3 and 21.)

Natriuretic Peptides

The natriuretic peptides (urodilatin, atrial natriuretic peptide [ANP], and brain natriuretic peptide [BNP]) promote diuresis and were described on p. 1327.

Diuretics as a Factor in Urine Flow

A **diuretic** is any agent that enhances the flow of urine. Clinically, diuretics interfere with renal sodium reabsorption and reduce extracellular fluid volume. Diuretics are commonly used to treat hypertension and edema caused by heart failure, cirrhosis, and nephrotic syndrome.

Different diuretics affect different sites of tubular function and may produce side effects that alter acid-base and electrolyte balance. Therefore, health professionals need to understand their indications for use, mechanisms of action, and toxic side effects. Diuretics are divided into five general categories: (1) osmotic diuretics, (2) carbonic anhydrase inhibitors (inhibitors of urinary acidification), (3) inhibitors of loop sodium or chloride transport, (4) aldosterone antagonists, and (5) aquaretics. (The physiologic mechanism related to each category is summarized in Table 37-2.)

Renal Hormones

The kidneys activate or synthesize a series of hormones that have significant systemic effects and include the active form of

vitamin D, erythropoietin, renin-angiotensin-aldosterone and natriuretic hormones (see p. 1327).

Vitamin D

Vitamin D is a hormone that can be obtained in the diet or synthesized by the action of ultraviolet radiation on cholesterol in the skin. These forms of vitamin D (cholecalciferol) are inactive and require two hydroxylations to establish a metabolically active form. The first step occurs in the liver with hydroxylation at carbon-25 (calcifediol), and the second hydroxylation occurs at the first carbon position in the kidneys and is stimulated by parathyroid hormone. The end product is 1,25-dihydroxycholecalciferol, or 1,25-dihydroxy-vitamin D_3 (1,25-OH_2D_3) (calcitriol), the active form of vitamin D.

Calcitriol (vitamin D_3) is necessary for the absorption of calcium and phosphate by the small intestine. A decreased plasma calcium level (less than 10 mg/dl) stimulates the secretion of parathyroid hormone. Parathyroid hormone then stimulates a sequence of events that help restore plasma calcium level back toward normal including:

- Calcium mobilization from bone
- Absorption of calcium and phosphate from the intestine by stimulating renal activation of vitamin D
- Increased renal calcium and phosphate reabsorption and decreased secretion

Serum phosphate level fluctuations also influence the renal hydroxylation of vitamin D. Decreased levels stimulate active 1,25-OH_2D_3 formation, and increased levels inhibit formation. This results in compensatory changes in phosphate absorption from bone and the intestine. The clinical significance of the role of the kidney in calcium and phosphate metabolism is evident in renal disease. Patients with renal disease have a deficiency of 1,25-OH_2D_3 and manifest symptoms of disturbed calcium and phosphate balance[18](see Chapter 38).

Erythropoietin

Erythropoietin is produced by the fetal liver and the adult kidney and is essential for normal erythropoiesis. In response to renal tissue hypoxia, peritubular fibroblasts in the kidneys release erythropoietin, which stimulates the bone marrow to increase the rate of red blood cell production (see Chapter 27). Individuals with chronic renal failure develop anemia related to reduced erythropoietin secretion. The anemia of chronic renal failure and cancer chemotherapy is treated with recombinant human erythropoietin (r-HuEPO). Erythropoietin also affects the endothelium and promotes angiogenesis, mitogenesis, and anti-apoptosis and is neurotrophic.[19]

TESTS OF RENAL FUNCTION

The Concept of Clearance

A number of specific renal functions can be measured by renal clearance. Renal clearance techniques determine how much of a substance can be cleared from the blood by the kidneys per given unit of time. The application of this principle permits an indirect measure of GFR, tubular secretion, tubular reabsorption, and renal blood flow.

Clearance and Glomerular Filtration Rate

The GFR provides the best estimate of functioning renal tissue. Damage to the glomerular membrane or loss of nephrons leads to a corresponding decrease in GFR. The measurement of GFR requires use of a substance that has a stable plasma concentration, is not protein bound, is freely filtered at the glomerulus, does not influence GFR, and is not secreted, reabsorbed, or metabolized by the tubules. *Inulin* (a fructose polysaccharide) is one substance that meets the criteria for measurement of GFR.

The kidney "clears" inulin from the plasma by filtering it at the glomerulus, reabsorbing nearly all of the fluid, and excreting the inulin left behind in the urine. The amount of inulin filtered is equal to the volume of plasma filtered (GFR) multiplied by the plasma concentration of inulin (P_{IN}). The amount of inulin in the urine is equal to a volume of urine per unit of time ($\dot{V}$) (usually 24 hours) multiplied by the inulin concentration of urine (U_{IN}). Because all the inulin filtered is excreted in the urine,

$$\text{GFR} \times P_{IN} = U_{IN} = \dot{V}$$

GFR can be calculated by rearranging the formula:

$$\text{GFR (ml/min)} = \frac{U_{IN} \times \dot{V}}{P_{IN}}$$

The accurate determination of **insulin clearance** requires constant infusion to maintain a stable plasma level. This is time consuming, inconvenient, and prone to error. Therefore, the clearance of *creatinine,* a natural substance produced by muscle and released into the blood at a relatively constant rate, is commonly used clinically. It is freely filtered at the glomerulus and is not reabsorbed by the renal tubules, but a small amount is secreted by the renal tubules. Therefore, creatinine clearance overestimates the GFR but within tolerable limits. **Creatinine clearance** provides a good estimate of GFR because only one blood sample is required in addition to a 24-hour volume of urine. The GFR estimated by creatinine clearance is calculated as follows:

$$\text{GFR (ml/min)} = \frac{U_{CR} \times \dot{V}}{P_{CR}}$$

Numerous formulas have been developed for estimating GFR using creatinine and other indicators such as cystatin C.[20]

Clearance and Renal Blood Flow

The standard clearance formula also can be used to estimate renal plasma flow (RPF) and RBF using a molecule called *para*-aminohippuric acid (PAH). Some PAH is filtered at the glomerulus, and most of the remainder is secreted into the tubules in one circulation through the kidney. If all the PAH were removed from the plasma during a single pass through the kidney, total RPF could be determined. Because the supporting and nonsecreting structures of the kidney receive 10%

to 15% of **effective renal blood flow (ERBF),** clearance of PAH measures only what is known as the **effective renal plasma flow (ERPF),** which is 85% to 90% of the true renal plasma flow:

$$ERPF = \frac{U_{PAH} \times \dot{V}}{P_{PAH}}$$

where U_{PAH} = concentration of PAH in urine, and P_{PAH} = concentration of PAH in plasma.

The estimation of ERBF can then be calculated by considering the hematocrit in the following formula:

$$ERBF = ERPF$$
$$1\text{-Hematocrit}$$
$$(1.0\text{-}0.45)$$

Blood Tests

Evaluation of the biochemical components of the blood and plasma provides valuable information regarding renal function.

Plasma Creatinine Concentration

A long-term decline in GFR over weeks or months is reflected in the **plasma creatinine (P_{CR}) concentration** (normal value = 0.7 to 1.2 mg/dl). The P_{CR} concentration has a stable value when the GFR is stable because creatinine has a constant rate of production as a product of muscle metabolism. The amount filtered is approximately equal to the amount excreted. When the GFR declines, the P_{CR} increases proportionately. Thus the GFR and P_{CR} are inversely related. If the GFR were to decrease by 50%, the filtration and excretion of creatinine would be reduced by 50% and creatinine would accumulate in plasma to twice the normal value. Therefore, elevated P_{CR} values represent decreasing GFR. In the new steady-state, however, the total amount of creatinine excreted in the urine would remain the same because of the proportionate decrease in GFR and increase in P_{CR}.

The application of this principle is simple and useful for monitoring progressive changes in renal function. The test is most valuable for monitoring the progress of chronic rather than acute renal disease because it takes 7 to 10 days for the plasma creatinine level to stabilize when GFR declines. Serial measures can be obtained over a long time and plotted as a curve of glomerular function. Normal P_{CR} value decreases with advanced age, since older adults experience a decrease in lean muscle mass. The P_{CR} value becomes elevated during trauma or breakdown of muscle tissue. In such instances the value is then not useful for estimating GFR.

Plasma Cystatin C Concentration

Serum concentrations of **cystatin C** (a plasma protein freely filtered at the glomerulus) have been proposed for estimations of GFR.[21] The reciprocal of the serum concentrations of cystatin C can be used as estimates of changes in GFR similar to measures of plasma creatinine concentration. The National Kidney Foundation publishes calculators for estimating GFR for monitoring renal failure.[22]

Blood Urea Nitrogen

The concentration of urea nitrogen in the blood reflects glomerular filtration and urine-concentrating capacity. Because urea is filtered at the glomerulus, **blood urea nitrogen (BUN)** levels increase as glomerular filtration drops. Because urea is reabsorbed by the blood through the permeable tubules, the BUN value rises in states of dehydration and acute and chronic renal failure when passage of fluid through the tubules is slowed. BUN value also varies as a result of altered protein intake and protein catabolism and therefore is a poor measure of GFR. The normal range for BUN value in the adult is 10 to 20 mg/dl of blood.

Urinalysis

Urinalysis is a noninvasive and relatively inexpensive diagnostic procedure. The best results are obtained from a fresh, cleanly voided specimen because decay permits changes in the composition of urine. Urinalysis includes evaluation of color, turbidity, protein, pH, specific gravity, sediment, and supernatant.

Urine color is normally a clear, light yellow because of urochrome and other pigments. When formed substances (crystals, blood cells, or casts) are in the urine, it appears turbid. Protein in the urine creates marked foaming when shaken, and the foam is yellow or orange when the urine contains bile pigments. Urine does not normally contain protein or bile.

Urine pH normally ranges between 5 and 6.5, but it may vary from 4.5 to 8. Urine is more alkaline after eating and then becomes less alkaline before the next meal. Because sleep is accompanied by intermittent hypoventilation, urine is more acidic on awakening.

Specific gravity is an estimated measure of the solute concentration of the urine. The specific gravity of any solution is measured by comparing the weight of the solution with an equal volume of distilled water. Hence specific gravity is not a true measure of the number or concentration of particles, but it correlates well with osmolality and is a useful clinical tool. Specific gravity usually is measured with a hydrometer in a cylinder of urine; the normal value is 1.016 to 1.022. Dipstick evaluations may be falsely high when urine pH is less than 6 and falsely low when the pH is more than 7.

The final urine osmolality is primarily a function of ADH, which controls water reabsorption in the collecting ducts. If the kidney is unable to concentrate or dilute urine, given a stimulus, the cause is usually a malfunction of the renal tubules or inappropriate ADH secretion by the posterior pituitary gland. The state of hydration also affects the urine specific gravity, so hydration status should be evaluated before making a diagnosis. This determination is helpful for differentiating oliguria caused by intrinsic renal disease from hypovolemia as a result of dehydration.

Urine Sediment

The urine sediment is examined microscopically and may contain cells, casts, crystals, and bacteria. Epithelial cells may be seen in the microscopic field because they are shed naturally throughout the urinary tract.

Red Blood Cells. Normal urine contains few or no red blood cells. If a large number of red cells are present, this is known

as **hematuria,** and the sediment may be red. An alkaline or hypotonic urine causes lysis of red cells, however, so that the cells will not be seen. Urine then will be positive for hemoglobin, and the specific gravity will be elevated. Hematuria can occur with the administration of anticoagulants and with several renal diseases.

Casts. **Casts** (accumulations of cellular precipitates) originate in the renal tubules, from which they take their shape. They are cylindrical with distinct borders. All casts have a precipitated microprotein matrix and arise primarily from the ascending limb of the distal tubule. Red cell casts indicate bleeding into the tubules; white cell casts are associated with an inflammatory process. Epithelial cell casts indicate degeneration of the tubular lumen or necrosis of the renal tubules. The type of cast identified suggests the disease process occurring in the kidney.

Crystals. Numerous kinds of **crystals** can be observed in the urine. They may be composed of cystine, uric acid, calcium oxalate, or phosphate. They may not be initially observable, but as the urine cools, crystals will form. Crystals tend to form in a concentrated acidic or alkaline urine. Generally they are not clinically significant. Crystal formation is diagnostically significant, usually indicating inflammation, infection, or a metabolic disorder.

White Blood Cells. White blood cells (WBCs) in the urine (a condition termed **pyuria**) are indicative of urinary tract infection, particularly when bacteria are present. Glomerulonephritis and nephrotic syndrome also may demonstrate pyuria but usually in combination with proteinuria, red cells, and casts. The finding of WBC casts reflects a kidney infection because these casts are not formed in the bladder or prostate. If WBCs are present in the urine, a culture should be done for specific identification of bacteria and sensitivity of bacteria to antibiotics.

Other Measures

Dipsticks and reagent strips are available for detecting other substances in the urine, including glucose, bilirubin, urobilinogen, leukocyte esterase and nitrates, ketones, proteins, hemoglobin, and myoglobin.

AGING AND RENAL FUNCTION

Throughout life the kidney responds to an increased workload by compensatory hypertrophy. This hypertrophy is marked in individuals who have donated a kidney for transplant or have lost functioning nephrons from trauma or disease. The glomeruli increase in diameter, and the tubules enlarge effectively to maintain the regulatory functions of the kidney. Hypertrophy occurs more rapidly and with a larger size increase in younger individuals and in those with high protein intake.

Changes in the kidneys occur throughout life, resulting in a reduction in size and a linear decrease in renal blood flow and GFR; however, it is less pronounced in healthy individuals.[23] The number of nephrons decreases with aging, possibly related to oxidative stress, inflammation, and associated clinical conditions (e.g., hypertension and diabetes mellitus).[24,25] The primary mechanism appears to be a change in the renal vasculature and perfusion pattern, which leads to a reduction in numbers of nephrons. The rate of nephron loss accelerates between 40 and 80 years of age. By 75 years of age the nephron population is reduced by 30% to 50%, with loss of renal mass occurring primarily in the cortex. Degenerative changes within nephrons also occur with aging. The glomerular capillaries become sclerotic and remaining glomeruli become hypertrophic.[26] The glomeruli may disappear completely. The arcuate and interlobular arteries become tortuous, contributing to ischemia. The loss of the glomerular tuft may cause a shunt between the afferent and efferent arterioles. Although loss of juxtaglomerular nephrons still allows the vasa recta to be perfused, the combination of events contributes to a reduced ability to excrete a concentrated urine.[27] Thus the specific gravity of the urine in older individuals tends to be on the low side of normal.

Tubular transport changes with aging, although under normal conditions the tubules function adequately. Adaptation to stressful conditions is more difficult. Glucose, bicarbonate, and sodium are not as efficiently reabsorbed, and hyperkalemia is more common because of decreased secretion. Response to acid or base loads is delayed and prolonged. Sudden or large changes in pH or fluid load may lead to serious imbalances with increased risk of hypervolemia or hypovolemia. Acute losses or chronic fluid deficits can lead to renal insufficiency in the older adult. Administration of drugs eliminated by renal processes may require dose modifications and more astute observations for toxic side effects.[28]

The T_m for glucose reabsorption decreases with age, contributing to a greater amount of glucose in the urine. This is an important consideration when glycosuria is used for screening or monitoring the process of diabetes mellitus in older adults. These changes occur independently of disease, however, indicating a normal process of aging. An age-related decline in renal activation of vitamin D decreases intestinal absorption of calcium, and older adults need more vitamin D to overcome diminishing renal function.[29] Previous or concurrent renal disease or urinary tract obstruction may amplify age-related changes in function.

Bladder symptoms are common among older adults and include frequency, urgency, and nocturia. Neurogenic and myogenic changes in bladder structure and function may contribute to some symptoms as well as influences outside the urinary tract. Changes in neurotransmission influence the micturition reflex and may lead to an overactive or underactive bladder.[30] Obstruction related to prostate hypertrophy may lead to urine retention with frequency, urgency, nocturia, and slow or intermittent urinary stream.

SUMMARY REVIEW

Structures of the Renal System

1. The kidneys are paired structures lying bilaterally between the twelfth thoracic and third lumbar vertebrae.
2. The kidney is composed of an outer cortex containing the glomeruli and an inner medulla containing the tubules and collecting ducts that drain into the calyces.
3. The calyces join to form the renal pelvis and are continuous with the upper end of the ureter.
4. The nephron is the urine-forming unit of the kidney and is composed of the glomerulus, proximal tubule, hairpin loops of Henle, distal tubule, and collecting duct.
5. The glomerulus contains loops of capillaries that loop in the Bowman capsule. The capillary walls serve as a filtration membrane for the formation of the primary urine. The layers of the glomerular capillary include the endothelium, basement membrane, and epithelium. The epithelium is composed of podocytes that interlock to provide filtration slits.
6. Mesangial cells and matrix lie between and support the glomerular capillaries in the Bowman capsule.
7. Juxtaglomerular cells secrete renin and are located around the afferent arteriole. They are contiguous with the sodium-sensing macula densa cells of the distal convoluted tubule.
8. The Bowman capsule is the space between the visceral and parietal epithelium.
9. The proximal tubule is lined with microvilli to increase surface area and enhance reabsorption.
10. The hairpin-shaped loops of Henle selectively transport solutes and water, contributing to the hypertonic state of the medulla.
11. The distal tubule adjusts acid-base balance by excreting acid into the urine and forming new bicarbonate ions.
12. The collecting duct contains principal cells that resorb sodium and water and excrete potassium and intercalated cells that secrete hydrogen or bicarbonate and potassium.
13. The ureters extend from the renal pelvis to the posterior wall of the bladder. Urine flows through the ureters by means of peristaltic contraction of the ureteral muscles.
14. The bladder is a bag composed of the detrusor and trigone muscles and innervated by parasympathetic fibers. When accumulation of urine reaches 250 to 300 ml, mechanoreceptors, which respond to stretching of tissue, stimulate the micturition reflex.

Renal Blood Flow

1. Renal blood flows at about 1000 to 1200 ml/min, or 20% to 25% of the cardiac output.
2. Blood flow through the glomerular capillaries is maintained at a constant rate in spite of a wide range of arterial pressures (autoregulation).
3. The GFR is the filtration of plasma per unit of time and is directly related to the perfusion pressure of renal blood flow.
4. Autoregulation of RBF and sympathetic neural regulation of vasoconstriction maintain a constant GFR.
5. The renal blood vessels are innervated by the sympathetic noradrenergic nerves that regulate vasoconstriction.
6. Renin is an enzyme secreted from the juxtaglomerular apparatus; it causes the generation of angiotensin I, which is converted to angiotensin II by the action of ACE. Angiotensin II is a potent vasoconstrictor and also stimulates release of aldosterone from the adrenal cortex. Thus the renin-angiotensin-aldosterone system is a regulator of renal blood flow and blood pressure.
7. Natriuretic peptides promote sodium and water loss by inhibiting aldosterone and increasing sodium chloride excretion.

Kidney Function

1. The major function of the nephron is urine formation, which involves the processes of glomerular filtration, tubular reabsorption, and tubular secretion and excretion.
2. Glomerular filtration is favored by capillary hydrostatic pressure and opposed by oncotic pressure in the capillary and hydrostatic pressure in the Bowman capsule. The balance of favoring and opposing filtration forces is the net filtration pressure (NFP).
3. The GFR is approximately 120 ml/minute, and 99% of the filtrate is reabsorbed.
4. The proximal convoluted tubule reabsorbs about 60% to 70% of the filtered sodium and water and 90% of other electrolytes.
5. Because most molecules are reabsorbed by active transport, the carrier mechanism can become saturated at the T_m. Molecules not reabsorbed are excreted with the urine.
6. The distal tubules actively reabsorb sodium and water and secrete potassium and hydrogen for the regulation of fluid, electrolyte, and acid-base balance.
7. The concentration of the final urine is a function of the level of ADH that stimulates the distal tubules and collecting ducts to reabsorb water. The countercurrent exchange system of the long loops of Henle and their accompanying capillaries establishes a concentration gradient within the renal medulla to facilitate the reabsorption of water from the collecting duct.
8. The distal nephron regulates acid-base balance by excreting hydrogen ions and forming new bicarbonate.
9. The kidney secretes or activates a number of hormones that have systemic effects, including vitamin D_3 (1,25-OH_2D_3) and erythropoietin, which stimulates erythropoiesis when there is hypoxia.

Tests of Renal Function

1. Tests that measure renal clearance indicate how much of a substance can be cleared from the blood by the kidneys per given amount of time.
2. Creatinine, a substance produced by muscle, is measured in plasma and urine to calculate a commonly used clinical measurement of GFR (creatinine clearance).
3. The plasma creatinine concentration, cystatin C plasma concentration, and BUN levels indicate glomerular function.

SUMMARY REVIEW—cont'd

Plasma creatinine and cystatin C are measured to monitor progressive renal dysfunction; BUN is an indicator of hydration status.

4. PAH clearance is used to determine renal plasma flow and blood flow.
5. Urinalysis involves evaluation of color, turbidity, protein, pH, specific gravity, sediment, and supernatant.
6. Presence of bacteria, red blood cells, white blood cells, casts, or crystals in the urine sediment may indicate a renal disorder.

Aging and Renal Function

1. As a person ages, a decrease occurs in the number of nephrons. Renal blood flow and glomerular filtration rate decline.
2. Tubular transport and reabsorption decrease with age. Response to acid-base changes and reabsorption of glucose are delayed. Drugs eliminated by the kidney can accumulate in the plasma, causing toxic reactions.
3. Neurogenic and myogenic changes in the bladder may lead to symptoms of urgency and frequency.

CHAPTER OUTLINE

Renal and urinary function can be affected by a variety of disorders. The most common type of urinary dysfunction is infection. Stones, tumors, or inflammation also can obstruct the urinary tract. Renal function can be impaired by disorders of the kidney itself or by many other systemic diseases and ultimately may result in acute kidney injury or chronic kidney disease. Because the kidney filters the blood, it is directly linked to every other organ system. Renal failure, whether acute or chronic, is life-threatening.

URINARY TRACT OBSTRUCTION

Urinary tract obstruction is an interference with the flow of urine at any site along the urinary tract (Figure 38-1). An obstruction may be anatomic or functional. It impedes flow proximal to the obstruction, dilates structures distal to the obstruction, increases risk for infection, and compromises renal function. Anatomic changes in the urinary system caused by obstruction are referred to as **obstructive uropathy.** The severity of an obstructive uropathy is determined by: (1) the location of the obstructive lesion, (2) the involvement of one or both upper urinary tracts (ureters and renal pelvis), (3) the completeness of the obstruction, (4) the duration of the obstruction, and (5) the nature of the obstructive lesion.[1,2] Obstructions may be relieved or partially alleviated by correction of the obstruction, although permanent impairments occur if a complete or partial obstruction persists over weeks to months or longer.

Upper Urinary Tract Obstruction

Common causes of upper urinary tract obstruction include stricture or congenital compression of a calyx or the ureteropelvic or ureterovesical junction (e.g., stones [calculi]); ureteral compression from an aberrant vessel, tumor, or abdominal inflammation and scarring (retroperitoneal fibrosis); or

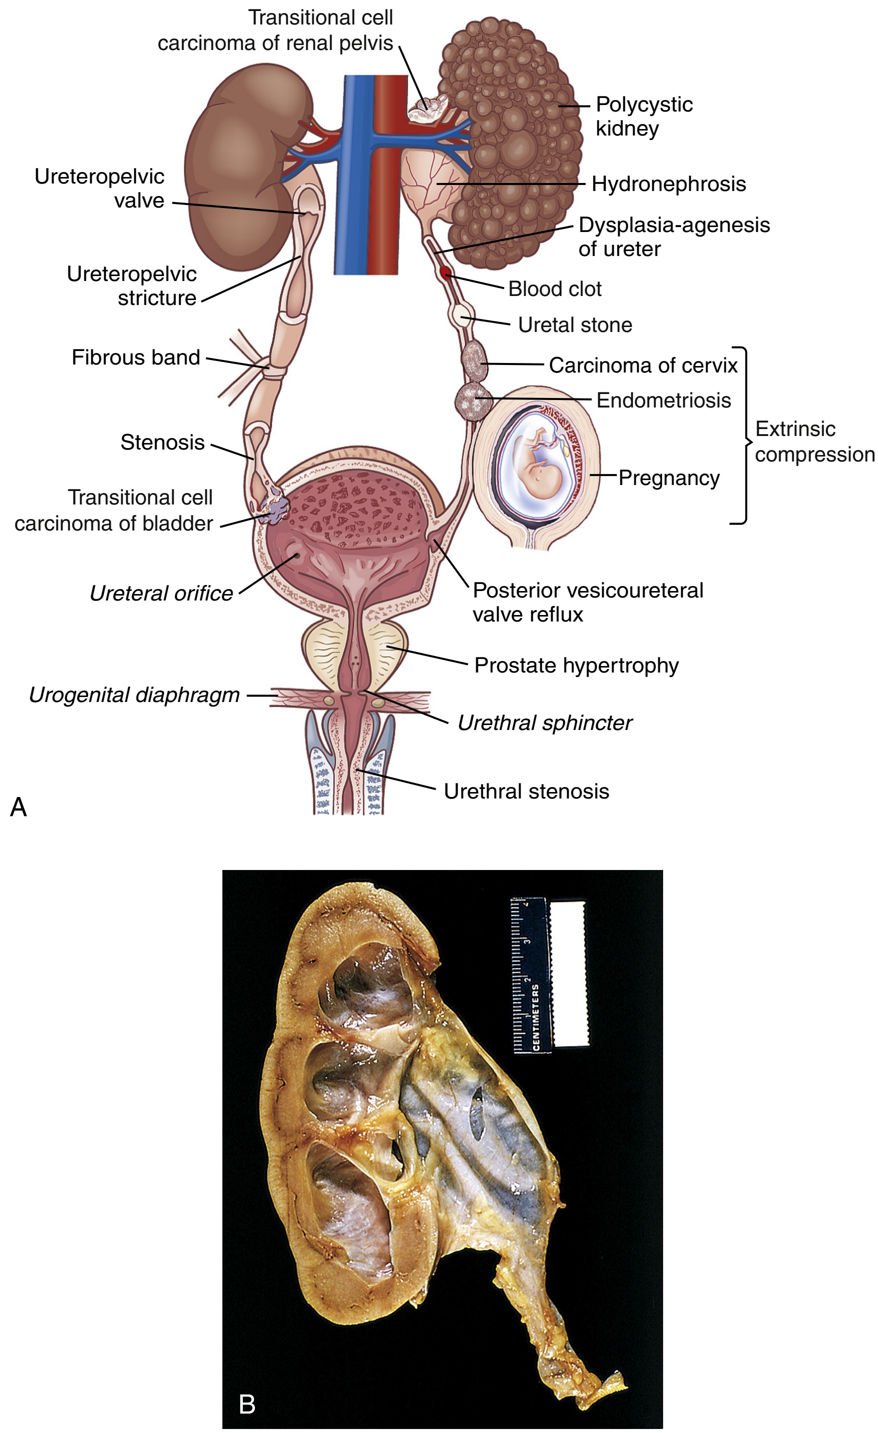

FIGURE 38-1 **Urinary Tract Obstruction and Hydronephrosis.** **A,** Causes of urinary tract obstruction. Terms in italics are normal structures. **B,** Hydronephrosis, marked dilation of renal pelvis and calyces with thinning of parenchyma.

ureteral blockage from stones or a malignancy of the renal pelvis or ureter.

Obstruction of the upper urinary tract causes dilation of the ureter, renal pelvis, calyces, and renal parenchyma proximal to the site of urinary blockage. Dilation of the ureter is referred to as **hydroureter** (accumulation of urine in the ureter), and dilation of the renal pelvis and calyces proximal to a blockage leads to **hydronephrosis** (enlargement of the renal pelvis and calyces) or **ureterohydronephrosis** (dilation of both the ureter and the pelvicaliceal system) (Figure 38-2). Dilation of the upper urinary tract is an early response to obstruction and reflects smooth muscle hypertrophy and accumulation of urine above the level of blockage (urinary stasis/retention). The increased pressure is transmitted to the glomerulus, which decreases filtration. Unless the obstruction is relieved, this dilation leads to enlargement with tubulointerstitial fibrosis and apoptosis affecting the distal nephron and renal function. **Tubulointerstitial fibrosis** is the deposition of excessive amounts of extracellular matrix

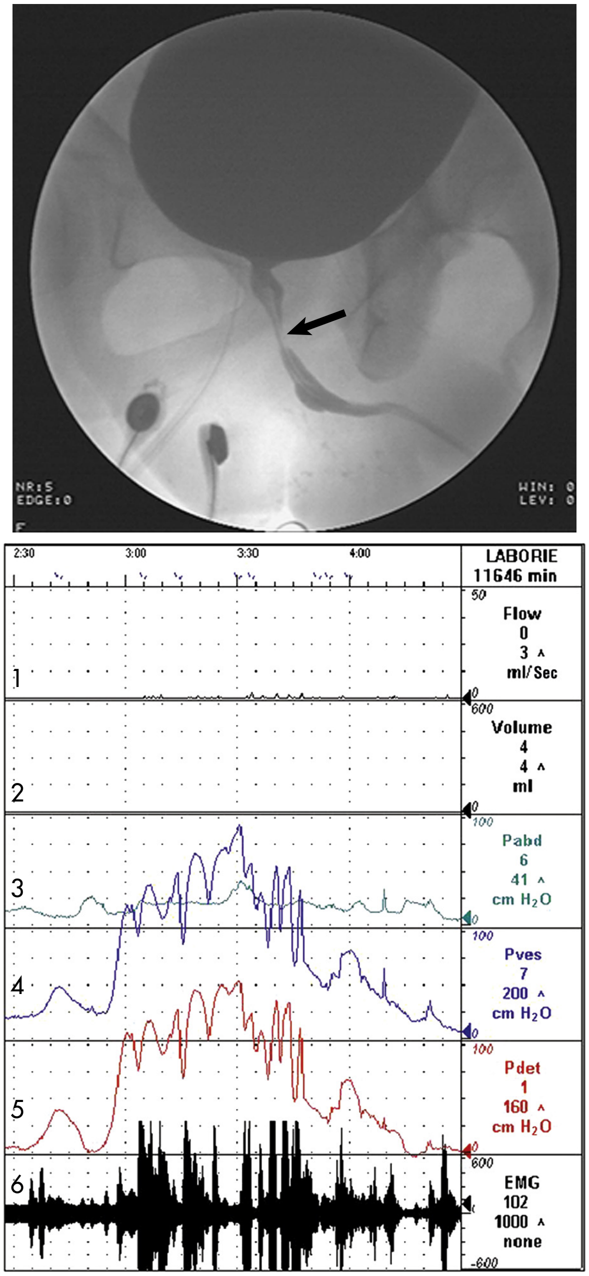

FIGURE 38-2 Neurogenic Detrusor Overactivity with Vesicosphincter. The arrow indicates narrowing of the striated sphincter consistent with electromyographic activity *(Line 6)* noted on the urodynamic tracing. Note the characteristic poor flow pattern *(Line 1)* with elevated voiding pressures *(Lines 4 and 5)* indicating obstruction. *Line 1* = Urine flow rate; *Line 2* = urine volume; *Line 3* = abdominal pressure *(Pabd); Line 4* = intravesicular (inside bladder) pressure *(Pves); Line 5* = detrusor muscle pressure *(Pdet); Line 6* = bladder electromyelogram *(EMG).*

(collagen and other proteins). Deposition of extracellular matrix is a normal process of organ repair and maintenance, and the deposition of extracellular matrix is balanced by its breakdown under the influence of metalloproteinases. Multiple cytokines and growth factors have been implicated in the process of tubulointerstitial fibrosis and irreversible loss of kidney function, including transforming growth factor-beta-1 (TGF-β1), angiotensin II, aldosterone, and various tumor necrosis factors. **Apoptosis** is a normal process that the body uses to replace damaged or senescent cells with new ones (see Chapter 1), but the imbalance in growth factors provoked by obstruction leads to excess cellular destruction and death, ultimately resulting in loss of functioning nephrons and kidney damage.

Tubulointerstitial fibrosis and apoptosis result in detectable damage to the distal renal tubules within approximately 7 days. By 14 days, obstruction has adversely affected both distal and proximal aspects of the nephron. Within 28 days the glomeruli of the kidney have been damaged and the renal cortex and medulla are reduced in size (thinned). Distal tubular damage occurs initially and decreases the kidney's ability to concentrate urine, causing an increase in urine volume despite a decrease in glomerular filtration rate (GFR). The affected kidney is unable to conserve sodium, bicarbonate, and water or to excrete hydrogen or potassium, leading to metabolic acidosis and dehydration. The magnitude of this damage, and the kidney's ability to recover normal homeostatic function, is affected by the severity and duration of the obstruction. With complete obstruction, damage to the renal tubules and compression of the renal vasculature occurs in a matter of hours, and irreversible damage occurs within 3 to 4 weeks. Nevertheless, even in the face of a complete obstruction, the human kidney may recover at least partial homeostatic function provided the blockage is removed within 56 to 69 days.[3,3a] This recovery requires approximately 4 months. Partial obstruction, in the absence of renal infection, leads to subtler but ultimately permanent impairments including loss of the kidney's ability to concentrate urine, reabsorb bicarbonate, excrete ammonia, or regulate metabolic acid-base balance if the obstruction is not relieved. Complete bilateral obstruction causes anuria because the retrograde increase in tubular hydrostatic pressure completely opposes glomerular filtration.

The body is able to partially counteract the negative consequences of unilateral obstruction by a process called **compensatory hypertrophy** and **hyperfunction.**[4] The compensatory response is the result of two growth processes: **obligatory growth** occurs under the influence of somatomedins, and **compensatory growth** occurs under the influence of a hormone or hormones that have not yet been identified. These processes cause the contralateral (unobstructed) kidney to increase the size of individual glomeruli and tubules but not the total number of functioning nephrons. The ability of the body to engage in compensatory hypertrophy and hyperfunction diminishes with age, and the process is reversible when relief of obstruction results in recovery of function by the obstructed kidney. Unilateral obstruction may remain silent for a long time.

Relief of bilateral, partial urinary tract obstruction or complete obstruction of one kidney is usually followed by a brief period of diuresis (commonly called **postobstructive diuresis**).[5] It is a physiologic response and is typically mild, representing a restoration of fluid and electrolyte imbalance caused by the obstructive uropathy. Alterations in tubular transport and water reabsorption and volume expansion contribute to the diuresis. Occasionally relief of obstruction will cause rapid excretion of large volumes of water, sodium, or other electrolytes, resulting in a urine output of 10 L/day or more (minimal normal daily urine output is approximately 720 ml/day). Rapid

postobstructive diuresis causes dehydration and fluid and electrolyte imbalances if not promptly corrected. Risk factors for severe postobstructive diuresis include bilateral obstruction, impairment of one or both kidneys' ability to concentrate urine or reabsorb sodium *(nephrogenic diabetes insipidus),* hypertension, edema and weight gain, congestive heart failure, and uremic encephalopathy.

Kidney Stones

Calculi, or **urinary stones (urolithiasis),** are masses of crystals, protein, or other substances that are a common cause of urinary tract obstruction in adults. They can be located in the kidneys, ureters, and urinary bladder. The prevalence of stones in the United States is approximately 6% in women and 15% in men, and is more common in whites.[6] The recurrence rate is approximately 30% to 50% within 5 years.[7] The risk of urinary calculi formation is influenced by a number of factors, including age, gender, race, geographic location, seasonal factors, fluid intake, diet, occupation, genetic predisposition, and other conditions including urinary tract infection, hypertension, atherosclerosis, metabolic syndrome, obesity, and diabetes.[8] Most persons develop their first stone before age 50 years. Geographic location influences the risk of stone formation because of indirect factors, including average temperature, humidity, and rain fall, and their influence on fluid and dietary patterns. Persons who regularly consume an adequate volume of water and those who are physically active are at reduced risk when compared with people who are inactive or consume lower volumes of fluid. Most kidney stones are unilateral and are a risk factor for chronic kidney disease and an increased risk for myocardial infarction.[9,10]

Urinary calculi can be classified according to the primary minerals (salts) that comprise the stones. The most common stone types include calcium oxalate or phosphate (70% to 80%), struvite (magnesium, ammonium, and phosphate) (15%), and uric acid (7%). Cystine stones are rare, less than 1%. Less common stone elements include cystine, 2,8-dihydroxyadeninuria (a rare genetic disorder that increases risk of xanthine stones), triamterene (a diuretic), and indinavir (a protease inhibitor used in management of human immunodeficiency virus [HIV] infection). Urinary calculi also can be classified according to location and size. *Staghorn calculi* are large and fill the minor and major calyces. *Non-staghorn calculi* are of variable size and are located in the calyces, in the renal pelvis, or at different sites along the ureter.

PATHOPHYSIOLOGY. Renal calculus formation is complex and related to: (1) supersaturation of one or more salts in the urine, (2) precipitation of the salts from a liquid to a solid state (crystals), (3) growth through crystallization or agglomeration (sometimes called aggregation), and (4) the presence or absence of stone inhibitors.[11] *Supersaturation* is the presence of a higher concentration of a salt within a fluid (in this case, the urine) than the volume is able to dissolve to maintain equilibrium. Human urine contains many positively and negatively charged ions capable of *precipitating* from solution and forming a variety of salts. The salts form crystals that are retained and grow into stones. *Crystallization* is the process by which crystals grow from a small *nidus* or nucleus to larger stones in the presence of supersaturated urine. Although supersaturation is essential for free stone formation, the urine need not remain continuously supersaturated for a calculus to grow once its nidus has precipitated from solution. Intermittent periods of supersaturation after the ingestion of a meal or during times of dehydration are sufficient for stone growth in many individuals. In addition, the apical papillae have interstitial sites where hydroxyapatite deposits (Randall plaque) become exposed and serve as sites for calcium oxalate stone formation (but not calcium phosphate stone formation).[12] *Matrix* is an organic material (i.e., mucoprotein) in which the components of a kidney stone are embedded.[11]

The pH of the urine also influences the risk of precipitation and calculus formation. An alkaline urinary pH significantly increases the risk of calcium phosphate stone formation, whereas acidic urine increases the risk of a uric acid stone. Cystine and xanthine precipitate more readily in acidic urine.

Stone or *crystal growth inhibiting substances,* including potassium citrate, pyrophosphate, and magnesium, are capable of crystal growth inhibition, thereby reducing the risk of calcium phosphate or calcium oxalate precipitation in the urine and preventing subsequent stone formation.

Retention of *crystal particles* occurs primarily at the papillary collecting ducts. Although most crystals are flushed from the tract through antegrade urine flow, urinary stasis, anatomic abnormalities, or inflamed epithelium within the urinary tract may prevent prompt flushing of crystals from the system, thus increasing the risk of calculus formation.

The size of a stone determines the likelihood that it will pass through the urinary tract and be excreted through micturition.[13] Stones smaller than 5 mm have about a 50% chance of spontaneous passage, whereas stones that are 1 cm have almost no chance of spontaneous passage. Nevertheless, the person with ureteral dilation from the previous passage of a stone may be able to excrete larger stones when compared with the person experiencing an initial obstructing calculus.

Calcium stones (urolithiasis) account for 70% to 80% of all stones requiring treatment. Calcium oxalate accounts for about 80% of these stones and calcium phosphate about 15%.[14] Both genetic and environmental factors may increase susceptibility. Most affected individuals have *idiopathic calcium oxalate urolithiasis (ICOU),* a condition whose exact etiology has not yet been defined. Stones can form freely in supersaturated urine or detach from interstitial sites of formation.[15] Hypercalciuria, hyperoxaluria, hyperuricosuria, hypocitraturia, mild renal tubular acidosis, crystal growth inhibitor deficiencies, and alkaline urine are associated with calcium stone formation.[16,17] Hypercalciuria and hyperoxaluria are usually attributable to intestinal hyperabsorption and less commonly to a defect in renal calcium reabsorption. Hyperparathyroidism and bone demineralization associated with prolonged immobilization are also known to cause hypercalciuria.

Struvite stones primarily contain magnesium-ammonium-phosphate as well as varying levels of matrix. Matrix forms in an alkaline urine and during infection with a urease-producing

TABLE 38-1 **TYPES OF INCONTINENCE**

TYPE	DESCRIPTION
Urge incontinence (most common in older adults)	Involuntary loss of urine associated with an abrupt and strong desire to void (urgency). Often associated with involuntary contractions of the detrusor. When associated with a neurologic disorder this is called detrusor hyperreflexia. When no neurologic disorder exists this is called detrusor instability. May be associated with decreased bladder wall compliance.
Stress incontinence (most common in women younger than 60 years and men who have had prostate surgery)	Involuntary loss of urine during coughing, sneezing, laughing, or other physical activity associated with increased abdominal pressure.
Overflow incontinence	Involuntary loss of urine with overdistention of the bladder. Associated with neurologic lesions below S1, polyneuropathies, and urethral obstruction (i.e., an enlarged prostate).
Mixed incontinence (most common in older women)	A combination of stress and urge incontinence.
Functional incontinence	Involuntary loss of urine caused by dementia or immobility.

Data from Agency for Healthcare Research and Quality: *Overview: urinary incontinence in adults, clinical practice guideline update,* Rockville, MD, 1996, Author. Available at www.ahrq.gov/clinic/uiovervw.htm.

bacterial pathogen, such as a *Proteus, Klebsiella,* or *Pseudomonas.* Struvite calculi may grow quite large and branch into a staghorn configuration **(staghorn calculus)** that approximates the pelvicaliceal collecting system. Women are at greater risk for struvite stones because they have an increased incidence of urinary tract infection (see p. 1349).

Uric acid is primarily a product of biosynthesis of endogenous purines and is secondarily affected by consumption of purines in the diet. Persons who excrete excessive uric acid in the urine, such as those with gouty arthritis, are at particular risk for **uric acid stones.** A consistently acidic urine greatly increases this risk. Cystine and xanthine are amino acids that precipitate more readily in acidic urine. *Cystinuria* and *xanthinuria* are genetic disorders of amino acid metabolism, and their excess in urine can cause **cystinuric,** or **xanthine, stone** formation in the presence of a low urine pH of 5.5 or less.

CLINICAL MANIFESTATIONS. **Renal colic,** described as moderate to severe pain often originating in the posterior hypochondrium (flank) and radiating to the groin, usually indicates obstruction of the renal pelvis or proximal ureter. Colic that radiates to the lateral flank or lower abdomen typically indicates obstruction in the midureter, and bothersome lower urinary tract symptoms (urgency, frequent voiding, urge incontinence) indicate obstruction of the lower ureter or ureterovesical junction. The pain can be severe and incapacitating and may be accompanied by nausea and vomiting. Gross (visible blood in the urine) or microscopic hematuria (three or more red blood cells per high power microscopic field) may be present.[18]

EVALUATION AND TREATMENT. The evaluation and diagnosis of urinary calculi are based on presenting symptoms and history combined with a focused physical assessment, imaging studies, and possibly a functional study of renal pelvic and ureteral pressures.[16] The history queries dietary habits; the age of the first stone episode; stone analysis; and presence of complicating factors, including recurrent urinary tract infection, hyperparathyroidism, or recent gastrointestinal or genitourinary surgery. Urinalysis (including pH) is obtained and a 24-hour urine is completed to identify calcium oxalate, citrate, and other significant constituents. In addition, every effort is made to retrieve and analyze calculi that are passed spontaneously or retrieved through aggressive intervention. Additional tests are obtained in selected individuals, such as those with suspected hyperparathyroidism or cystine or uric acid stones, in order to diagnose and manage underlying metabolic disorders. Imaging of kidney stones includes plain abdominal radiography, ultrasound, intravenous pyelogram, computed tomography, and magnetic resonance imaging.[19]

The goals of treatment are to manage acute pain, promote stone passage, reduce the size of stones already formed, and prevent new stone formation. The components of treatment include: (1) administering parenteral and/or oral analgesics for acute pain, (2) providing medical therapy to promote stone passage (alpha antagonists or calcium channel blockers), (3) reducing the concentration of stone-forming substances by increasing urine flow rate with high fluid intake, (4) decreasing the amount of stone-forming substances in the urine by decreasing dietary intake or endogenous production or by altering urine pH,[20] and (5) removing stones using percutaneous nephrolithotomy, ureteroscopy, or ultrasonic or laser lithotripsy to fragment stones for excretion in the urine.[21,22] Obstructing kidney stones with a suspected proximal urinary tract infection are urologic emergencies requiring emergent decompression and antibiotics.[23]

Lower Urinary Tract Obstruction

Obstructive disorders of the lower urinary tract (LUT) are primarily related to storage of urine in the bladder or emptying of urine through the bladder outlet. The causes of the obstruction include neurogenic and anatomic alterations or, in some instances, a combination of both. Incontinence is a common symptom. Types of incontinence are reviewed in Table 38-1.

Neurogenic Bladder

Neurogenic bladder is a general term for bladder dysfunction caused by neurologic disorders. The types of dysfunction are related to the sites in the nervous system that control sensory and motor bladder function (Figure 38-3). Lesions that develop in upper motor neurons of the brain and spinal cord result in **dyssynergia** (loss of coordinated neuromuscular contraction) and overactive or hyperreflexive bladder function. Lesions in

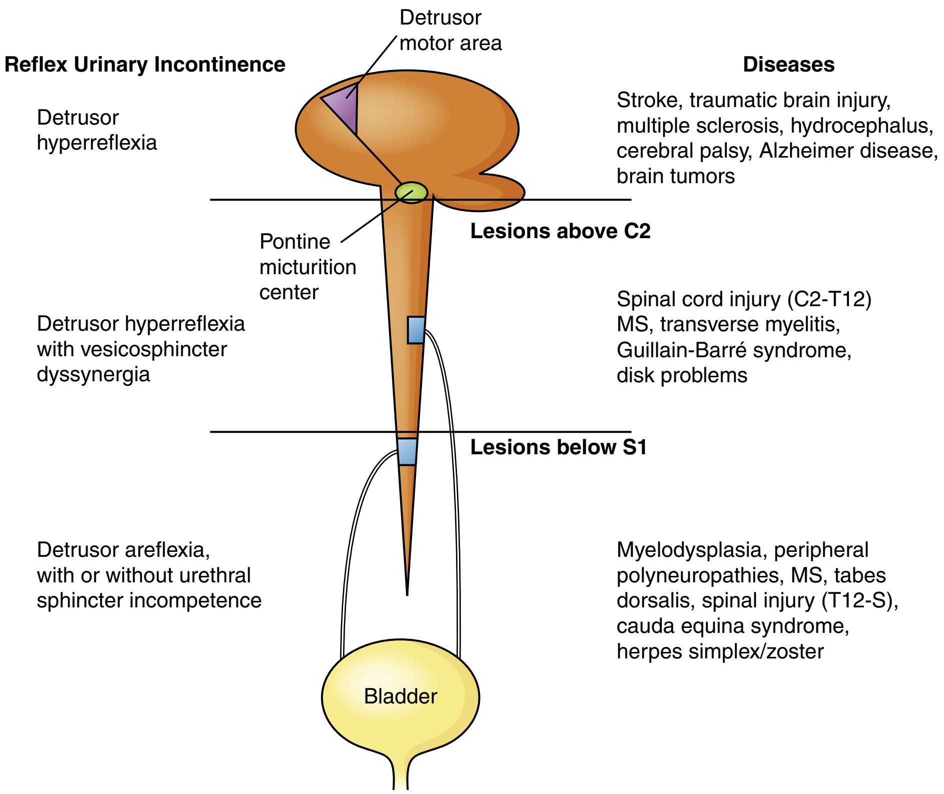

FIGURE 38-3 Causes of Neurogenic Bladder and Reflex Incontinence. (Adapted from Doughty DB, editor: *Urinary and fecal incontinence: current management concepts,* ed 3, Philadelphia, 2006, Mosby.)

the sacral area of the spinal cord or peripheral nerves result in underactive, hypotonic, or atonic (flaccid) bladder function, often with loss of bladder sensation.

Neurologic disorders that develop above the pontine micturition center result in **detrusor hyperreflexia,** also known as an uninhibited or reflex bladder. This is an upper motor neuron disorder in which the bladder empties automatically when it becomes full and the external sphincter functions normally. Because the pontine micturition center remains intact, there is coordination between detrusor muscle contraction and the relaxation of the urethral sphincter. Stroke, traumatic brain injury, dementia, and brain tumors are examples of disorders that result in detrusor hyperreflexia. Symptoms include urine leakage and incontinence.

Neurologic lesions that occur below the pontine micturition center but above the sacral micturition center (between C2 and S1) are also upper motor neuron lesions and result in **detrusor hyperreflexia with vesicosphincter (detrusor sphincter) dyssynergia.** There is loss of pontine coordination of detrusor muscle contraction and external sphincter relaxation, so both the bladder and the sphincter are contracting at the same time, causing a functional obstruction of the bladder outlet.[24] Spinal cord injury, multiple sclerosis, Guillain-Barré syndrome, and intervertebral disk problems are causes of this disorder. There is diminished bladder relaxation during storage with small urine volumes and high intravesicular (inside the bladder) pressures. This results in an overactive bladder syndrome with symptoms of urgency, frequency, urge incontinence, and increased risk for urethral turbulence and urinary tract infection.

Lesions that involve the sacral micturition center (below S1; may also be termed *cauda equina syndrome*) or peripheral nerve lesions result in **detrusor areflexia** (acontractile detrusor), a lower motor neuron disorder. The result is an acontractile detrusor or atonic bladder with retention of urine and distention. If the sensory innervation of the bladder is intact, the full bladder will be sensed but the detrusor may not contract. This is an *underactive bladder syndrome* and may have symptoms of stress and overflow incontinence. Myelodysplasia, multiple sclerosis, tabes dorsalis, and peripheral polyneuropathies are associated with this disorder.

Overactive Bladder Syndrome

Overactive bladder syndrome (OAB) is a chronic syndrome of detrusor overactivity in the absence of infection. It is estimated that 29.8 million adults over the age of 40 have bothersome OAB symptoms.[25] OAB is characterized by urgency with involuntary detrusor contractions during the bladder filling phase. The contraction may be spontaneous or provoked and associated with hyperexcitable nerves or involuntary reflexes.[26] There is coordination between the contracting bladder and the external sphincter, but the detrusor is too weak to empty the bladder, resulting in urinary retention with overflow or stress incontinence. Overactive bladder is defined by the International Continence Society as a *symptom syndrome* of urgency, with or without urge incontinence and usually associated with frequency and nocturia.[27] Overactive bladder syndrome affects millions of men, women, and children; adults are often reluctant to discuss this syndrome with their healthcare provider.

Sexual dysfunction and bowel problems often accompany OAB. Diagnosis is usually made by evaluation of symptoms. Urodynamic evaluation confirms the diagnosis. Treatment options include lifestyle modifications, behavioral therapy, pharmacotherapy (e.g., antimuscarinics), neuromodulation, botulinum toxin therapy, and surgical interventions. When left untreated, OAB is costly, impairs health and quality of life, causes depression, and leads to social isolation.[28,29] OAB is a risk for urinary tract infection and a risk for falls in older adults.[30]

Obstructions to Urine Flow

Anatomic causes of resistance to urine flow include urethral stricture, prostatic enlargement in men, pelvic organ prolapse in women, and tumor compression. Symptoms of lower urinary tract obstruction are more common in men and include: (1) frequent daytime voiding (urination more than every 2 hours while awake); (2) nocturia (awakening more than once each night to urinate for adults less than 65 years of age or more than twice for older adults); (3) bothersome urgency, often combined with hesitancy; (4) dysuria; (5) poor force of stream; (6) intermittency of urinary stream; and (7) feelings of incomplete bladder emptying despite micturition.

A **urethral stricture** is a narrowing of its lumen. It occurs when infection, injury, or surgical manipulation produces a scar that reduces the caliber of the urethra. The vast majority of urethral strictures occur in men; they are rare in women.[31,32] The severity of obstruction is influenced by its location within the urethra, its length, and the minimum caliber of urethral lumen within the stricture. Specifically, proximal urethral strictures cause more severe obstruction than do strictures of the distal urethra, longer strictures tend to be more obstructive, and the magnitude of blockage is in *reverse* proportion to the urethral caliber.[33]

Prostate enlargement is caused by acute inflammation, benign prostatic hyperplasia, or prostate cancer (see Chapter 25). Each of these disorders can cause encroachment on the urethra with obstruction to urine flow and the symptoms summarized previously.

Severe **pelvic organ prolapse** (see Chapter 24) in a woman causes bladder outlet obstruction when, most commonly, a cystocele (the downward protrusion of the bladder into the vagina) descends below the level of the urethral outlet.[34] Cystoceles (see Figure 24-11) that reach or protrude beyond the vaginal introitus create the greatest risk for obstruction, particularly if the bladder neck (in females the bladder neck and proximal urethra constitute the internal sphincter of the bladder) has been surgically repaired without simultaneous repair of the cystocele.[35] In men the bladder may rarely herniate into the scrotum, causing a similar type of obstruction.

Partial obstruction of the bladder outlet or urethra initially causes an increase in the force of detrusor contraction. If the blockage persists, afferent nerves within the bladder wall are adversely affected, leading to urinary urgency and, in some cases, overactive detrusor contractions (a myogenic cause of overactive bladder). When obstruction persists, there is an increased deposition of collagen within the smooth muscle bundles of the detrusor muscle *(trabeculation)*, possibly in an attempt to increase the force of its contraction strength. Ultimately, the bladder wall loses its ability to stretch and accommodate urine, a condition called **low bladder wall compliance,** and the detrusor loses its ability to contract efficiently. Low bladder wall compliance chronically elevates intravesicular pressure, greatly increasing the problems of hydroureter, hydronephrosis, and impaired renal function.

EVALUATION AND TREATMENT. Although the history and physical examination are critical to the evaluation of lower urinary tract disorders, it must be remembered that no symptom or cluster of symptoms has been identified that accurately differentiates the various causes of these disorders. For example, symptoms such as urgency, urge incontinence, frequent urination, and nocturia may develop because of overactive bladder or either increased or decreased bladder outlet resistance. Reduced resistance is associated with the symptom of stress incontinence (incontinence with coughing or sneezing) and symptoms of increased resistance are similar to those of bladder outlet obstruction, including poor force of urinary stream, hesitancy, and feelings of incomplete bladder emptying.

Various diagnostic tests assist with evaluation. A *cystometric test* uses a catheter and manometer to evaluate bladder urine volume and pressure in relation to involuntary bladder contraction (the leak point pressure) and the urge to void. The *post-void residual urine* is measured by catheterization within 5 to 15 minutes of urination or through a bladder ultrasound machine that measures bladder height and width to provide an approximation of urine within the vesicle. This measurement may be combined with *uroflowmetry,* a graphic representation of the force of the urinary stream expressed as milliliters voided per second. Each of these measurements assesses the lower urinary tract's efficiency in evacuating urine through micturition but neither differentiates poor detrusor contraction strength from obstruction as a cause of urinary retention. Instead, *multichannel urodynamic testing* is used to identify obstruction, quantify its severity, and measure detrusor contraction strength (see Figure 38-2). *Video-urodynamic recordings* can also demonstrate overactive bladder and detrusor sphincter dyssynergia. An evaluation of renal function, including functional imaging studies and measurement of serum creatinine level, is completed particularly when obstruction is severe and associated with elevated residuals or urinary tract infection. *Electromyography* measures electrical activity in the bladder neck using surface or needle electrodes.

Because the bladder neck consists of circular smooth muscle with adrenergic innervation, detrusor sphincter dyssynergia may be managed by α-adrenergic blocking (antimuscarinic) medications or botulinum toxin.[36] Obstruction that is not adequately managed by pharmacotherapy may require bladder neck incision. Detrusor sphincter dyssynergia may be managed by intermittent catheterization in combination with higher dose antimuscarinic drugs to prevent overactive detrusor contractions and associated dyssynergia while ensuring regular, complete bladder evacuation through catheterization. Alternatively, men with dyssynergia may be managed by condom catheter containment, supplemented by an α-adrenergic blocking drug or transurethral sphincterotomy (surgical

incision of the striated sphincter) in order to relieve obstruction. Low bladder wall compliance may be managed by antimuscarinic drugs and intermittent catheterization; however, more severe cases may require augmentation enterocystoplasty (enlargement of the low compliant bladder wall using a detubularized piece of small bowel), urinary diversion, or long-term indwelling catheterization.[37] Prostate enlargement is managed by treating the underlying cause of the prostate enlargement with medication or surgery. Acute prostatitis is initially managed by broad-spectrum antibiotics until the results of a urine culture are obtained. Urinary retention may require transient placement of a suprapubic catheter. The management of benign prostatic hyperplasia and treatment options for prostate cancer are presented in Chapter 25.

Urethral stricture is treated with urethral dilation accomplished by using a steel instrument shaped like a catheter (urethral sound) or a series of incrementally increasing diameter catheter-like tubes (filiforms and followers). Long, dense strictures typically require surgical urethroplasty to prevent recurrence.

A pessary (rubber or silicone device designed to compensate for vaginal wall prolapse) may be inserted to mechanically reverse severe pelvic organ (bladder, uterus, or rectum) prolapse. Depending on the device, the woman may be able to remove, cleanse, and replace the pessary, or it may be changed during a clinic visit. Intravaginal hormone replacement therapy and regular follow-up visits are critical to the long-term success of a pessary.[38] Alternatively, pelvic organ prolapse may be repaired surgically; the procedure may be combined with a urethral suspension to correct stress urinary incontinence or rectocele repair.[39]

Tumors

Renal Tumors

Renal tumors account for about 65,150 (3.9%) new cancer cases and 13,680 (2.3%) deaths in 2013.[40] There are a number of different types of kidney tumors. **Renal adenomas** (benign tumors) are uncommon but are increasing in number. The tumors are solid and encapsulated and are usually located near the cortex of the kidney. Because they can become malignant, they are usually surgically removed. **Renal transitional cell carcinoma (RTCC)** is rare and primarily arises in the renal parenchyma and renal pelvis. **Renal cell carcinoma (RCC)** is the most common renal neoplasm (85% to 90% of all renal neoplasms) (Figure 38-4). Renal cell carcinoma usually occurs in men (two times more often than in women) between 50 and 60 years of age and the incidence is increasing. Blacks have a higher incidence and mortality. Risk factors include cigarette smoking, obesity, hypertension, and advanced stage chronic renal failure (CRF).[41,42] Five-year survival for all stages is about 50% and about 10% for stage IV cancer (metastatic disease).[43]

PATHOGENESIS. Renal cell carcinomas are adenocarcinomas and the etiology is unknown. They are classified according to cell type and extent of metastasis. *Clear cell tumors,* the most common, are dominated by mutations of the von Hippel-Lindau *(VHL)* gene located on chromosome 3p in 90% of cases. They present a better prognosis than papillary (10%),

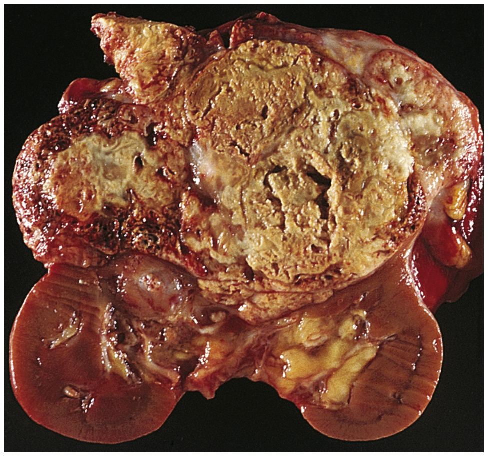

FIGURE 38-4 Renal Cell Carcinoma. Renal cell carcinomas usually are spheroidal masses composed of yellow tissue mottled with hemorrhage, necrosis, and fibrosis. (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

chromophobe (5%), oncocytoma (3% to 4%), collecting duct tumors (1%), or unclassified (rare) tumors.[44] Clear cell and papillary tumors arise from proximal tubular epithelium. Chromophobe, oncocytoma, and collecting duct tumors are believed to arise from the distal nephron epithelium. Confinement within the renal capsule, together with treatment, is associated with a better survival rate. The tumors usually occur unilaterally (see Figure 38-4). About 25% to 30% of individuals with RCC present with metastasis (stage IV).[45,46] The most common sites of distant metastasis are the lung, lymph nodes, liver, bone, thyroid, and central nervous system.[47,48]

CLINICAL MANIFESTATIONS. The classic clinical manifestations of renal tumors are hematuria, dull and aching flank pain, and palpable flank mass in thinner individuals. Systemic manifestations usually represent an advanced stage of disease and include weight loss, fatigue, intermittent fever from tumor cytokines, anemia from hematuria and lack of erythropoietin, polycythemia from tumor secretion of erythropoietin, hypertension from elevated renin levels, and alterations in liver function tests. All of these symptoms occur in less than 10% of cases. Further, they represent an advanced stage of disease, whereas earlier stages are often silent.

EVALUATION AND TREATMENT. Diagnosis is based on the clinical symptoms, plain x-ray films of the abdomen, intravenous pyelography, renal angiography, and computed tomography (CT). (Staging of renal cell carcinoma is presented in Table 38-2.) Staging systems using molecular tumor markers (measurable biologic molecules released from a tumor or the host tissues that distinguish a malignancy) are rapidly advancing.[49] Treatment for localized disease is surgical removal of the affected kidney (radical nephrectomy) or partial nephron sparing nephrectomy for smaller tumors. Surgery is combined with the use of chemotherapeutic agents, although RCC is resistant to conventional chemotherapy.[50] Use of traditional cytokine therapy, specifically high-dose interleukin-2, is limited by significant toxicity (hypotension requiring vasopressor support, oliguria, pulmonary congestion, arrhythmias, and neurologic toxicity).[51] Agents targeting the vascular endothelial

II	Invasion through renal capsule and renal vein but within surrounding fascia ≥7 cm in size.
III	Involvement of adrenal glands and vena cava and one nearby lymph node:
	T3a-T3c, N0, M0: The main tumor has reached the adrenal gland, the fatty tissue around the kidney, the renal vein, and/or the large vein (vena cava) leading from the kidney to the heart. It has not spread beyond Gerota's fascia. There is no spread to lymph nodes or distant organs.
	T1a-T3c, N1, M0: The main tumor can be any size and may be outside the kidney, but it has not spread beyond Gerota's fascia. The cancer has spread to one nearby lymph node but has not spread to distant lymph nodes or other organs.
IV	Distant metastases (e.g., liver, lung, bones, brain) and more than one lymph node:
	T4, N0-N1, M0: The main tumor has invaded beyond Gerota's fascia. It has spread to no more than one nearby lymph node. It has not spread to distant lymph nodes or other organs.
	Any T, N2, M0: The main tumor can be any size and may be outside the kidney. The cancer has spread to more than one nearby lymph node but has not spread to distant lymph nodes or other organs.
	Any T, Any N, M1: The main tumor can be any size and may be outside the kidney. It has spread to distant lymph nodes and/or other organs.

growth factor pathway and the mammalian target of rapamycin (mTOR) have shown efficacy in randomized clinical trials for treatment of metastatic disease.[52,53] There is ongoing research to identify molecular tumor markers that predict individual response to targeted molecular therapies.[54] Radiation therapy may be used for palliation, and new techniques using stereotactic radiofrequency ablation, cryoablation, and laparoscopy are promising. Tumor obstruction is relieved by placement of ureteral catheters or nephrostomy tubes or by completion of urinary diversion procedures. Survival is related to tumor grade, tumor cell type, and extent of metastasis.

Bladder Tumors

Bladder tumors represent about 4.5% of all malignant tumors and are the fourth most common malignancy in men. Approximately 72,570 people developed bladder cancer with 15,210 deaths (2.5% of all cancer deaths) in 2013.[40] The development of bladder cancer is most common in men older than 60 years. **Urothelial (transitional cell) carcinoma** is the most common bladder malignancy, appearing on the inner lining of the bladder.

PATHOGENESIS. The risk of primary bladder cancer is greater among people who smoke or are exposed to any of the following: metabolites of aniline dyes or other aromatic amines or chemicals, high levels of arsenic in drinking water, or heavy consumption of phenacetin.[55] Oncogenes of the *ras* gene family and tumor-suppressor genes including *TP53* mutations and inactivation of *retinoblastoma gene (pRb)* are implicated in bladder cancer. Loss of heterozygosity at chromosome 9 has been found in all stages of urothelial cell carcinoma.[56] The tumor is usually composed of uroepithelial cells (cells lining the bladder, ureters, urethra, and renal pelvis), most have a papillary growth pattern (a tuftlike lesion attached to a stalk), and they rarely progress to invasive disease (Figure 38-5). Nonpapillary tumors (10% to 30% of bladder tumors) are not as common as papillary tumors, but they tend to be more invasive and have a poorer prognosis. Carcinoma in situ can present with papillary

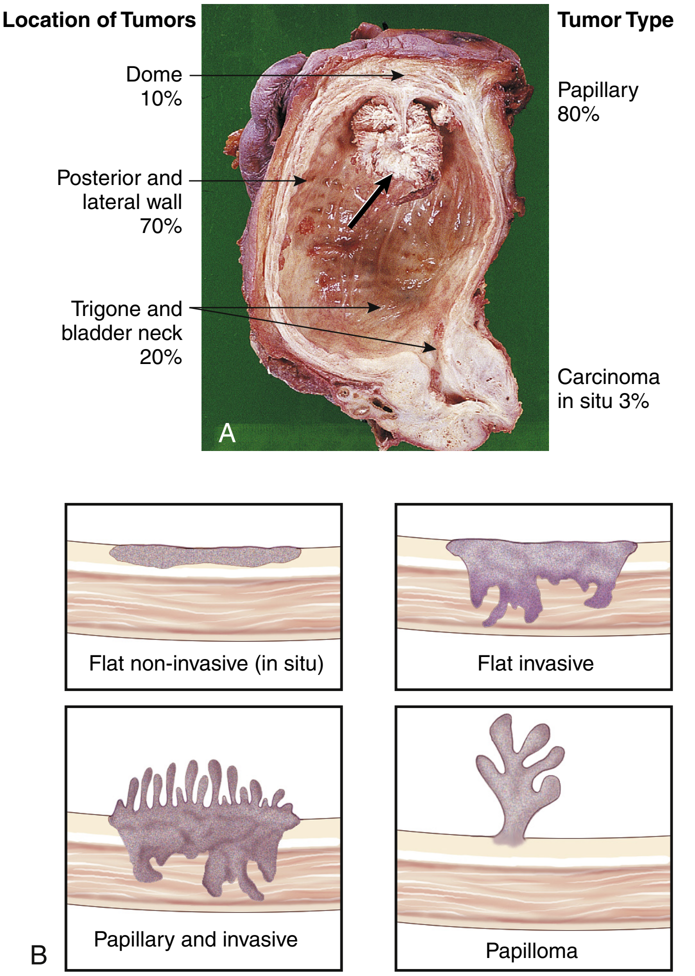

FIGURE 38-5 Carcinoma of the Bladder. **A,** Papillary transitional cell carcinoma arising in the dome of the bladder as a cauliflower-like lesion *(black arrow);* location and frequency of bladder tumor types noted. **B,** Bladder cancer with morphologic patterns of most common tumors. TABLE 38-3 STAGING OF BLADDER CARCINOMA (TNM SYSTEM)

STAGE	DESCRIPTION
Primary Tumor	
T0	No primary tumor identified
Ta	Noninvasive papillary carcinoma—not in bladder muscle
Tis	Carcinoma in situ (CIS)
T1	Tumor invades connective tissue
T2	Tumor invades detrusor muscle
T3	Invasion of fatty tissue around bladder
T4	Tumor has invaded adjacent structures
Region of Lymph Nodes	
N0	No lymph node involvement
N1 to N3	Lymph node metastasis to pelvic or adjacent region
Distant Metastasis	
M0	No metastasis
M1	Distant metastasis

tumors.[57] Worldwide, renal squamous cell carcinoma is the most prevalent and certain forms present at a higher stage and with a poorer prognosis.[58] Metastasis is usually to lymph nodes, liver, bones, lungs, and adrenal glands. Staging for bladder carcinoma is presented in Table 38-3. Secondary bladder cancer develops by invasion of cancer from bordering organs, such as cervical carcinoma in women or prostatic carcinoma in men.

CLINICAL MANIFESTATIONS. Gross painless microscopic hematuria is the archetypal clinical manifestation of bladder cancer. Episodes of hematuria tend to recur, and they are often accompanied by bothersome lower urinary tract symptoms including daytime voiding frequency, nocturia, urgency, and urge urinary incontinence. Flank pain may occur if tumor growth obstructs one or both ureterovesical junctions. Bothersome lower urinary tract symptoms are particularly intense in individuals with carcinoma in situ. Metastasis is the cause of death from bladder cancer, usually from high-grade muscle-invasive tumors.[59]

EVALUATION AND TREATMENT. Urinalysis for evidence of hematuria in the absence of infection provides a useful screening tool for high-risk patients. Urine cytology (pathologic analysis of sloughed cells within the urine) is completed in individuals with evidence of hematuria from unknown causes; cystoscopy or fluorescence cystoscopy with tissue biopsy can confirm the diagnosis. Biologic markers for the diagnosis and prognosis of bladder cancer are under investigation (e.g., cadherins, cyclooxygenase-2 [COX-2] protein, karyopherin-α2 [KPNA2], tyrosine kinase HER2 [RTOG-0524], and epidermal growth factor receptor [EGFR)]).[60,61]

Newer magnetic resonance techniques are helpful for local staging and whole-body computed tomography detects metastasis.[62] Transurethral resection or laser ablation, combined with intravesical chemotherapy or immunotherapy, is effective for superficial tumors. Radical cystectomy with urinary diversion and adjuvant chemotherapy is required for locally invasive tumors, and radiation therapy may be used to support palliative or adjuvant treatment for muscle-invasive tumors.[63-65]

URINARY TRACT INFECTION

Causes of Urinary Tract Infection

A **urinary tract infection (UTI)** is an inflammation of the urinary epithelium usually caused by bacteria from gut flora. A UTI can occur anywhere along the urinary tract including the urethra, bladder, ureter, or kidney. At risk are premature newborns; prepubertal children; sexually active and pregnant women; women treated with antibiotics that disrupt vaginal flora; spermicide users; estrogen-deficient postmenopausal women; individuals with indwelling catheters; and persons with diabetes mellitus, neurogenic bladder, or urinary tract obstruction (see What's New? Catheter-Associated Urinary Tract Infections). UTIs are commonly classified by their location or complicating factors: *cystitis* (bladder inflammation), *pyelonephritis* (inflammation of upper urinary tract), *uncomplicated UTI* (occur in a normally functioning urinary system), and *complicated UTI* (occur with defects in the urinary system

WHAT'S NEW?

Catheter-Associated Urinary Tract Infections

Catheter-associated urinary tract infections are the most common healthcare-associated infection worldwide, and most individuals are asymptomatic. Appropriate indications for use of catheters include acute urinary retention or obstruction; perioperative applications in select procedures; and the frequent, accurate measurement of urine output in critically ill individuals. Other uses include sacral or perineal wound healing with incontinence and immobilization from unstable spine or pelvic fractures. The smallest bore catheter should be used and inserted under aseptic conditions and removed as soon as possible. Some reviews recommended the use of silver alloy or antimicrobial-impregnated catheters. The system is maintained using a closed-drainage system that is replaced if the system is disconnected. The drainage bag is kept below the level of the bladder. Prophylactic antibiotics are not recommended except in special cases (e.g., before traumatic urinary tract interventions). Bacteriuria develops in several ways: periurethral microorganisms may be introduced at the time of catheterization; contaminated urine from the drainage bag or tubing may reflux back into the bladder; and microorganisms can be introduced when there is a break in the closed system. Additionally, bacterial biofilm develops along the inside and outside of the tubing, providing an environment that allows for bacterial colonization and spread with protection against host defenses and antibiotics. *Proteus mirabilis* and *Providencia stuartii* are known to produce greater amounts of biofilm and their adhesion factors and motility allow them to ascend more rapidly in the urinary tract. *E. coli* is the most common pathogen associated with short-term catheterization.

Data from Agency for Healthcare Research and Quality National Guideline Clearinghouse: Catheter-associated UTIs. In *Guidelines on urological infections,* updated December 23, 2011, available at www.guideline.gov/content.aspx?id=34100; Tambyah PA, Oon J: *Curr Opin Infect Dis* 25(4):365–370, 2012; Beattie M, Taylor J: *J Clin Nurs* 20(15-16):2098–2108, 2011; Conway LJ, Larson EL: *Heart Lung* 41(3):271–283, 2012; Nicolle LE: *Infect Dis Clin North Am* 26(1):13–27, 2012; Chenoweth C, Saint S: *Crit Care Clin* 29(1):19-32, 2013.

or in individuals with health problems that compromise host defenses or response to treatment).

Host Defense Mechanisms and Urinary Tract Infection

Host defense mechanisms maintain a sterile posterior urethra and bladder in a healthy individual. Even if bacteria manage to enter the bladder, these defense mechanisms prevent it from clinging to the walls of the bladder or ascending to the upper urinary tracts.[66] Several factors normally combine to protect against UTI. Most bacteria are washed out of the urethra during micturition. The low pH and high osmolality of urea, the presence of Tamm-Horsfall protein, and the presence of secretions from the uroepithelium provide a bactericidal effect. The ureterovesical junction closes during bladder contraction, preventing reflux of urine to the ureters and kidneys. Periurethral mucus-secreting glands surround the distal two thirds of the female urethra. Mucus from these glands traps bacteria before it can ascend from the proximal urethra to the bladder. In men, the length of the male urethra and secretions from the prostate and accessory periurethral glands combine to form a protective barrier against infection. In addition, the urethral sphincter mechanism acts as a mechanical barrier to bacterial ascent from the distal urethra.

Bacteria that successfully ascend the urethra face detection and destruction by components of the body's immune system provided they come into contact with the bladder wall. Protective uroepithelial immune responses include Toll-like receptor (e.g., TLR4) recognition of pathogen-associated molecular patterns on the bacteria, neutrophil and macrophage recruitment and phagocytosis, and the presence of antimicrobial proteins (defensins, cathelicidin, and Tamm-Horsfall protein). Susceptibility to infection also is influence by genetic variation in the host immune response to bacterial virulence and to the virulence of the pathogen.[67] Unfortunately, time is required for the immune system to respond to the potential threat, and this period may provide adequate time for bacteria or other pathogens to reproduce several times.

The efficiency of the bladder's defenses is also influenced by the person's Lewis blood group.[68] This taxonomy is based on recognition of inherited antigens associated with the ABO blood factors. Individuals with certain Lewis blood groups are more prone to UTIs because they secrete fewer antigens capable of resisting bacterial adherence by pili formation.

Most people are able to rapidly rid the urinary tract of invading bacteria, but some show evidence of bacteria in the urine that does not provoke an infection. This condition, called **asymptomatic bacteriuria,** does not harm urinary function or require intervention except in pregnant women.[69] A UTI occurs when a pathogen circumvents or overwhelms the host's defense mechanisms and rapidly reproduces.

Virulence of Uropathogens. **Virulence** is a pathogen's ability to evade or overwhelm the host defense mechanisms and cause disease in a host (see Chapter 10). Several factors contribute to bacterial virulence within the urinary tract, including the ability of uropathic bacteria to adhere (attach) to the uroepithelium. Uropathic strains of *Escherichia coli* have *type-1 pili*. Type-1 pili have adhesins that allow them to bind to mucosal cellular receptors and enter uroepithelial cells and resist flushing during normal micturition. Once inside the cell, they can persist quiescently for long periods and cause recurrent infection or multiply rapidly, safe from host defenses and protected from antibiotic therapy.[70] Additionally, uropathic strains have pyelonephritis-associated fimbriae *(P. fimbriae)* that bind to the uroepithelial P-blood group antigen (present in most of the human population) and readily ascend the urinary tract. Strains of *E. coli* also produce *siderophores* for acquiring nutrient iron, are resistant to bactericidal effects of complement, and express toxins including *cytotoxin necrotizing factor-1* and *hemolysins*. Certain bacterial species also enhance their virulence by acting together to form a biofilm that enhances colonization and resists efficiency of innate host defense mechanisms and antimicrobial therapy, particularly in catheter-associated UTI.[71,72]

Types of Urinary Tract Infection

Acute Cystitis

Acute cystitis is an inflammation of the bladder and is the most common site of UTI. Cystitis is more common in women because of the shorter urethra and the closeness of the urethra to the vagina and anus (increasing the possibility of bacterial contamination).[73]

The morphologic appearance of the bladder through cystoscopy describes different types of cystitis. With mild inflammation, the mucosa is hyperemic (red). More advanced cases may show diffuse hemorrhage (termed *hemorrhagic cystitis*), pus formation, or suppurative exudates (termed *suppurative cystitis*) on the epithelial surface of the bladder. Prolonged infection may lead to sloughing of the bladder mucosa with ulcer formation (termed *ulcerative cystitis*). The most severe infections may cause necrosis of the bladder wall (termed *gangrenous cystitis*). Generally, infections are mild, without complications, and occur in individuals with a normal urinary tract. Acute cystitis may occur alone or in association with pyelonephritis, prostatitis, or kidney stones.

PATHOPHYSIOLOGY. Two factors account for the presence of a UTI: the efficiency of defense mechanisms within the host (individual) and the virulence of the pathogen (bacterium, fungus, or parasite). The most common infecting microorganisms are uropathic strains of *E. coli* (80% to 85%) and the second most common is *Staphylococcus saprophyticus* (10%). Less common microorganisms include *Klebsiella, Proteus, Pseudomonas,* fungi, viruses, parasites, or tubercular bacilli. Bacterial contamination of the normally sterile urine usually occurs by retrograde movement of gram-negative bacilli into the urethra and bladder and then to the ureter and kidney. Some women may be genetically susceptible to certain strains of *E. coli* attachment and may harbor pathogenic strains in their vaginal flora.[73] In rare instances bloodstream infections (sepsis) can spread to the bladder tissue.

Fungal infections are comparatively uncommon. The most common pathogen is *Candida,* but multiple fungal species may colonize the urinary tract or urinary catheters and produce symptomatic UTIs, particularly in those who are immunosuppressed.[74]

Infection initiates an inflammatory response and the symptoms of cystitis. The inflammatory edema in the bladder wall stimulates discharge of stretch receptors, initiating symptoms of bladder fullness with small volumes of urine and producing the urgency and frequency of urination associated with cystitis.

Schistosomiasis haematobium is the most common cause of parasitic invasion of the urinary tract on a global basis; it infects more than 200 million people.[75] Although rare among people living in the United States, the parasite dwells in waters of the various rivers of fresh water bodies in Africa, South America, and Pacific Rim countries. It usually enters the human by swimming up the urethra while the host swims or is partly submerged in an infected body of water. The parasite burrows into the walls of the urinary tract, causing inflammation and scarring of the urinary tract, and an increased risk for urothelial malignancies or renal failure.[76]

CLINICAL MANIFESTATIONS. Many individuals with bacteriuria are asymptomatic. Clinical manifestations of cystitis are related to the host inflammatory response and usually include frequency, urgency, dysuria (painful urination), and suprapubic and low back pain. Hematuria, cloudy and foul-smelling urine, and flank pain are more serious symptoms. Approximately 10% of individuals with bacteriuria have no symptoms and have low TLR4 levels,[77] and 30% of individuals with symptoms are abacteriuric. Older adults with cystitis may be asymptomatic or demonstrate confusion or vague abdominal discomfort. Older adults with recurrent UTI and other concurrent illness have a higher risk of morbidity and mortality.[78]

EVALUATION AND TREATMENT. Infections are diagnosed by urine culture of specific microorganisms with counts of 10,000/ml or more from freshly voided urine. Dipstick urinalysis and microscopy are adequate to diagnose an uncomplicated UTI, but urine culture is critical for complicated infections.[79] Risk factors, such as a urinary tract obstruction, which are associated with a complicated UTI, should be identified and treated. Increased fluid intake and analgesics can relieve symptoms. Evidence of bacteria from urine culture and antibiotic sensitivity warrants treatment with a microorganism-specific antibiotic to eradicate the underlying pathogen. A single large dose of antibiotic or a 3-day course may be effective when symptoms are of short duration and there are no complications. A treatment period of 3 to 7 days is most common depending on antimicrobial selection; older adults with obstructive disorders may require 7 to 14 days of treatment. Frequent, recurrent, acute uncomplicated UTI requires low-dose antimicrobial therapy from 6 months to 2 years or prophylactic treatment, depending on frequency and individual responses.[80] Follow-up urine cultures should be obtained 1 week after initiation of treatment and at monthly intervals for 3 months. Clinical symptoms are frequently relieved, but bacteriuria may still be present, particularly with the development of antimicrobial-resistant bacterial strains. Repeat cultures should be obtained every 3 to 4 months until 1 year after treatment for evaluation of recurrent infection. Urosepsis and septic shock are medical emergencies that usually demand parenteral, broad-spectrum antibiotic therapy and may require hospitalization. A UTI caused by *Schistosomiasis* is treated with praziquantel, and vaccines are under development.[81]

Painful Bladder Syndrome/Interstitial Cystitis

Painful bladder syndrome/interstitial cystitis (PBS/IC) is a condition that includes **nonbacterial infectious cystitis** (viral, mycobacterial, chlamydial, fungal) and **noninfectious cystitis** (radiation, chemical, autoimmune, hypersensitivity).[82] It occurs most commonly in women ages 20 to 40 years who have symptoms of cystitis, such as frequency, urgency, dysuria, and nocturia, for more than 6 weeks duration but with negative urine cultures and no other known etiology. Nonbacterial infectious cystitis is most common among those who are immunocompromised. Noninfectious cystitis is associated with radiation or chemotherapy treatment for pelvic and urogenital cancers.

The cause of PBS/IC is unknown, but an autoimmune reaction may be responsible for the inflammatory response, which includes mast cell activation, altered epithelial permeability, neuroinflammation, and increased sensory nerve sensitivity.[83] The inflammation is associated with a derangement of the glycosaminoglycan layer of the bladder mucosa that makes it more susceptible to penetration by bacteria and noxious urinary solutes. Inflammation and fibrosis of the bladder wall are accompanied by the presence of hemorrhagic ulcers (Hunner ulcers) and bladder volume may decrease as a result of fibrosis, particularly in older individuals.[84] More recently, the identification of antiproliferative factor (APF), a protein expressed by the bladder uroepithelium in those with IC, is important. APF appears to block the normal growth of cells that line the inside wall of the bladder and indirectly increases bladder sensation.[85] Characteristic symptoms of IC include bladder fullness, frequency (including nocturia), small urine volume, and chronic pelvic pain with symptoms lasting longer than 9 months. Chronic pain and sleep deprivation can lead to depression. Diagnosis of IC requires the exclusion of other diagnoses, and extensive evaluations are completed.[86] No single treatment is effective. Oral and intravesical therapies, sacral nerve stimulation, and onabotulinumtoxinA are used for symptom relief. Surgery is used in refractory cases.[87] More research is needed to understand the pathogenesis and treatment of this disease.

Acute Pyelonephritis

Pyelonephritis is an infection of one or both upper urinary tracts (ureter, renal pelvis, and kidney interstitium). Common causes are summarized in Table 38-4. Urinary obstruction and reflux of urine from the bladder (vesicoureteral reflux) are the most common underlying risk factors. Most cases occur in young adult women.

PATHOPHYSIOLOGY. Microorganisms usually associated with acute pyelonephritis include *E. coli, Proteus,* or *Pseudomonas.* The latter two microorganisms are more commonly associated with infections after urethral instrumentation or urinary tract surgery. These microorganisms also split urea into ammonia, making alkaline urine that increases the risk of stone formation. The infection is probably spread by ascending uropathic

TABLE 38-4 COMMON CAUSES OF PYELONEPHRITIS

PREDISPOSING FACTORS	PATHOLOGIC MECHANISMS
Kidney stones	Obstruction and stasis of urine contributing to bacteriuria and hydronephrosis; irritation of epithelial lining with entrapment of bacteria
Vesicoureteral reflux	Chronic reflux of urine up the ureter and into kidney during micturition, contributing to bacterial infection
Pregnancy	Dilation and relaxation of ureter with hydroureter and hydronephrosis; partly caused by obstruction from enlarged uterus and partly from ureteral relaxation caused by higher progesterone levels
Neurogenic bladder	Neurologic impairment interfering with normal bladder and urethral sphincter contraction with residual urine and ascending infection
Instrumentation	Introduction of organisms into urethra and bladder by catheters and endoscopes introduced into the urinary tract for diagnostic purposes
Female sexual trauma	Movement of organisms from the urethra into the bladder with infection and retrograde spread to kidney

microorganisms along the ureters, but dissemination also may occur by way of the bloodstream. The inflammatory process is usually focal and irregular, primarily affecting the pelvis, calyces, and medulla. The infection causes medullary infiltration of white blood cells with renal inflammation, renal edema, and purulent urine. In severe infections, localized abscesses may form in the medulla and extend to the cortex. Primarily affected are the renal tubules; the glomeruli usually are spared. Necrosis of renal papillae can develop. After the acute phase, healing occurs with deposition of scar tissue, fibrosis, and atrophy of affected tubules (Figure 38-6). Acute pyelonephritis rarely causes renal failure.[88]

CLINICAL MANIFESTATIONS. The onset of symptoms is usually acute, with fever, chills, and flank or groin pain. Symptoms characteristic of a UTI, including frequency, dysuria, and costovertebral tenderness, may precede systemic signs and symptoms. Older adults may have nonspecific symptoms, such as low-grade fever and malaise.

EVALUATION AND TREATMENT. Differentiating symptoms of cystitis from those of pyelonephritis by clinical assessment alone is difficult. The specific diagnosis is established by urine culture, urinalysis, and clinical signs and symptoms. White blood cell casts indicate pyelonephritis, but they are not always present in the urine. Complicated pyelonephritis requires blood cultures and urinary tract imaging.[89]

Uncomplicated acute pyelonephritis responds well to 2 to 3 weeks of microorganism-specific antibiotic therapy. Follow-up urine cultures are obtained at 1 and 4 weeks after treatment if symptoms recur. Antibiotic-resistant microorganisms or reinfection may occur in cases of urinary tract obstruction or reflux.[90] Intravenous pyelography and voiding cystourethrography identify surgically correctable lesions.

FIGURE 38-6 Pyelonephritis. *(Right)* Small, shrunken, irregularly scarred kidney of an individual with chronic pyelonephritis. *(Left)* Kidney is of normal size but also shows scarring on the upper pole. (From Damjanov I: *Pathology for the health professions,* ed 4, Philadelphia, 2012, Saunders.)

Chronic Pyelonephritis

Chronic pyelonephritis is a persistent or recurrent infection of the kidney leading to scarring of the kidney. One or both kidneys may be involved. The specific cause of chronic pyelonephritis may be unknown (idiopathic) or associated with vesicoureteral reflux or renal stones. Recurrent infections from acute pyelonephritis may be associated with chronic pyelonephritis. Causes other than chronic pyelonephritis include drug toxicity from analgesics such as nonsteroidal anti-inflammatory drugs, ischemia, irradiation, and immune-complex diseases.

PATHOPHYSIOLOGY. Chronic urinary tract obstruction prevents elimination of bacteria and starts a process of progressive inflammation, alterations of the renal pelvis and calyces, destruction of the tubules, atrophy or dilation and diffuse scarring, and, finally, impaired urine-concentrating ability, leading to chronic kidney failure. The lesions of chronic pyelonephritis are sometimes termed *chronic interstitial nephritis* because the inflammation and fibrosis are located in the interstitial spaces between the tubules (see Figure 38-6).

CLINICAL MANIFESTATIONS. The early symptoms of chronic pyelonephritis are often minimal and commonly include frequency, dysuria, and flank pain, and may include hypertension. Progression of disease leads to renal failure, particularly in the presence of other risk factors (i.e., obstructive uropathy or diabetes mellitus). There is an inability to conserve sodium with loss of tubular function, and development of hyperkalemia and metabolic acidosis. Risk for dehydration must be considered if there is loss of the ability to concentrate the urine.

EVALUATION AND TREATMENT. Urinalysis, intravenous pyelography, and ultrasound are used diagnostically. Treatment is related to the underlying cause. Obstruction must be relieved. Antibiotics may be given, with prolonged antibiotic therapy for recurrent infection.

GLOMERULAR DISORDERS

Glomerulonephritis

Glomerulonephritis is an inflammation of the glomerulus caused by *primary glomerular injury,* including immunologic

responses, ischemia, free radicals, drugs, toxins, vascular disorders, and infection. *Secondary glomerular injury* is a consequence of systemic diseases, including diabetes mellitus, systemic lupus erythematosus, and, less commonly, congestive heart failure and HIV-related kidney disease. Glomerular disease is a significant cause of chronic kidney disease and end-stage renal failure worldwide.[91,92]

Acute Glomerulonephritis

Acute glomerulonephritis includes renal diseases in which glomerular inflammation is caused by immune mechanisms that damage the glomerular capillary filtration membrane including the endothelium, basement membrane, and epithelium (podocytes). Mesangial expansion can be a component of the disease. The classic symptoms include sudden onset of hematuria including red blood cell casts and proteinuria, and in more severe cases, these symptoms are also accompanied by edema, hypertension, and impaired renal function. Nonimmune acute glomerular injury is related to ischemia, toxin exposure, drugs, vascular disorders, and infection with direct injury to glomerular cells.

PATHOPHYSIOLOGY. Immune mechanisms and inflammation are a major cause of injury for both primary and secondary types of acute glomerulonephritis (Figure 38-7). Immune injury includes: (1) deposition of circulating antigen-antibody immune complexes on the glomerulus (type III hypersensitivity reaction); (2) antibodies reacting in situ against planted antigens within the glomerulus (type III hypersensitivity); (3) action of antibodies directed against the glomerular capillary wall (antiglomerular basement membrane antibodies), the least common and most severe form of immune injury (type II hypersensitivity); and (4) cell-mediated immune injury (type IV hypersensitivity) (Table 38-5). In nearly all types of acute glomerulonephritis, the epithelial or podocyte layer of the glomerular capillary membrane is disturbed with loss of negative charges and changes in membrane permeability; the mesangial matrix may be expanded or the basement membrane thickened (see Figure 38-7). Different causes of injury may result in more than one type of glomerular lesion; thus lesions are not necessarily disease specific (Table 38-6). Many types of acute glomerulonephritis occur, most often in children or young adults, including acute postinfectious glomerulonephritis, Henoch-Schönlein purpura nephritis, and minimal change nephropathy (lipoid nephrosis) associated with nephrotic syndrome. Details of these diseases are presented in Chapter 39. The types, causes, and histopathology of acute glomerulonephritis are summarized in Table 38-7. The mechanisms of acute glomerulonephritis are presented next and include IgA nephropathy, membranous glomerulonephritis, crescentic or rapidly progressive glomerulonephritis, mesangial proliferative glomerulonephritis, and membranous proliferative glomerulonephritis.

IgA nephropathy (Berger disease) is the most common form of idiopathic acute glomerulonephritis in developed countries, especially Asia. The cause is unknown and more commonly affects children and young adults aged 20 to 30 years. It occurs almost twice as often in males as in females and is rare in blacks. Henoch-Schönlein purpura is a milder systemic form of the disease that presents with hematuria and occurs more often in children (see Chapter 39). Abnormal glycosylated IgA-1 (galactose-deficient IgA-1) is produced by the bone marrow. Glycan-specific IgG and IgA antibodies are formed against abnormal IgA-1, can activate complement, and bind to glomerular mesangial cells, stimulating them to proliferate, secrete extracellular matrix proteins, and release inflammatory cytokines and chemokines (interleukin-6, tumor necrosis factor-alpha, and transforming growth factor-beta 1) that cause injury. The immune response contributes to diffuse mesangioproliferative glomerular injury and glomerulosclerosis, which is reversible.[93] A genetic factor may promote the overproduction of IgA-1.[94] B cells that respond to mucosal infections, particularly tonsillitis, might produce the nephritogenic IgA-1 molecule.[95]

The disease manifests with gross or microscopic (30% to 40%) hematuria 24 to 48 hours after an upper respiratory or gastrointestinal tract viral infection. Proteinuria, edema, and hypertension are more severe symptoms and must be treated to prevent future loss of kidney function.[96] Diagnosis is made by renal biopsy. Treatment includes angiotensin-converting enzyme (ACE) inhibitors as first-line therapy, with glucocorticoids added when severe proteinuria is present.[97] The disease is more mild in children than in adults.[98] Tonsillectomy combined with steroid-pulse therapy has promoted clinical remission among individuals with the disease in Japan.[99,100] The prognosis is variable, with 20% to 40% of cases progressing to renal failure over a period of years. Long-term follow-up consists of evaluating blood pressure, urinalysis, proteinuria levels, and renal function every 6 to 12 months.[101,102]

Membranous nephropathy, also known as **membranous glomerulonephritis,** is one of the most common causes of acute glomerulonephritis. Primary membranous nephropathy is caused by subepithelial deposition of circulating antibodies or antibodies (IgG4 subclass) formed in situ to antigens (M-type phospholipase A_2 receptor [PLA2R] protein) located on glomerular podocytes. The antigen-antibody complexes activate C5b-C9 fragments of complement (the membrane attack complex) with injury and release of inflammatory mediators by mesangial and epithelial cells, resulting in increased membrane permeability, thickening of the glomerular membrane, and ultimately glomerular sclerosis. Secondary membranous nephropathy is associated with various disorders including infections (e.g., hepatitis), systemic lupus erythematosus, drugs, and some cancers. Proteinuria and nephrotic syndrome are common manifestations.[103,104]

Rapidly progressive (crescentic) glomerulonephritis (RPGN), also known as subacute or extracapillary glomerulonephritis, develops over days to weeks. The disease affects primarily adults in their fifties and sixties and may be idiopathic or associated with a proliferative glomerular disease (diffuse proliferation of extracapillary cells), such as lupus or poststreptococcal glomerulonephritis. Antiglomerular basement membrane antibodies and antineutrophil cytoplasmic antibodies are associated with glomerular injury.[105,106] There is accumulation of T

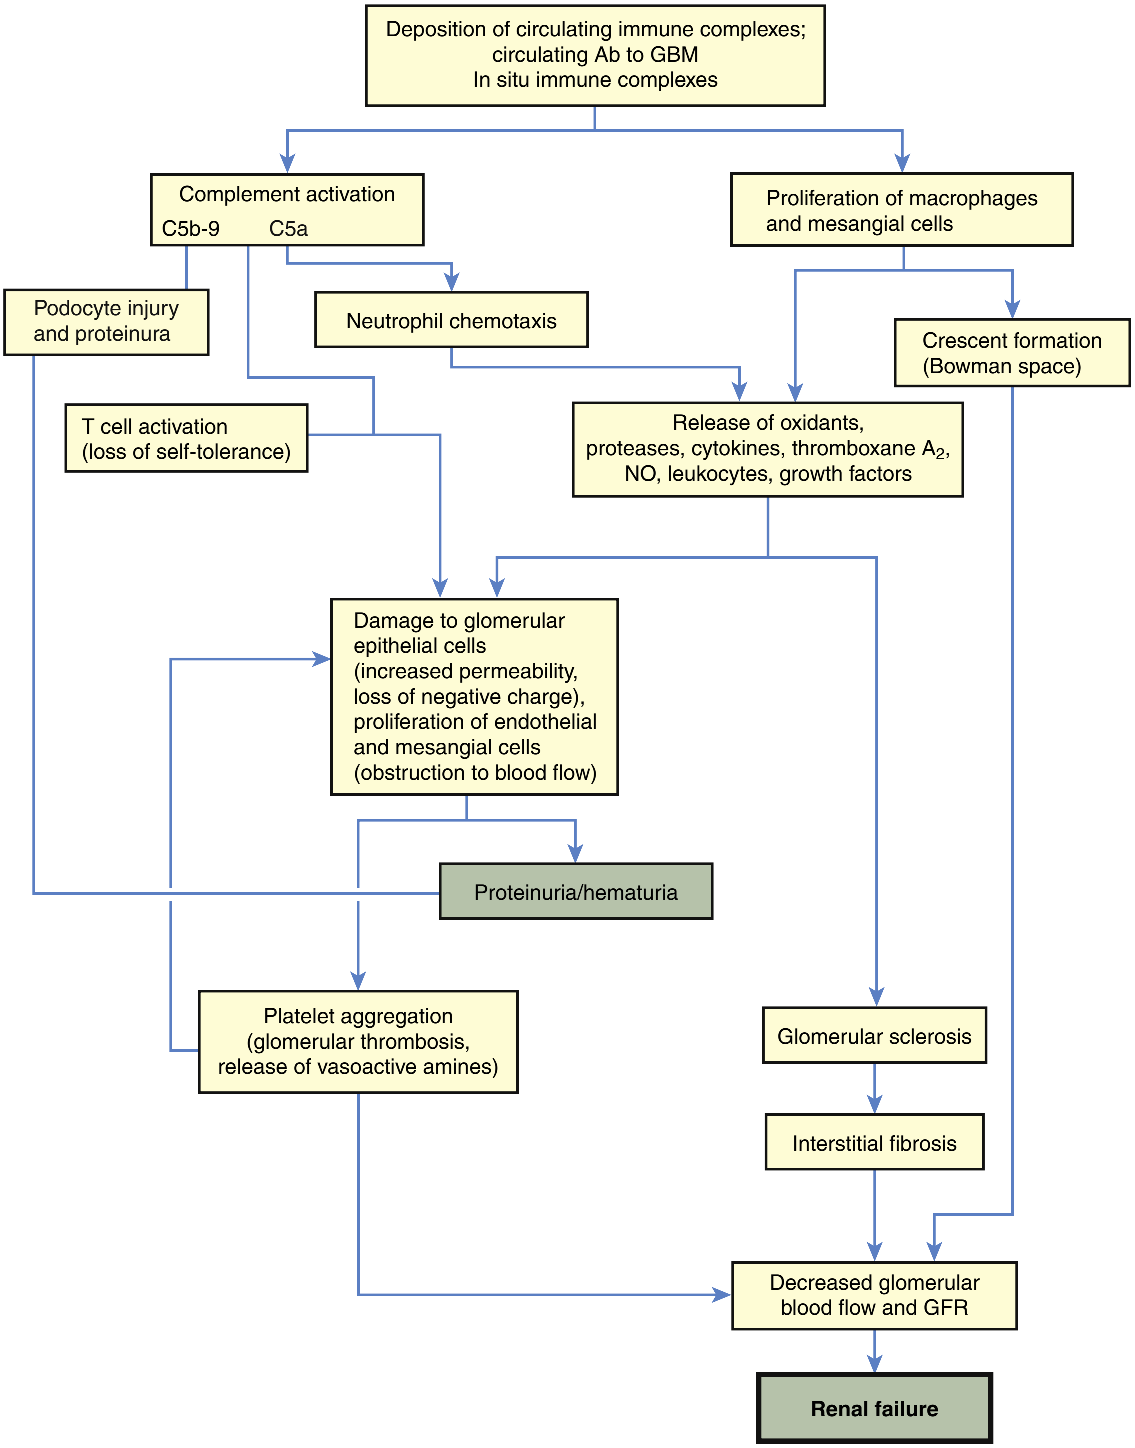

FIGURE 38-7 Mechanisms of Glomerular Injury. *Ab,* Antibody; *GBM,* glomerular basement membrane; *GFR,* glomerular filtration rate; *NO,* nitric oxide.

cells and macrophages with extensive proliferation of glomerular epithelial cells into the Bowman space. The accumulation of cells promotes crescent formation (the shape of the Bowman capsule). Heparin-binding epidermal growth factor–like growth factor (HB-EGF) released from glomerular epithelial cells is associated with the proliferation.[107] Typically the glomerular injury is accompanied by a rapid decline in glomerular function, progressing to renal failure in a few weeks or months. Hematuria is common and may or may not be accompanied by proteinuria, edema, or hypertension. There are three types of RPGN distinguished by immunofluorescence and electron microscopic study of the renal biopsy (Figure 38-8).[108] They are summarized in Table 38-7.

RPGN has a relatively poor prognosis if not diagnosed and treated early. Anticoagulants may be of some benefit in reducing the fibrin component of crescent formation. Plasmapheresis

TABLE 38-5 IMMUNOLOGIC PATHOGENESIS OF GLOMERULONEPHRITIS

GLOMERULAR INJURY	MECHANISM
Soluble immune-complex glomerulonephritis (90%)	Formation of antibodies stimulated by the presence of endogenous or exogenous antigens results in circulating soluble antigen-antibody complexes, which are deposited in glomerular capillaries, or the in situ formation of immune complexes to planted antigens or to structural components within the glomerulus; glomerular injury occurring with complement deposition and activation and release of immunologic substances that lyse cells and increase membrane permeability; immune deposits with a microscopic appearance that fluoresce in a *granular pattern* when stained with fluorescein and viewed under ultraviolet light; severity of glomerular injury related to the number of complexes formed; a type III hypersensitivity reaction
Antiglomerular basement membrane glomerulonephritis (5%)	Antibodies are formed and act directly against the glomerular basement membrane; immune response that causes crescent formation and a *linear pattern* of immunofluorescence; generally associated with rapidly progressive renal failure such as Goodpasture syndrome (type II hypersensitivity reaction)
Alternative complement pathway	A relatively obscure mechanism associated with low levels of complement and membranoproliferative glomerulonephritis
Cell-mediated immunity	A delayed hypersensitivity response that damages the glomerulus; actual cellular mechanism not clearly understood but may involve cytokine secretion, activation of effector cells such as macrophages or by inducing autoantibodies or immune complexes; cytotoxic CD8+ T-cell responses and failure of regulatory T cells may represent two additional types of antirenal hypersensitivity*

TABLE 38-6 CLASSIFICATION OF GLOMERULAR LESIONS

LESION	DISTRIBUTION WHEN MANY GLOMERULI CONSIDERED
Diffuse	Relatively uniform involvement of most (>50%) or all glomeruli; most common form of glomerulonephritis
Focal	Changes in only some glomeruli (>50%), whereas others are normal
LESION	**DISTRIBUTION WHEN SINGLE GLOMERULI CONSIDERED**
Global	A lesion involving the entire glomerulus
Segmental-local	Changes in one part of the glomerulus with other parts unaffected
LESION	**LESION CHARACTERISTICS**
Mesangial	Deposits of immunoglobulins in the mesangial matrix; mesangial cell proliferation
Membranous	Thickening of the glomerular capillary wall with immune deposits (i.e., IgG and C3)
Proliferative	Increase in the number of glomerular cells: endothelial, epithelial, mesangial
Sclerotic	Glomerular scarring from previous glomerular injury
Crescentic	Accumulation of proliferating cells within Bowman space, making the appearance of a crescent
Interstitial fibrosis	Scarring between the glomerulus and the tubules

is usually combined with corticosteroids and immunosuppression therapy. Dialysis or transplantation is required when failure is irreversible.[109-111]

Mesangial proliferative glomerulonephritis is usually idiopathic and involves deposits of immune complex in the mesangium with mesangial cell proliferation. It can be associated with IgA nephropathy, lupus nephritis, or early diabetic nephropathy. Mesangial expansion reduces blood flow and alters filtration membrane permeability with development of hematuria, proteinuria, hypertension, and uremia (nephritic syndrome).

Membranoproliferative glomerulonephritis (MPGN) is usually idiopathic and involves proliferation of mesangial cells and formation of crescents related to the deposition of complement (C3 component) and inflammatory injury. This disease is rare and occurs more commonly in children and young adults. Hypocomplementemia is associated with all types of MPGN and they are differentiated by light microscopy. All three types stain positive for complement component C3. The subtypes are summarized in Table 38-7. Injury to the glomerular capillary wall in all types of MPGN can cause proteinuria, hematuria, nephrotic syndrome, and acute or chronic kidney failure.[112,113]

The immune injury of acute glomerulonephritis is caused by activation of biochemical mediators of inflammation (i.e., complement cytokines from leukocytes and fibrin) and begins after the antibody or antigen-antibody complexes have deposited or formed in the glomerular capillary wall. Complement is deposited with the antibodies, and its activation can cause cell lysis or serve as a chemotactic stimulus for attraction of neutrophils, monocytes, and T lymphocytes.[114] Activated platelets can further the inflammatory reaction by releasing lysosomal enzymes, reactive oxygen species, and cytokines. These inflammatory mediators injure the glomerular filtration membrane, including endothelial cells, glomerular basement membrane, and epithelial cells (podocytes). The injury increases glomerular membrane permeability and reduces glomerular membrane surface area (podocyte injury). There also may be swelling and proliferation of mesangial cells and expansion of the extracellular matrix in the Bowman space, contributing to crescent

TABLE 38-7 TYPE, CAUSE, AND HISTOPATHOPHYSIOLOGY OF ACUTE GLOMERULONEPHRITIS

TYPE AND CAUSE	HISTOPATHOPHYSIOLOGY
Associated with Nephritic Syndrome	
Acute postinfectious glomerulonephritis (PIGN) (e.g., group A beta-hemolytic streptococci [more common in children]; staphylococcus [more common in older adults])	Subepithelial deposits of IgG and complement complexes; infiltration of neutrophils and monocytes; proliferation of mesangial and epithelial cells with occlusion of glomerular capillary blood flow and decreased glomerular filtration; usually diffuse lesions
Rapidly progressive or crescentic glomerulonephritis (a clinical syndrome): *Type I:* Formation of IgG antibodies against pulmonary capillary and glomerular basement membrane (Goodpasture syndrome); activation of complement and neutrophils; more common in young men; causes pulmonary hemorrhage and renal failure *Type II:* Mesangial immune complex deposition (PIGN, SLE, IgA nephropathy) *Type III:* Pauci-immune, lack of anti-GBM antibodies or immune complexes; presence of serum antineutrophil cytoplasmic (ANC) antibodies associated with systemic vasculitides (usually idiopathic); nonspecific response to glomerular injury; can occur in any severe glomerular disease	Accumulation of fibrin, macrophages, and epithelial cell proliferation into the Bowman space forms crescents and occludes glomerular capillary blood flow decreasing glomerular filtration; antiglomerular basement membrane antibodies lead to necrotizing, proliferative glomerulonephritis, and renal failure; diffuse lesions
Mesangial proliferative glomerulonephritis Can be associated with IgA nephropathy or lupus nephritis	Deposits of immune complexes in the mesangium with mesangial cell proliferation; results in decreased glomerular blood flow and glomerular filtration; leads to hematuria/proteinuria and nephrotic syndrome
Associated with Nephrotic Syndrome	
Minimal change nephropathy (lipoid nephrosis) Glomerular basement membrane appears normal Most common cause of nephrotic syndrome in children (see Chapter 39) Usually idiopathic	Glomeruli look normal under light microscopy; electron microscopy reveals uniform diffuse effacement of epithelial (podocyte) foot processes; loss of negative charge in basement membrane and increased permeability lead to severe proteinuria and nephrotic syndrome
Focal segmental glomerulosclerosis Usually idiopathic Can be associated with HIV infection, IgA nephropathy	Focal proliferation of endothelial and mesangial cells and glomerulosclerosis from hyaline deposits in segmental parts of the glomerular membrane; there is effacement (thinning or deletion) of epithelial podocytes, with a significant increase in pore size resulting in proteinuria and nephrotic syndrome; can progress to involve entire glomerulus and development of tubulointerstitial fibrosis
Membranous nephropathy (autoimmune response to unknown renal antigen) Usually idiopathic; can be associated with systemic diseases (i.e., hepatitis B virus, hepatitis C virus, systemic lupus erythematosus, solid malignant tumors)	Diffuse thickening of glomerular basement membrane and capillary wall from deposits of antibody, complement, and release of inflammatory cytokines; increased permeability with proteinuria and leading cause of nephrotic syndrome in white adults
Membranoproliferative (MPGN) Usually idiopathic; associated with hypocomplementemia *Type I:* Activation of classical complement pathway with nephrotic syndrome (hepatitides B and C, SLE) *Type II:* Activation of alternate complement pathway with hematuria (idiopathic); no circulating immune complexes *Type III:* Activation of alternative complement pathway with nephrotic syndrome; can be familial	Mesangial cell proliferation; thickening of basement membrane; subendothelial deposits of immune complex occlude glomerular capillary blood flow and decrease glomerular filtration; diffuse lesions
IgA nephropathy (Berger disease) Usually idiopathic (can be associated with cirrhosis and minimal change disease); elevated IgA plasma levels (also see Henoch-Schönlein purpura nephritis in Chapter 39)	Mesangial proliferation with deposition of IgA; release of inflammatory mediators with cellular proliferation; crescent formation, glomerulosclerosis, interstitial fibrosis, decreased GFR and hematuria; usually focal, some diffuse lesions

formation (deposition of substances in the Bowman space forming the shape of a crescent moon) and decreased glomerular blood flow.[115] The result is decreased driving hydrostatic pressure, decreased GFR, and alterations in microcirculatory blood flow within the renal cortex (hypoxic injury).[116]

Loss of the negative electrical charge across the glomerular filtration membrane and increase in filtration pore size enhance movement of proteins into the urine. Proteins are normally repelled because they also have a negative charge. Red blood cells also escape if pore size is large enough. Proteinuria (excess protein in the urine, usually albumin) or hematuria (blood in the urine), or both, develop. The severity of glomerular damage and decline in glomerular function is related to the size, number, and location (focal or diffuse) of cells injured, the

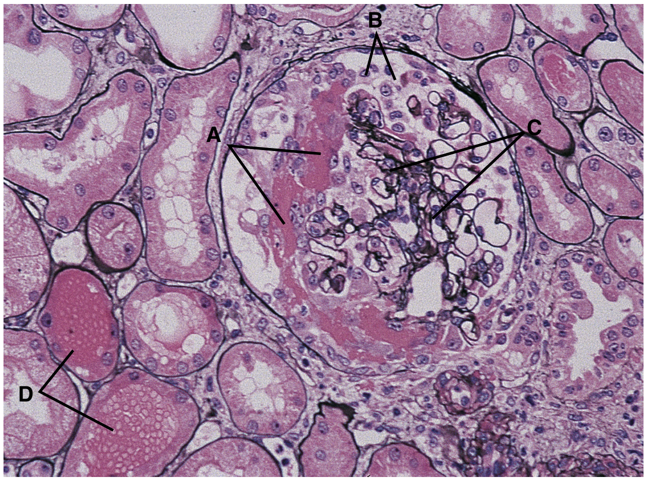

FIGURE 38-8 Antiglomerular Basement Membrane Nephritis. Glomerulus with a fresh crescent consisting of fibrin and cells in the Bowman space *(A)*. There is disruption of the basement membrane of the Bowman capsule, with migration of cells from the interstitium into the Bowman space *(B)*. The capillary tufts *(C)* are distorted and compressed because of the crescent. Note the free erythrocytes in tubular lumina *(D)*. The interstitium is mildly edematous. (Periodic acid–methenamine silver stain.) (Modified from Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

duration of antigen exposure, and the type of antigen-antibody complexes.

CLINICAL MANIFESTATIONS. The onset of glomerular disease may be sudden or insidious and significant loss of nephron function can occur before symptoms develop. Acute glomerulonephritis may be silent, mild, moderate, or severe in symptom presentation.

Two major symptoms distinctive of more severe glomerulonephritis are: (1) hematuria with red blood cell casts, and (2) proteinuria exceeding 3 g/day to 5 g/day with albumin (macroalbuminuria) as the major protein. Nephrotic syndrome is associated with gross proteinuria (see p. 1358). Red blood cells escaping through the glomerular membrane produce a smoky, brown-tinged urine; red blood cell casts; and an accompanying proteinuria, which is associated with nephritic syndrome (see p. 1358). Glomerular bleeding provides prolonged contact with the acidic urine and transforms hemoglobin to methemoglobin, which has a brownish color and no blood clots. In comparison, bleeding from sites lower in the urinary tract produces a pink- or red-colored urine.

Different types of glomerulonephritis may be associated with different patterns of urinary sediment. Urine with **nephrotic sediment** contains massive amounts of protein and lipids and either a microscopic amount of blood or no blood. Urine in diseases associated with a **nephritic sediment** is characterized by the presence of blood in the urine with red cell casts, white cell casts, and varying degrees of protein, which usually is not severe. The sediment of chronic glomerular disease has waxy casts, granular casts, and less protein and blood than found in nephrotic or nephritic sediment.

Severe or progressive glomerular disease causes oliguria (urine output of 30 ml/hour or less), hypertension, and renal failure. Focal lesions tend to produce less severe clinical symptoms. Salt and water are reabsorbed, contributing to fluid volume expansion, edema, and hypertension.

EVALUATION AND TREATMENT. The diagnosis of glomerular disease is confirmed by the progressive development of clinical manifestations and laboratory findings of abnormal urinalysis with proteinuria, red blood cells, white blood cells, and casts. Reduced GFR during glomerulonephritis is evidenced by elevated plasma urea, cystatin C, and creatinine concentrations, or by reduced renal creatinine clearance (see Chapter 37). Renal biopsy provides a specific determination of renal injury and type of pathologic condition. Patterns of antigen-antibody complex deposition or formation within the glomerular capillary filtration membrane have been established using light, electron, and immunofluorescent microscopy. Electron microscopy differentiates morphologic changes within the glomerular capillary wall (e.g., subendothelial and mesangial electron-dense deposits, increased mesangial matrix, mesangialization of capillary loops, and foot process fusion). Staining with fluorescein identifies different antibodies (i.e., immunoglobulin G [IgG] or IgA) and their configurations when viewed under ultraviolet light with light microscopy (see Figure 39-5, *C,* p. 1382).

Management principles for treating glomerulonephritis are related to treating the primary cause; preventing or minimizing immune responses; and correcting accompanying problems, such as edema and hypertension. Specific treatment regimens are necessary for particular types of glomerulonephritis. Antibiotic therapy is essential for the management of underlying infections that may be contributing to ongoing antigen-antibody responses. Corticosteroids decrease antibody synthesis and suppress inflammatory responses. Cytotoxic agents (e.g., cyclophosphamide) may be used to suppress the immune response in corticosteroid-resistant cases. Anticoagulants may be useful for controlling fibrin crescent formation in rapidly progressive glomerulonephritis.

Chronic Glomerulonephritis

Chronic glomerulonephritis encompasses glomerular diseases with a progressive course leading to chronic kidney disease (see p. 1364). There may be no history of renal disease before the diagnosis. Proteinuria and hypercholesterolemia have been associated with progressive glomerulosclerosis, tubulointerstitial fibrosis, and tubular atrophy.[117] The primary cause may be difficult to establish because advanced pathologic changes may obscure specific disease characteristics (Figure 38-9). Renal insufficiency usually begins to develop after 10 to 20 years, followed by nephrotic syndrome and an accelerated progression to end-stage kidney failure. Symptom patterns vary depending on the underlying cause. Corticosteroids usually do not change the course of chronic glomerular disease, and dialysis or kidney transplantation ultimately may be needed. Diabetes mellitus and systemic lupus erythematosus are common secondary causes of chronic glomerular injury.

Diabetic nephropathy develops from metabolic (advanced glycosylated end products), inflammatory (transforming growth factor-beta and protein kinase C), and microvascular complications related to chronic hyperglycemia (see Chapter 22). Changes in the glomerulus are characterized by podocyte

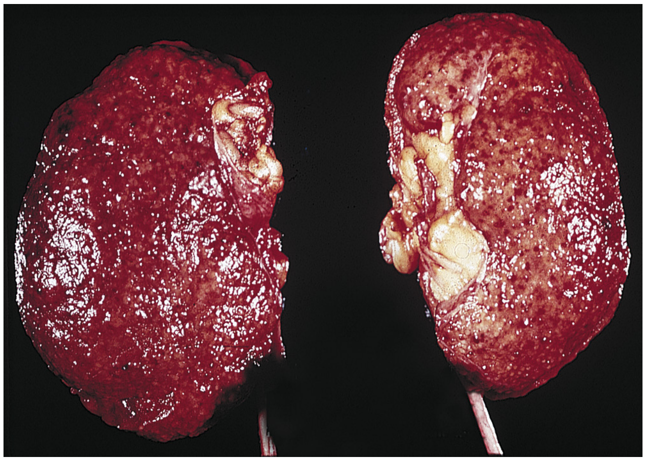

FIGURE 38-9 Chronic Glomerulonephritis. The kidneys appear small, are uniformly shrunken, and have a finely granular external surface. (From Damjanov I: *Pathology for the health professions,* ed 4, Philadelphia, 2012, Saunders.)

injury, progressive thickening and fibrosis of the glomerular basement membrane, and expansion of the mesangial matrix (diffuse diabetic glomerulosclerosis) with proteinuria and progression to chronic renal failure.[118] Diabetic nephropathy is the most common cause of chronic kidney disease and end-stage renal failure, but has been declining since 1995.[119-121]

Lupus nephritis is an inflammatory complication of the chronic autoimmune syndrome systemic lupus erythematosus (see Chapter 9). The renal component of the disease is caused by the formation of autoantibodies against double-stranded DNA and nucleosomes with glomerular deposition of the immune complexes triggering of alpha-interferon dependent antiviral immune responses.[121a] There is complement activation and a cascade of inflammatory events results in damage to the glomerular membrane with mesangial expansion (see Chapter 8). Different glomerular lesion patterns are identifiable on biopsy including membranous, mesangial, membranoproliferative, and diffuse proliferative glomerulonephritis; and tubular fibrosis can be present (see Table 38-6).[122,123] Symptom presentation is variable depending on lesion involvement and can include proteinuria, microscopic hematuria, edema, and other signs of nephrotic syndrome. Disease progression may be silent or may progress to end-stage kidney failure over a period of years. Treatment includes the use of immunosuppressive agents.[123a]

Nephrotic and Nephritic Syndromes

Nephrotic syndrome is the excretion of 3.0 g or more of protein in the urine per day, hypoalbuminemia (less than 3.0 g/dl), and peripheral edema. Nephrotic syndrome is characteristic of glomerular injury. *Primary causes of nephrotic syndrome* include minimal change disease (lipoid nephrosis), membranous glomerulonephritis, and focal segmental glomerulosclerosis (see Table 38-7). *Secondary forms of nephrotic syndrome* occur in systemic diseases including diabetes mellitus, amyloidosis, systemic lupus erythematosus, and Henoch-Schönlein purpura (see Chapter 39). Nephrotic syndrome also is seen with certain drugs, infections, malignancies, and vascular disorders. Familial forms

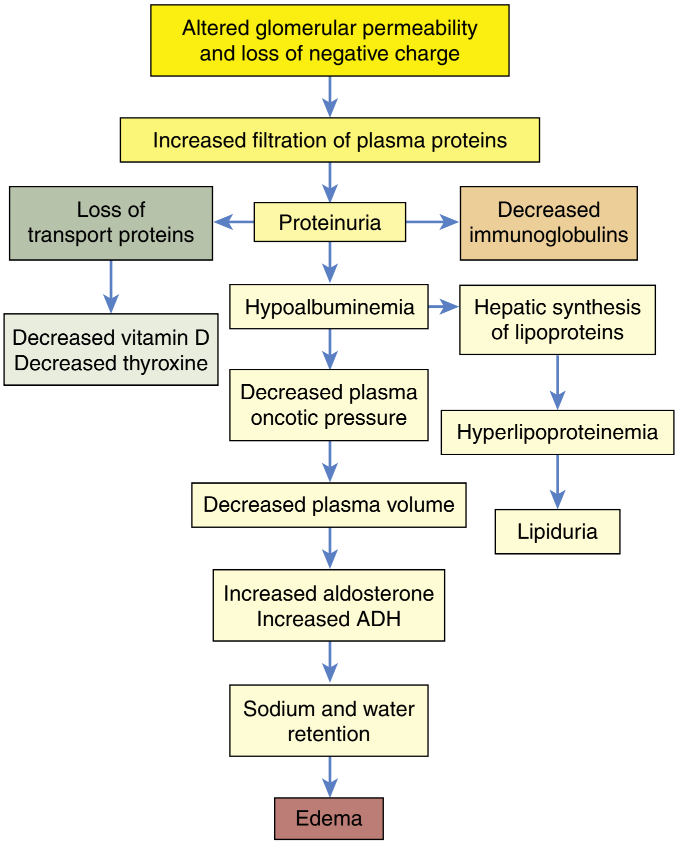

FIGURE 38-10 Pathophysiology of Nephrotic Syndrome.

of nephrotic syndrome result from genetic defects that affect the function and composition of the glomerular capillary wall (i.e., Alport syndrome with alterations in basement membrane type IV collagen).[124] It often signifies a more serious prognosis when present as a secondary complication. Nephrotic syndrome is more common in children than in adults (see Chapter 39).

In **nephritic syndrome,** the presenting symptom is hematuria (usually microscopic) and red blood cell casts are present in the urine in addition to proteinuria, which is not severe. This syndrome is caused by increased permeability of the glomerular filtration membrane with pore sizes large enough to allow the passage of red blood cells and protein. Nephritic syndrome is associated with postinfectious glomerulonephritis, rapidly progressive (crescentic) glomerulonephritis, IgA nephropathy (see Chapter 8 for types of immunoglobulins), lupus nephritis, and diabetic nephropathy (see Table 38-7). The pathophysiology is related to immune injury of the glomerulus as previously described and can occur simultaneously with nephrotic syndrome. Hypertension, uremia, and oliguria occur in advanced stages of disease. The symptoms and treatment are similar to those for nephrotic syndrome.[125]

PATHOPHYSIOLOGY. Disturbances in the glomerular basement membrane (GBM) and podocyte injury lead to increased permeability to protein and loss of electrical negative charge (see Chapter 37).[126] Loss of plasma proteins, particularly albumin and some immunoglobulins, occurs across the injured glomerular filtration membrane (Figure 38-10). Sustained proteinuria can result in the release of inflammatory mediators and

TABLE 38-8 CLINICAL MANIFESTATIONS OF NEPHROTIC SYNDROME

MANIFESTATIONS	CONTRIBUTING FACTORS	RESULT
Proteinuria	Increased glomerular permeability, decreased proximal tubule reabsorption	Edema, increased susceptibility to infection from loss of immunoglobulins
Hypoalbuminemia	Increased urinary losses of protein	Edema
Edema	Hypoalbuminemia (decreased oncotic pressure, sodium and water retention, increased aldosterone and antidiuretic hormone [ADH] secretion), unresponsiveness to atrial natriuretic peptides	Soft, pitting, generalized edema
Hyperlipidemia	Decreased serum albumin; increased hepatic synthesis of very-low-density lipoproteins; increased cholesterol, phospholipids, triglycerides	Increased atherogenesis
Lipiduria	Sloughing of tubular cells containing fat (oval fat bodies); free fat from hyperlipidemia	Fat droplets that may float in urine
Decreased vitamin D	The globulin to which 1,25-dihydroxy-vitamin D_3 is attached for transport passes through the glomerulus and is lost in the urine	Decreased absorption of calcium from gut Risk for osteodystrophies
Hypothyroidism	Loss of thyroid-binding globulin and other thyroid hormone transport proteins in the urine	May have no symptoms; may have elevated thyroid-stimulating hormone

cytokines by tubular cells with influx of leukocytes resulting in progressive glomerulosclerosis and renal fibrosis.[127] Hypoalbuminemia results from urinary loss of albumin combined with a diminished synthesis of replacement albumin by the liver. Albumin is lost in the greatest quantity because of its high plasma concentration and low molecular weight. Decreased dietary intake of protein from anorexia or malnutrition or accompanying liver disease may also contribute to lower levels of plasma albumin. Loss of albumin stimulates lipoprotein synthesis by the liver and hyperlipidemia. Loss of immunoglobulins may increase susceptibility to infections. Sodium retention also is associated with nephrotic syndrome contributing to the development of edema and ascites. The exact mechanism is unknown but the site of retention is the distal tubules and collecting ducts.[128]

CLINICAL MANIFESTATIONS. Many clinical manifestations of nephrotic syndrome are related to loss of serum proteins (Table 38-8) and retention of sodium. They include edema, hyperlipidemia, lipiduria, vitamin D deficiency, and hypothyroidism.[129,130] Vitamin D deficiency is related to loss of serum transport proteins and decreased vitamin D activation by the kidney. Hypothyroidism can result from urinary loss of thyroid-binding protein and thyroxine but there may be no symptoms. Alterations in coagulation factors cause hypercoagulability and may lead to thromboembolic events, particularly in young adults.[131]

EVALUATION AND TREATMENT. Nephrotic syndrome is diagnosed when the protein level in a 24-hour urine collection is greater than 3.0 g. Serum albumin level decreases (to less than 3 g/dl), and concentrations of serum cholesterol, phospholipids, and triglycerides increase. Fat bodies may be present in the urine. The specific pathologic condition is identified by renal biopsy.

Nephrotic syndrome is commonly treated with a normal-protein (i.e., 1 g/kg body weight/day) low-fat diet, salt restriction, diuretics, immunosuppression, and heparinoids. When diuretics are used, care must be taken to observe for hypovolemia and hypokalemia or potassium toxicity in the presence of renal insufficiency. Aldactone may be combined with loop diuretics to suppress aldosterone activity to conserve potassium. Corticosteroids or cyclophosphamide may be particularly effective for the initial treatment of steroid-dependent nephrotic syndrome in children. Immunosuppressive drugs and angiotensin-converting enzyme inhibitors are used with steroid-resistant nephrotic syndrome.[132,133]

ACUTE KIDNEY INJURY

Classification of Kidney Dysfunction

Kidney injury may be acute and rapidly progressive (within hours), and the process may be reversible. Kidney failure also can be chronic, progressing to end-stage kidney failure over a period of months or years. The terms *renal insufficiency, renal failure, uremia,* and *azotemia* are associated with decreasing renal function but are not specific in relation to cause of kidney disease. Often they are used synonymously, although with some distinctions. Generally, **renal insufficiency** refers to a decline in renal function to about 25% of normal or a GFR of 25 to 30 ml/minute. Levels of serum creatinine and urea are mildly elevated. **Renal failure** refers to significant loss of renal function. When less than 10% of renal function remains, this is termed **end-stage kidney disease (ESKD).** Specific criteria for acute renal dysfunction are discussed in the next section. **Uremia** is a syndrome of renal failure and includes elevated blood urea and creatinine levels accompanied by fatigue, anorexia, nausea, vomiting, pruritus, and neurologic changes. Uremia represents numerous consequences related to renal failure, including retention of toxic wastes, deficiency states, electrolyte disorders, and immune activation promoting a proinflammatory state. **Azotemia** is characterized by increased serum urea levels and frequently increased creatinine levels as well. Renal insufficiency or renal failure causes azotemia. Both azotemia and uremia indicate an accumulation of nitrogenous waste products in the blood, a common characteristic that explains the overlap in definitions of terms.

TABLE 38-9 RIFLE CRITERIA FOR ACUTE RENAL DYSFUNCTION/FAILURE

CATEGORY	GFR CRITERIA	URINE OUTPUT (UO) CRITERIA
Risk	Increased creatinine × 1.5 or GFR decrease >25%	UO <0.5 ml/kg/hr × 6 hr
Injury	Increased creatinine × 2 or GFR decrease >50%	UO <0.5 ml/kg/hr × 12 hr
Failure	Increased creatinine × 3 or GFR decrease >75%	UO <0.3 ml/kg/hr × 24 hr or anuria
Loss	Persistent ARF: complete loss of kidney function >4 weeks	
ESKD	End-stage kidney disease: complete loss of kidney function >3 months	
AKIN 1	Increased S_{Creat} by 1.5-2 × above baseline or by 0.3 mg/dl	UO <0.5 ml/kg/hr × 6 hr
AKIN 2	Increased S_{Creat} by 2-3 × above baseline	UO <0.5 ml/kg/hr × 12 hr
AKIN 3	Increased S_{Creat} by >3 × above baseline or by ≥0.3 mg/dl in patients with baseline S_{Creat} >4 mg/dl	UO <0.3 ml/kg/hr × 24 hr or anuria for 12 hr

Acute Kidney Injury

Acute kidney injury (AKI) affects about 5% of hospitalized individuals and has a mortality of 50% to 80%.[134] AKI is a sudden decline in kidney function with a decrease in glomerular filtration and accumulation of nitrogenous waste products in the blood as demonstrated by an elevation in plasma creatinine and blood urea nitrogen levels. The term *acute kidney injury* is preferred to the term **acute renal failure** because it captures the diverse nature of this syndrome, ranging from minimal or subtle changes in renal function to complete renal failure requiring renal replacement therapy. Classification criteria have been developed to guide the diagnosis of renal injury described by the acronym RIFLE (*R* = risk, *I* = injury, *F* = failure, *L* = loss, and *E* = end-stage kidney disease [ESKD]) representing renal dysfunction of increasing severity (Table 38-9).[135,136]

PATHOPHYSIOLOGY. AKI commonly results from extracellular volume depletion, decreased renal blood flow, or toxic/inflammatory injury to kidney cells that results in alterations in renal function that may be minimal or severe. Even small changes in renal function may be associated with significant morbidity and mortality. The etiologies of AKI can be described considering three categories of injury: (1) renal hypoperfusion (prerenal AKI); (2) disorders involving the renal parenchymal or interstitial tissue (intrarenal or intrinsic AKI); and (3) disorders associated with acute urinary tract obstruction (postrenal AKI) (Table 38-10). Most types of AKI are reversible if diagnosed and treated early.

TABLE 38-10 CLASSIFICATION OF ACUTE KIDNEY INJURY

AREA OF DYSFUNCTION	POSSIBLE CAUSES
Prerenal	Hypovolemia
	Hemorrhagic blood loss (trauma, gastrointestinal bleeding, complications of childbirth)
	Loss of plasma volume (burns, peritonitis)
	Water and electrolyte losses (severe vomiting or diarrhea, intestinal obstruction, uncontrolled diabetes mellitus, inappropriate use of diuretics)
	Systemic hypotension or hypoperfusion
	Septic shock systemic inflammation
	Cardiac failure or shock
	Massive pulmonary embolism
	Stenosis or clamping of renal artery
	Increased intra-abdominal pressure (abdominal compartment syndrome)
Intrarenal	Acute tubular necrosis (postischemic or nephrotoxic)
	Glomerulopathies
	Acute interstitial necrosis (tumors or toxins)
	Vascular damage
	Malignant hypertension, vasculitis
	Coagulation defects
	Renal artery/vein occlusion
	Bilateral acute pyelonephritis
Postrenal	Obstructive uropathies (usually bilateral—fibrosis)
	Ureteral destruction (edema, tumors, stones, clots)
	Bladder neck obstruction (enlarged prostate)
	Neurogenic bladder

Prerenal acute kidney injury is the most common cause of AKI. Reduced effective arterial blood volume causes renal hypoperfusion that occurs rapidly over a period of hours with elevation of BUN and plasma creatinine levels. During the early phases of hypoperfusion protective autoregulatory mechanisms maintain GFR at a relatively constant level through afferent arteriolar dilation and efferent arteriolar vasoconstriction (mediated by angiotensin II). Tubuloglomerular feedback mechanisms also maintain GFR and distal tubular nephron flow (see Chapter 37). The GFR ultimately declines because of the decrease in filtration pressure. Poor perfusion can result from renal artery thromobosis, hypotension related to hypovolemia (dehydration, diarrhea, fluid shifts) or hemorrhage, renal vasoconstriction and alterations in renal regional blood flow, microthrombi, or kidney edema that restricts arterial blood flow.[137] Sepsis/septic shock and cardiogenic shock following cardiac surgery are the most common causes of AKI in the intensive care unit.[138] AKI may occur during chronic kidney failure if a sudden stress is imposed on already marginally functioning kidneys, hastening the progression to end-stage kidney disease. Failure to restore blood volume or blood pressure and oxygen delivery can cause cell injury and acute tubular necrosis and apoptosis or acute interstitial necrosis, a more severe form of AKI.

Intrarenal (intrinsic) acute kidney injury (AKI) may result from ischemic acute tubular necrosis (ATN), nephrotoxic ATN

(i.e., exposure to radiocontrast media or antibiotics), acute glomerulonephritis, vascular disease (malignant hypertension, disseminated intravascular coagulation, and renal vasculitis), allograft rejection, or interstitial disease (drug allergy, infection, tumor growth). **Acute tubular necrosis (ATN)** caused by ischemia is the most common cause of intrarenal AKI. It occurs most often after surgery (40% to 50% of cases) but is also associated with severe sepsis; obstetric complications; and severe trauma, including severe burns; or small vessel vasculitis. A combination of events and predisposing factors leads to the greatest risk for acute renal failure. The terms *acute tubular necrosis* and *acute kidney injury* are sometimes used interchangeably, but the conditions are not the same because acute kidney injury can occur without ATN. ATN is generally described as postischemic or nephrotoxic or it can be a combination of both. Postischemic ATN involves persistent hypotension, hypoperfusion, and hypoxemia, producing ischemia and reduced levels of ATP and generating toxic oxygen-free radicals with loss of antioxidant protection that causes cell swelling, injury, and necrosis. Activation of inflammatory cells (e.g., neutrophils, macrophages, and lymphocytes) and complement and release of inflammatory cytokines contribute to tubular injury.[139] Transport of sodium and other molecules is disrupted with damage primarily to the proximal tubular epithelium and shedding of the brush border with the appearance of tubular granular casts in the urine. Ischemic necrosis tends to be patchy and may be distributed along any part of the nephron tubules. Injury is most severe in the outer medulla with scattered necrosis in the cortex and loss of cells along the tubular epithelium.[140] Severe disease of the glomeruli (i.e., acute or rapidly progressive glomerulonephritis) or renal microvascular disorders can also cause intrinsic kidney injury. Oliguria is common (urine output less than 30 ml/hour) with intrarenal AKI, but anuria is rare. Creatinine values in septic renal injury may not reflect renal injury because sepsis decreases production of creatinine without major alterations in body weight, hematocrit level, or amount of extracellular fluid. Creatinine level usually increases with decreased renal blood flow and decreased GFR. However, in sepsis-induced AKI, creatinine values can remain within normal ranges and may be related to alterations in intrarenal microcirculatory blood flow that are different from the kidney ischemia that develops related to systemic hypotension and hypoperfusion of nonseptic AKI.[141,142]

Nephrotoxic ATN can be produced by numerous antibiotics, but the aminoglycosides (gentamicin, tobramycin) are the major culprits. The drugs tend to accumulate in the renal cortex and may not cause renal failure until after treatment is complete. Radiocontrast media (x-ray media) and cisplatin also may be nephrotoxic. Dehydration, advanced age, concurrent renal insufficiency, and diabetes mellitus tend to enhance nephrotoxicity from either aminoglycosides or radiocontrast media. Other substances such as carbon tetrachloride, heavy metals (mercury, arsenic), methoxyflurane anesthesia, or bacterial toxins may promote renal failure. Endogenous substances toxic to renal tubules are excessive myoglobin (oxygen-transporting substance in muscles) and hemoglobin. Necrosis and tubular cell apoptosis caused by nephrotoxins are usually uniform and limited to the proximal tubules. The high surface area of the brush border (microvilli) of the proximal tubular cells and the reabsorption properties of epithelial cells make them more vulnerable to toxic injury.[143]

Postrenal acute kidney injury is rare and usually occurs with urinary tract obstruction that affects the kidneys bilaterally (e.g., bilateral ureteral obstruction, bladder outlet obstruction–prostatic hypertrophy, tumors or neurogenic bladder, and urethral obstruction). The obstruction causes an increase in intraluminal pressure upstream from the site of obstruction with a gradual decrease in GFR. A pattern of several hours of anuria with flank pain followed by polyuria is a characteristic finding. This type of AKI can occur after diagnostic catheterization of the ureters, a procedure that may cause edema with obstruction of the tubular lumen.

Oliguria (less than 400 ml of urine output per day) can occur in AKI, and three mechanisms have been proposed to account for the decrease in urine output. All three mechanisms probably contribute to oliguria in varying combinations and degrees throughout the course of the disease (Figure 38-11). These mechanisms are as follows[144]:

1. *Alterations in renal blood flow.* Efferent arteriolar vasoconstriction may be produced by intrarenal release of angiotensin II or by redistribution of blood flow from the cortex to the medulla. Autoregulation of blood flow may be impaired, resulting in decreased GFR. Changes in glomerular permeability and decreased GFR also may result from the ischemia.
2. *Tubular obstruction.* Advanced injury with necrosis of the tubules causes sloughing of cells, cast formation, or ischemic edema that results in tubular obstruction, which in turn causes a retrograde increase in pressure and reduces the GFR. Renal failure can occur within 24 hours.
3. *Backleak.* Glomerular filtration remains normal, but tubular reabsorption or "leak" of filtrate is accelerated as a result of permeability caused by ischemia and increased tubular pressure from obstruction.

CLINICAL MANIFESTATIONS. The clinical progression of acute kidney injury, particularly acute tubular necrosis, occurs in three phases: initiation phase, maintenance phase, and recovery phase. The *initiation phase* is the phase of reduced perfusion or toxicity in which renal injury is evolving, usually lasting 24 to 36 hours. Prevention of injury is possible during this phase. The *maintenance* or *oliguric phase* is the period of established renal injury and dysfunction after the initiating event has been resolved and may last from weeks to months. Urine output is lowest during this phase, and serum creatinine, blood urea nitrogen, and serum potassium levels increase; metabolic acidosis develops; and there is salt and water overload. The *recovery phase* is the interval when renal injury is repaired and normal renal function is reestablished. GFR returns toward normal but the regenerating tubules cannot concentrate the filtrate. Diuresis is common during this phase, with a decline in serum creatinine and urea levels and an increase in creatinine clearance. Polyuria can result in excessive loss of sodium, potassium, and water. Fluid and electrolyte balance requires careful maintenance.

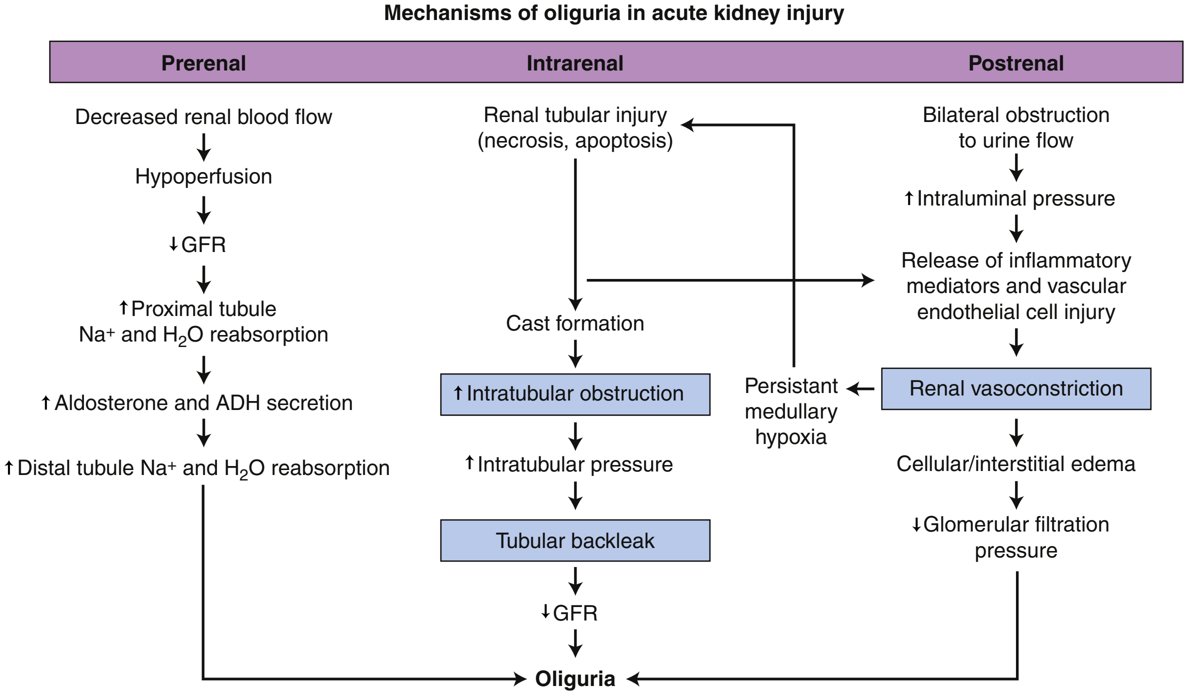

FIGURE 38-11 Acute Kidney Injury and Mechanisms of Oliguria. *ADH,* Antidiuretic hormone; *GFR,* glomerular filtration rate.

Oliguria begins within 1 day after a hypotensive event and lasts for 1 to 3 weeks, but it may regress in several hours or extend for several weeks, depending on the duration of ischemia or severity of toxic injury and the initiation of treatment. **Anuria** (urine output less than 50 ml/day) is uncommon in ATN, and 10% to 20% of cases have nonoliguric failure. Anuria involves both kidneys and suggests bilateral renal artery occlusion, obstructive uropathy, or acute cortical necrosis. **Nonoliguric renal failure** usually represents less severe injury and is associated with toxin exposure or drug toxicity. The renal tubules have impaired reabsorption and concentration and dilution function. The urine output may be greater than 2 L per day, but the BUN and plasma creatinine concentrations increase.

Other early manifestations depend on the underlying cause of renal failure. Individuals who have experienced trauma or surgery or people in a catabolic state may have more rapid elevations in BUN level. They are prone to hyperkalemia and metabolic acidosis related to decreased potassium level and hydrogen excretion. Renal phosphate excretion is decreased, causing hyperphosphatemia. Fluid retention may cause edema. Symptoms of congestive heart failure develop in persons with cardiac disease. Nausea, vomiting, and fatigue accompany uremia and electrolyte imbalances. Wound healing is delayed, and the risk of infection, particularly pneumonia, is greater. Nonoliguric renal failure generally has a better prognosis because of fewer complications and regeneration of the tubular epithelium. Individuals with oliguria may require maintenance dialysis to attenuate symptoms of renal failure.

As renal function improves during the recovery phase, increase in urine volume (diuresis) is progressive. During the early diuretic phase the tubules are still recovering secretory and reabsorptive function. Sodium and potassium are lost in the urine, and the risk for hypokalemia is greater. Volume depletion may ensue, with fluid losses of 3 to 4 L/day. Fluid and electrolyte balance must be carefully monitored and excessive urinary losses replaced. Return to normal status may take 3 to 12 months. Approximately 30% of individuals do not have full recovery of a normal GFR or tubular function and progress to end-stage kidney disease.[145]

EVALUATION AND TREATMENT. The diagnosis of AKI is related to the cause of the disease. The history can help distinguish the different etiologies of AKI. Prerenal causes are associated with a history of blood volume depletion or other causes of poor kidney perfusion (e.g., shock, heart failure, renal artery thrombi). Intrinsic causes include exposure to nephrotoxins and infection. Postrenal causes are associated with obstructive uropathies (e.g., an enlarged prostate or stones). The diagnostic challenge is to differentiate prerenal acute renal injury from acute tubular necrosis. Urine composition may provide helpful diagnostic clues to changes in tubular function (Table 38-11).

The ratios of the BUN to plasma creatinine concentration and fractional excretion of sodium (the ratio of filtered sodium to excreted sodium) are helpful diagnostic indicators because the tests reflect renal tubular reabsorption ability. In prerenal AKI, tubular function is maintained and salt, water, and urea are reabsorbed. With ATN, reabsorption and urinary concentration abilities are compromised. Other causes of renal failure also may exhibit similar clinical findings. *Cystatin C,* a serum protein constantly produced by nucleated cells, is freely filtered by the glomerulus, and its concentration can serve as a measure of GFR and may be useful for detecting early changes in glomerular filtration rate.[146] Serial measurements of plasma creatinine concentration provide an index of renal function during

TABLE 38-11 URINE CHARACTERISTICS OF PRERENAL AND INTRINSIC ACUTE KIDNEY INJURY

DIAGNOSTIC INDEX	PRERENAL	ATN
Urine volume	<400 ml	<400 ml
Urine specificity	1.016-1.020	1.010-1.012
Urine osmolality	>500 mOsm	<300 mOsm
Urine sodium	<10 mEq/L	>30 mEq/L
BUN/plasma	>15:1	<15:1 creatinine
FE_{Na}	<1% (also seen in acute glomerulonephritis	>1% (also seen in urinary tract obstruction and renal parenchymal disease)
Urine sediment	Usually no cells, some hyaline casts	Brown granular casts, epithelial cells

ATN, Acute tubular necrosis; *BUN,* blood urea nitrogen; *FE_{Na},* fractional excretion of sodium.

the recovery phase. However, changes in serum creatinine level occur only if more than 50% of glomerular filtration is lost and are often delayed by more than 24 hours. Such diagnostic delays make the implementation of early therapy very difficult, contributing to disease progression and mortality. Advances are being made in the use of biomarkers that allow assessment of kidney injury before elevation of serum creatinine level (see What's New? Biomarkers and Acute Kidney Injury).

Prevention of AKI and maintenance of renal perfusion involve maintenance of fluid volume before and after surgery or diagnostic procedures or when nephrotoxic drugs or contrast agents are in use. There is no specific treatment for acute renal failure. The primary goal of therapy, once AKI has occurred, is to maintain the individual's life until renal function has recovered. Management principles directly related to physiologic alterations generally include (1) correcting fluid and electrolyte disturbances, (2) managing blood pressure, (3) preventing and treating infections, (4) maintaining nutrition, and (5) remembering that certain drugs or their metabolites are not excreted and can be toxic. Fluid and electrolyte replacement must be carefully calculated with consideration of urine losses, insensible losses (up to 1000 ml/day), and production of endogenous water by oxidation (450 ml/day). Overhydration of patients dilutes their plasma sodium concentration. Metabolic acidosis is usually not treated until serum bicarbonate concentration is less than 15 mEq/L.[147]

Hyperkalemia can be managed by restricting dietary sources of potassium, using non–potassium-sparing diuretics, or using cation ion exchange resins, which may be administered orally or rectally. These resins exchange potassium for another cation, such as sodium in the bowel, and the potassium is then excreted attached to the resin. With severe hyperkalemia (more than 6.5 mEq/L), dialysis may be required or potassium can be driven back temporarily into the cells by administering glucose and insulin or by infusing sodium bicarbonate or albuterol. Glucose metabolism causes potassium to move to the intracellular fluid, and insulin infusions therefore can be effective in shifting potassium from the extracellular to intracellular space, along with the transport of glucose, within 30 minutes. (Glucose metabolism is discussed in Chapter 1 and Chapter 21.) Using sodium bicarbonate to cause alkalemia also shifts potassium into cells in exchange for hydrogen ions. However, use of sodium bicarbonate in AKI is controversial.[148] Careful monitoring of the electrocardiogram for peaking T waves is essential for individuals with hyperkalemia. Intravenous infusion of calcium is the most rapid method of treating cardiac effects of hyperkalemia. Calcium decreases the threshold potential and reduces the membrane excitability caused by hyperkalemia (see Chapter 3). Calcium should be used only in emergencies, however, because hypercalcemia also may cause cardiac arrest.

Azotemia is generally controlled and nutrition maintained with a low-protein, high-carbohydrate diet. Essential amino acid replacement can be given orally or parenterally. Adequate carbohydrate intake slows protein catabolism and helps prevent release of potassium from cellular breakdown. Because sepsis is a common serious and potentially fatal complication of renal failure, observation for signs of infection and early treatment with antibiotics are necessary. Drug dosage levels may require adjustment if they are metabolized or excreted by the kidneys. Recovery may take up to 1 year.

Continuous renal replacement therapy (**CRRT [hemodialysis]**) (mechanical removal of water, electrolytes, and toxins from the blood) is indicated for uncontrollable hyperkalemia or acidosis or severe fluid overload. CRRT is particularly promising in critically ill people with multiple organ dysfunction or

WHAT'S NEW?

Biomarkers and Acute Kidney Injury

Rising serum creatinine concentrations and urine output have conventionally determined evolving acute kidney injury (AKI). However, these changes may occur 2 to 3 days after the initiating renal insult and delay potentially effective therapies that are limited to the early stage of injury. New biomarkers are under investigation that would enhance the differential diagnosis of kidney injury and dysfunction and provide guidance for very early treatment before a rise in serum creatinine level. Candidate molecules include neutrophil gelatinase–associated lipocalin, urinary cystatin C, kidney injury molecule-1, IL-18, renal vanin-1 protein, and hematopoietic growth factor–inducible neurokinin 1. A recent multicenter prospective study in the emergency department found levels of urinary neutrophil gelatinase–associated lipocalin and urinary kidney injury molecule-1 more predictive than serum creatinine level in identifying risk for AKI. Future research is necessary to clarify whether serial measurements of a specific biomarker or the use of a panel of biomarkers may be more useful for diagnosis and predicting severity and duration of AKI.

sepsis. The timing and optimal dose-response relationships for CRRT are under investigation.[149,150]

CHRONIC KIDNEY DISEASE

Chronic kidney disease (CKD) is the progressive loss of renal function associated with systemic diseases such as hypertension, diabetes mellitus, systemic lupus erythematosus, or intrinsic kidney disease, including kidney stones, acute kidney injury, chronic glomerulonephritis, chronic pyelonephritis, obstructive uropathies, or vascular disorders. The National Kidney Foundation (www.kidney.org/professionals/) defines kidney damage as a GFR less than 60 ml/min/1.73 m^2 for 3 months or more, irrespective of cause. *Chronic kidney disease* is the preferred terminology and is referenced to declining GFR. The terms *renal insufficiency* and *chronic renal failure* are still often used to describe declining renal function, but they do not have the specificity of the stages recommended by the National Kidney Foundation (Table 38-12). CKD decreases filtration and tubular functions with consequences manifested throughout all organ systems (Table 38-13).

PATHOPHYSIOLOGY. The kidneys have a remarkable ability to adapt to loss of nephron mass. Symptomatic changes resulting from increased levels of creatinine, urea, and potassium and alterations in salt and water balance usually do not become apparent until renal function declines to less than 25% of normal when adaptive renal reserves have been exhausted.

Different theories have been proposed to account for the adaptation to loss of renal function. The *intact nephron hypothesis* proposes that loss of nephron mass with progressive kidney damage causes the surviving nephrons to sustain normal kidney function. These nephrons are capable of a compensatory hypertrophy and expansion or hyperfunction in their rates of filtration, reabsorption, and secretion and can maintain adaptive changes in solute and water regulation in the presence of overall declining GFR. Although the urine of an individual with chronic kidney failure may contain abnormal amounts of protein and red and white blood cells or casts, the major end products of excretion are similar to those of normally functioning kidneys until the advanced stages of renal failure when there is a significant reduction of functioning nephrons.[151] With severe or repeated injury, epithelial cells have an impaired proliferative response resulting in interstitial capillary loss and fibroblast proliferation. The progressive process of glomerulosclerosis and tubulointerstitial fibrosis contributes to end-stage kidney disease.[152] The *particular location of kidney damage* also can influence loss of kidney function. For example, tubular interstitial diseases damage primarily the tubular or medullary parts of the nephron, producing problems such as renal tubular acidosis, salt wasting, and difficulty diluting or concentrating the urine. When the damage is primarily vascular or glomerular, proteinuria, hematuria, and nephrotic syndrome are more prominent. A summary of factors involved in the progression of chronic kidney disease is outlined in Table 38-14 and Figure 38-12.

The factors that contribute to the pathogenesis of CKD are complex and involve the interaction of many cells, cytokines, and structural alterations. Two factors that have consistently been recognized to advance renal disease are proteinuria and angiotensin II activity. Glomerular hyperfiltration and increased glomerular capillary permeability lead to proteinuria. Proteinuria contributes to tubulointerstitial injury by accumulating in the interstitial space and activating complement proteins and other mediators and cells, such as macrophages, that promote inflammation and progressive fibrosis.[153] Angiotensin II activity is elevated with progressive nephron injury. **Angiotensin II** promotes glomerular hypertension and hyperfiltration caused by efferent arteriolar vasoconstriction and also promotes systemic hypertension. The chronically high intraglomerular pressure increases glomerular capillary permeability, contributing to proteinuria. Angiotensin II also may promote the activity of

TABLE 38-13 SYSTEMIC EFFECTS OF CHRONIC KIDNEY DISEASE AND UREMIA

SYSTEM	MANIFESTATIONS	MECHANISMS	TREATMENT
Skeletal	Spontaneous fractures and bone pain Deformities of long bones	Chronic kidney disease-mineral bone disorder: bone inflammation with fibrous degeneration related to hyperparathyroidism; bone resorption associated with vitamin D and calcium deficiency	Control of hyperphosphatemia to reduce hyperparathyroidism; administration of calcium and aluminum hydroxide antacids, which bind phosphate in the gut, together with a phosphate-restricted diet; vitamin D replacement; avoidance of magnesium antacids because of impaired magnesium excretion
Cardiopulmonary	Pulmonary edema, Kussmaul respirations	Fluid overload associated with pulmonary edema and metabolic acidosis leading to Kussmaul respirations	ACE inhibitors; combination of propranolol, hydralazine, and minoxidil for those with high levels of renin; bilateral nephrectomy with dialysis or transplantation
Cardiovascular	Left ventricular hypertrophy, cardiomyopathy, and ischemic heart disease; hypertension, dysrhythmias, accelerated atherosclerosis; pericarditis with fever, chest pain, and pericardial friction rub	Extracellular volume expansion and hypersecretion of renin associated with hypertension; anemia increases cardiac workload; hyperlipidemia promotes atherosclerosis; toxins precipitate into pericardium	Volume reduction with diuretics that are not potassium sparing (to avoid hyperkalemia); lipid lowering drugs; blood pressure–lowering strategies; dialysis
Neurologic	Encephalopathy (fatigue, loss of attention, difficulty with problem solving); peripheral neuropathy (pain and burning in the legs and feet, loss of vibration sense and deep tendon reflexes); loss of motor coordination, twitching, fasciculations, stupor, and coma with advanced uremia	Progressive accumulation of uremic toxins associated with end-stage renal disease Stroke or intracerebral hemorrhage associated with chronic dialysis	Dialysis or successful kidney transplantation
Endocrine	Restricted growth in children Higher incidence of goiter Osteomalacia	Elevated parathyroid hormone levels Decreased thyroid hormone	Endogenous recombinant human growth hormone; thyroid hormone replacement Same as skeletal above
Hematologic	Anemia, usually normochromic normocytic; platelet disorders with prolonged bleeding times	Reduced erythropoietin secretion and reduced red cell production; uremic toxins shorten red blood cell survival and alter platelet function	Dialysis; recombinant human erythropoietin (controversial) and iron supplementation; conjugated estrogens; DDAVP (1-deamino-[8-D-arginine] vasopressin); transfusion
Gastrointestinal	Anorexia, nausea, vomiting; mouth ulcers, stomatitis, urinous breath (uremic factor), hiccups, peptic ulcers, gastrointestinal bleeding, and pancreatitis associated with end-stage renal failure	Retention of metabolic acids and other metabolic waste products	Protein-restricted diet for relief of nausea and vomiting; Na^+-based alkali or alkali-inducing food
Integumentary	Abnormal pigmentation and pruritus	Retention of urochromes, contributing to sallow, yellow color; high plasma calcium levels and neuropathy associated with pruritus	Dialysis with control of serum calcium and phosphate levels
Immunologic	Increased risk of infection that can cause death; increased risk of carcinoma	Suppression of cell-mediated immunity; reduction in number and function of lymphocytes, diminished phagocytosis	Routine dialysis
Reproductive	Sexual dysfunction: menorrhagia, amenorrhea, infertility, and decreased libido in women; decreased testosterone levels, infertility, and decreased libido in men	Dysfunction of ovaries and testes; presence of neuropathies	No specific treatment

TABLE 38-14 **FACTORS REPRESENTING PROGRESSION OF CHRONIC KIDNEY DISEASE**

FACTOR	CHARACTERISTICS
Proteinuria	Glomerular hyperfiltration of protein contributes to tubular intestinal injury by accumulating in the interstitial space and promoting inflammation and progressive fibrosis.
Creatinine and urea clearance	In chronic renal failure, the GFR falls and the plasma creatinine concentration increases by a reciprocal amount; because there is no regulatory adjustment for creatinine, plasma levels continue to rise and serve as an index of changing glomerular function. As GFR declines, urea clearance increases. (**Note:** Urea is filtered and reabsorbed and varies with the state of hydration.)
Sodium and water balance	In chronic renal failure, sodium load delivered to nephrons exceeds normal, so excretion must increase; thus less is reabsorbed. Obligatory loss occurs, leading to sodium deficits and volume depletion. As GFR is reduced, ability to concentrate and dilute urine diminishes.
Phosphate and calcium balance	Changes in acid-base balance affect phosphate and calcium balance. The major disorders associated with chronic renal failure are reduced renal phosphate excretion, decreased renal synthesis of 1,25-$(OH)_2$-vitamin D_3, and hypocalcemia. Hypocalcemia leads to secondary hyperparathyroidism, GFR falls, and progressive hyperphosphatemia, hypocalcemia, and dissolution of bone result.
Hematocrit	Lack of erythropoietin and anemia accompany chronic renal failure. Lethargy, dizziness, and low hematocrit are common.
Potassium balance	In chronic renal failure, tubular secretion of potassium increases until oliguria develops. Use of potassium-sparing diuretics also may precipitate elevated serum potassium levels. As disease progresses, total body potassium levels can rise to life-threatening levels and dialysis is required.
Acid-base balance	In early renal insufficiency, acid excretion and bicarbonate reabsorption are increased to maintain normal pH. Metabolic acidosis begins when GFR reaches 30% to 40%. Metabolic acidosis and hyperkalemia may be severe enough to require dialysis when end-stage renal failure develops.
Dyslipidemia	Chronic hyperlipidemia may induce glomerular and tubulointerstitial injury contributing to the progression of chronic kidney disease.

GFR, Glomerular filtration rate.

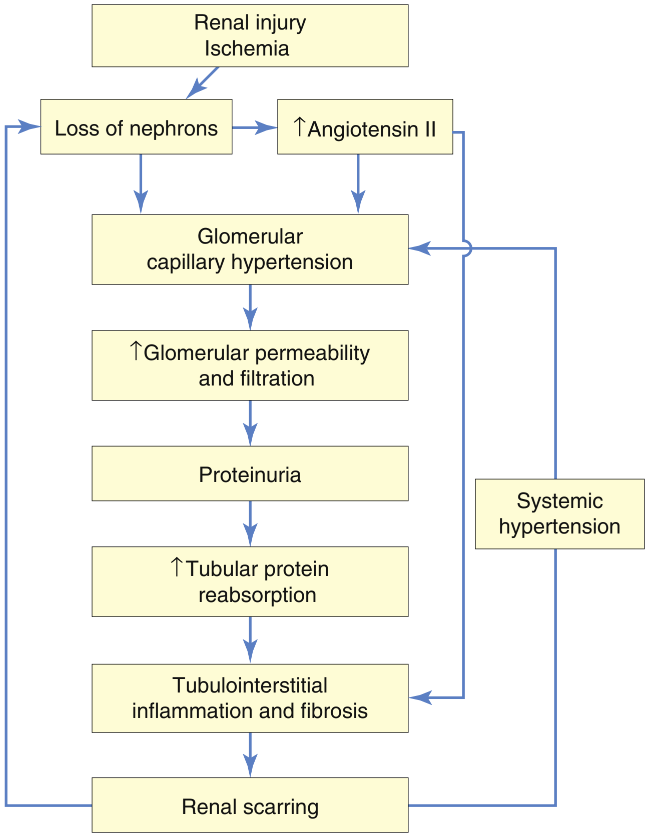

FIGURE 38-12 Mechanisms Related to the Progression of Chronic Kidney Disease.

inflammatory cells and growth factors that participate in tubulointerstitial fibrosis and scarring (see Figure 38-12).[154]

CLINICAL MANIFESTATIONS. The clinical manifestations of chronic kidney disease are often described using the terms azotemia and uremia. Azotemia is manifested by increased levels of serum urea, serum creatinine, and other nitrogenous compounds related to decreasing kidney function. Uremia is a proinflammatory state with many systemic effects known as **uremic syndrome**[155] and is associated with the accumulation of urea and other nitrogenous compounds and toxins. Sources of toxins include the accumulation of end products of protein metabolism, alterations in fluid and electrolytes, metabolic acidosis, intestinal absorption of toxins produced by gut bacteria, and results of altered renal hormone synthesis (i.e., anemia, hyperphosphatemia, and hypocalcemia). Generally, the symptoms include hypertension, anorexia, nausea, vomiting, diarrhea or constipation, malnutrition and weight loss, pruritus, edema, anemia, and neurologic, cardiovascular disease, and skeletal changes. The many systemic manifestations associated with uremia are summarized in Table 38-13, p. 1365, and Figure 38-13.

Creatinine and Urea Clearance

Creatinine is constantly released from muscle and excreted primarily by glomerular filtration. In CKD, as the GFR declines, the plasma creatinine level increases by a reciprocal amount to maintain a constant rate of excretion (Figure 38-14). Because no significant tubular adjustment occurs for creatinine (i.e., tubular secretion), the plasma levels continue to increase as the GFR decreases. Therefore, measures of plasma creatinine can serve as an index of changing glomerular function. The clearance of *urea* follows a similar pattern, but urea is filtered

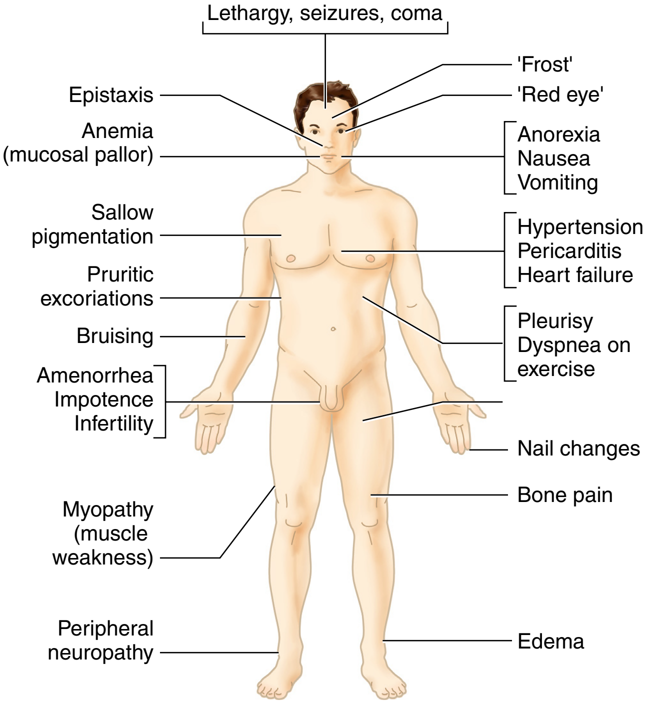

FIGURE 38-13 Common Signs and Symptoms of Kidney Dysfunction (See Text for Reference Site). (From Goldman L, Schafer AI: *Goldman's Cecil medicine,* ed 24, Philadelphia, 2012, Saunders; redrawn from Forbes CD, Jackson WF: *Color atlas and text of clinical medicine,* ed 3, London, 2003, Mosby.)

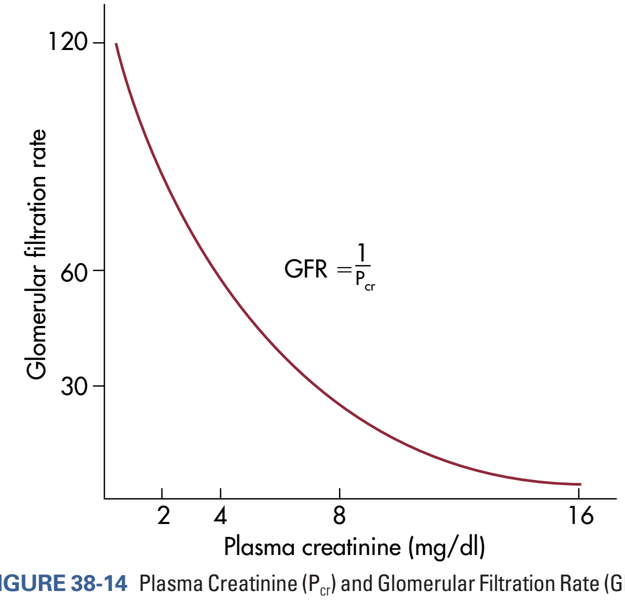

FIGURE 38-14 Plasma Creatinine (P_{cr}) and Glomerular Filtration Rate (GFR).

as well as reabsorbed and varies with the state of hydration; it is not a good index of GFR. However, as the GFR decreases, plasma urea concentration also increases.[156]

Fluid and Electrolyte Balance

Fluid and electrolyte and acid-base balances are significantly disturbed with chronic kidney disease. A summary of electrolyte and acid-base balance alterations is presented in Table 38-15.

Levels of *sodium* must be regulated within narrow limits because sodium is the major extracellular solute. In CKD sodium and water balance is maintained very close to normal until the development of stage V ESKD. This occurs because of the increased fractional excretion of sodium, particularly in the distal nephron, in relation to decreasing GFR. Hormones including aldosterone, prostaglandins, and natriuretic peptides also modulate sodium excretion and their levels are elevated with progressive renal failure. Individual variation in the underlying pathology of CKD must be considered in the management of sodium intake or restriction. Sodium wasting may be present with tubulointerstitial causes of CKD and there may also be extra renal losses of sodium from vomiting, diarrhea, or fever. Sodium retention is more likely in ESKD particularly in the presence of nephrotic syndrome or heart failure. Sodium retention contributes to hypertension, edema, heart failure, and mortality. Management of salt and water balance requires individual assessment, and both hyponatremia and hypernatremia require management.[157]

The regulation of *water balance* and osmolality is normally achieved by urinary concentration mediated by antidiuretic hormone (ADH). As GFR is reduced, ability to concentrate and dilute the urine diminishes. In earlier stages of renal failure, this may be caused by osmotic diuresis produced by increased fractional excretion of solutes by the remaining nephrons or by a decreased tubular response to ADH. Individual nephrons can maintain water balance until severe renal failure occurs and GFR declines to 15% to 20% of normal with extensive loss of nephron and tubular function. At this stage the urinary concentration becomes fixed and approaches that of the plasma at 285 mOsm/L with a specific gravity of about 1.010.

Urinary excretion of *potassium* is related primarily to distal tubular secretion mediated by aldosterone and sodium-potassium adenosine triphosphatase (see Chapter 3). In renal failure there is increased tubular secretion that provides effective regulation until the onset of oliguria. With hyperkalemia larger amounts of potassium can be eliminated through the bowel.[158]

Although nonoliguric patients can maintain potassium excretion with normal dietary intake, they are more prone to develop hyperkalemia with increased loading (i.e., use of salt substitutes). Use of potassium-sparing diuretics, such as spironolactone (aldactone), volume depletion, acute infection, severe acidosis, or marked hyperglycemia also may precipitate elevated levels of serum potassium.[159] With progression of disease to end-stage renal failure (ESRF), total body potassium can increase to life-threatening levels and must be controlled by dietary restriction, loop diuretics, cation exchange resins, and dialysis. Severe acute hyperkalemia is treated with intravenous calcium gluconate, intravenous dextrose and insulin, and nebulized or intravenous salbutamol (sympathetic beta$_2$ agonist, promotes Na^+-K^+-ATPase pump and intracellular movement of potassium). Renal replacement therapy may be required (support of renal function using hemodialysis or peritoneal dialysis).[160]

The intake of a normal diet produces 50 to 100 mEq of hydrogen per day. These ions are secreted from the renal tubules and excreted in the urine combined with phosphate and ammonia buffers (buffering is described in Chapter 3). *Metabolic acidosis* (Chapter 3) develops when GFR decreases to less than 20% to 25%

TABLE 38-15 ELECTROLYTE AND ACID-BASE ALTERATIONS OF CHRONIC KIDNEY DISEASE

FACTOR	CHARACTERISTICS
Sodium and water balance	In chronic renal failure, sodium load delivered to nephrons exceeds normal, so excretion must increase; thus less is reabsorbed. Obligatory loss occurs, leading to sodium deficits and volume depletion. As GFR is reduced, ability to concentrate and dilute urine diminishes.
Phosphate and calcium balance	Changes in acid-base balance affect phosphate and calcium balance. The major disorders associated with chronic renal failure are reduced renal phosphate excretion, decreased renal synthesis of 1,25-$(OH)_2$-vitamin D_3 (calcitriol), and hypocalcemia. Hypocalcemia leads to secondary hyperparathyroidism, GFR falls, and progressive hyperphosphatemia, hypocalcemia, and dissolution of bone result.
Potassium balance	In chronic renal failure, tubular secretion of potassium increases until oliguria develops. Use of potassium-sparing diuretics also may precipitate elevated serum potassium levels. As disease progresses, total body potassium levels can rise to life-threatening levels and dialysis is required.
Acid-base balance	In early renal insufficiency, acid excretion and bicarbonate reabsorption are increased to maintain normal pH. Metabolic acidosis begins to develop when GFR decreases to 30% to 40% of normal. When end-stage renal failure develops, the metabolic acidosis may be severe enough to require dialysis.

GFR, Glomerular filtration rate.

TABLE 38-16 CALCIUM AND PHOSPHATE METABOLISM IN CHRONIC KIDNEY DISEASE

KIDNEY	PLASMA	BONE
Decreased renal production of vitamin D_3	Decreased calcium absorption from gut Decreased ionized calcium Increased PTH secretion (secondary hyperparathyroidism)	Decreased calcium deposition
Decreased phosphate excretion	Elevated phosphate Formation of $CaHPO_4$	Release of calcium and phosphate Osteitis fibrosa, osteomalacia, calcium deposits in soft tissue (occurs when kidney fails to respond to PTH secretion because of loss of renal mass and calcium and phosphate continues to be absorbed from bone)

$CaHPO_4$, Calcium hydrogen phosphate; *PTH,* parathyroid hormone.

of normal. The causes of acidosis are primarily related to decreased hydrogen ion elimination and decreased bicarbonate reabsorption. With end-stage renal failure, metabolic acidosis may be severe enough to require alkali therapy and dialysis. Bicarbonate levels should be maintained at about 22 mEq/L.[161]

Calcium, Phosphate, and Bone

Bone and skeletal changes develop with alterations in **calcium** and **phosphate metabolism** (Table 38-16). These changes begin when the GFR decreases to 25% or less. *Hypocalcemia* is accelerated by impaired renal synthesis of 1,25-dihydroxy-vitamin D_3 (calcitriol) with decreased intestinal absorption of calcium. Renal phosphate excretion also decreases and the increased serum phosphate binds calcium, further contributing to hypocalcemia. Acidosis also contributes to a negative calcium balance. Decreased serum calcium level stimulates parathyroid hormone secretion with mobilization of calcium from bone and may cause calcium levels to approach normal. The combined effect of *hyperparathyroidism* and *vitamin D deficiency* can result in renal osteodystrophies (i.e., *osteomalacia* and *osteitis fibrosa* with increased risk for fractures) (see Chapter 44).[162] Other consequences of secondary hyperparathyroidism include soft tissue and vascular calcification, cardiovascular disease, and, less commonly, calcific uremic arteriolopathy.[163]

Protein, Carbohydrate, and Fat Metabolism

Protein, carbohydrate, and fat metabolism are altered in chronic kidney disease (CKD). *Proteinuria* and a catabolic state contribute to a negative nitrogen balance. Levels of serum proteins diminish, including albumin, complement, and transferrin, and there is loss of muscle mass. Proteinuria may independently cause renal damage by promoting tubular inflammation and fibrosis.[153] The amount of proteinuria is also related to the extent of renal injury and predicts disease progression.[164] Monitoring of proteinuria using the albumin to creatinine ratio among all individuals with CKD who are not receiving chronic dialysis therapy has been recommended as a quality performance measure for improving patient outcomes.[165]

Hyperinsulinemia and glucose intolerance related to insulin resistance are common and may be related to alterations in adipokines that interfere with insulin action and oxidative stress that contribute to renal tubular and vascular injury in both nondiabetic and diabetic CKD.[166] Hyperparathyroidism also decreases insulin sensitivity and impairs glucose tolerance. High levels of adiponectin have been associated with increased mortality in CKD.[167]

Dyslipidemia is common among individuals with CKD. There is a high ratio of low-density lipoprotein (LDL) to high-density lipoprotein (HDL), high levels of triglycerides, and accumulation

of LDL particles with accelerated atherosclerosis and vascular calcification. Uremia causes a deficiency in lipoprotein lipase and decreased hepatic triglyceride lipase. Decreased lipolytic activity results in a reduction in HDL level. Apolipoprotein B concentration is also elevated, thereby accelerating atherogenesis.[168,169]

Cardiovascular System

Cardiovascular disease (Chapter 32) is a major cause of morbidity and mortality in CKD. Proinflammatory mediators, oxidative stress, altered vitamin D metabolism, and metabolic derangements are significant contributors. Declining erythropoietin production causes anemia, which reduces oxygen delivery to the myocardium. Elevated renin level stimulates the secretion of aldosterone, increasing sodium and water reabsorption. *Hypertension* is the result of excess sodium and fluid volume. *Dyslipidemia* occurs early in CKD. Arterial wall thickness increases with decreased elastic fibers and increased extracellular matrix. Atheromatous plaque and arterial calcification contribute to loss of vessel elasticity and obstruction and are accelerated by the oxidative stress of CKD. Macrovascular disease is responsible for increased risk for ischemic heart disease, left ventricular hypertrophy, congestive heart failure, stroke, and peripheral vascular disease in individuals with uremia.[170] Endothelial cell dysfunction and calcium deposits lead to a loss of vessel elasticity and vascular calcification.[171] The resulting vascular disease increases the risk for *ischemic heart disease, left ventricular hypertrophy, congestive heart failure, stroke,* and *peripheral vascular disease* in individuals with uremia. *Pericarditis* can develop from inflammation caused by the presence of uremic toxins. Accumulation of fluid in the pericardial space can compromise ventricular filling and cardiac output.

Pulmonary System

Pulmonary edema results from fluid overload and congestive heart failure. *Dyspnea* is common in ESKD. Metabolic acidosis can cause Kussmaul respirations.

Hematologic System

Hematologic alterations include *normochromic normocytic anemia, impaired platelet function,* and *hypercoagulability*. Inadequate production of erythropoietin decreases red blood cell production and is the most significant factor in contributing to anemia. Chronic inflammation, iron deficiency, and decreased half-life of erythrocytes are also contributing factors. Anemia contributes to decreased tissue oxygenation and contributes to progression of kidney disease. Low levels of hemoglobin and symptoms of anemia, such as lethargy, weakness, and dizziness, are common findings. Treatment of anemia includes erythropoiesis stimulating agents (i.e., recombinant human erythropoietin) and intravenous iron.[172]

Disorders of hemostasis in CKD are primarily related to defective platelet aggregation and impaired adhesion of platelets to the vascular endothelium. The consequence is an increased bleeding tendency manifested by bruising, epistaxis and other mucosal bleeding, gastrointestinal bleeding, and cerebrovascular hemorrhage.[173,174] Adequate dialysis improves platelet function. Alterations of individual clotting factors, fibrin, thrombin, and fibrinolysis contribute to alterations of blood coagulation and can promote a hypercoagulable state and thrombosis with increased risk for myocardial infarction and stroke.[175,176]

Immune System

Immune system dysregulation with immune suppression, deficient response to vaccination, and increased risk for infection develops with CKD. Chemotaxis, phagocytosis, antibody production, and cell-mediated immune responses are suppressed.[177] Malnutrition, metabolic acidosis, hyperglycemia, or effects of hemodialysis may amplify immunosuppression.

Neurologic System

Neurologic symptoms are common and progressive with CKD and are related to uremic toxicity, chronic hyperkalemic depolarization, and anemia.[178] Symptoms may include headache, drowsiness, pain, sleep disorders, impaired concentration, memory loss, and impaired judgment. Neuromuscular irritation can cause hiccups, muscle cramps, and muscle twitching. In advanced stages of renal failure, symptoms may progress to seizures and coma. Peripheral neuropathies also develop with impaired sensations, decreased tendon reflexes, muscle weakness, and muscle atrophy, most commonly in the lower extremities.

Gastrointestinal System

Gastrointestinal complications are common in individuals with CKD. Uremic gastroenteritis can cause bleeding ulcer and significant blood loss. Nonspecific symptoms include anorexia, nausea, vomiting, and constipation or diarrhea. Uremic fetor is a form of bad breath caused by the breakdown of urea by salivary enzymes. Malnutrition is common.

Endocrine and Reproductive Systems

Endocrine and reproductive alterations develop with progression of CKD. Males and females have a decrease in the levels of circulating sex steroid hormones. Males often experience a reduction in testosterone levels and may be impotent. Oligospermia and germinal cell dysplasia can result in infertility. Females have reduced estrogen levels, amenorrhea, and difficulty maintaining a pregnancy to term. A decrease in libido occurs in both genders.[179,180]

Insulin resistance is common in uremia. Low-grade systemic inflammation and oxidative stress may be contributing factors with increased risk for cardiovascular disease. As CKD progresses the ability of the kidney to degrade insulin is reduced, and the half-life of insulin is prolonged. Individuals with diabetes mellitus and CKD need to carefully manage their insulin dosages. Low-protein diets and renal replacement therapy improve insulin sensitivity.[181,182]

CKD also causes alterations in thyroid hormone metabolism and low thyroid hormone levels and is known as nonthyroidal illness syndrome (euthyroid sick syndrome). Low-grade inflammation and oxidative stress may be contributing factors.[183] Uremia also reduces conversion of T_3 to T_4.[183] A low-protein, low-phosphorus diet may improve thyroid hormone function.[184]

Integumentary System

Skin changes are associated with other complications that develop with CKD. Anemia can cause pallor and bleeding into the skin and results in hematomas and ecchymosis. Retained urochromes manifest as a sallow skin color. Hyperparathyroidism and uremic skin residues (known as uremic frost) are associated with irritation and pruritus with scratching, excoriation, and increased risk for infection.[185]

EVALUATION AND TREATMENT. Early screening and evaluation of CKD are based on risk factors, history, presenting signs and symptoms, and diagnostic testing.[186] Prediction equations are used for estimating GFR from serum creatinine values or creatinine clearance may be completed. Markers of kidney damage include urine protein, particularly albumin, and examination of urine sediment. New biomarkers for predicting progression of CKD are being evaluated.[187] Ultrasound, CT scan, or plain x-ray films will show small kidney size. Renal biopsy confirms the diagnosis.

Management involves dietary control, including management of protein intake, vitamin D supplementation, sodium and fluid maintenance, potassium restriction, adequate caloric intake, management of dyslipidemias, and erythropoietin as needed[188,189] (see Nutrition & Disease: Chronic Kidney Disease). ACE inhibitors or receptor blockers are often used to control systemic hypertension and provide renoprotection, particularly in the presence of diabetes mellitus.[190,191] ESKD related to diabetic nephropathy can be significantly reduced with control of hyperglycemia, hypertension, and hyperlipidemia.[121,192] ESKD is treated with dialysis, supportive therapy, and renal transplantation.

NUTRITION & DISEASE

Chronic Kidney Disease

The malnutrition-inflammation complex syndrome or protein-energy wasting is a common condition associated with renal failure and leads to accelerated atherosclerosis and cardiovascular disease and increased mortality for individuals on maintenance dialysis. Elevated levels of leptin, ghrelin, and inflammatory cytokines, including interleukin-6, tumor necrosis factor-alpha, and interferon, suppress appetite and cause muscle proteolysis, decreased protein assimilation, and hypoalbuminemia. Reduced renal function, oxidative stress, decreased levels of antioxidants, infection, exposure to dialysis tubing and membranes during hemodialysis, and back-filtration of contaminants during hemodialysis contribute to inflammation. Acidosis also acts synergistically with inflammatory cytokines and insulin resistance to promote mitochondrial dysfunction and protein catabolism. The provision of nutrients, including adequate calories along with protein supplementation that includes amino acids, in the form of intradialytic parenteral nutrition or enteral feeding during dialysis, assists a person to meet the metabolic requirements. Dietary supplements of antioxidants, such as vitamins A and C, selenium, and carotinoids, are required. Low-protein, low-phosphorous, and low-sodium diets assist with reducing proteinuria, preventing hyperphosphatemia and secondary hyperparathyroidism, and lowering blood pressure. The vegetarian nature of renal diets may improve lipid profiles. Adequate nutritional support promotes renal recovery and may prevent consequences of muscle weakness and immune dysfunction.

SUMMARY REVIEW

Urinary Tract Obstruction

1. Obstruction can occur anywhere in the urinary tract, and may be anatomic or functional, including renal stones, tumors, an enlarged prostate gland, or urethral strictures. The most serious complications are hydronephrosis, hydroureter, ureterohydronephrosis, and infection caused by the accumulation of urine behind the obstruction.
2. Compensatory hypertrophy and hyperfunction of the opposite kidney compensate for loss of function of the kidney with obstructive disease.
3. Relief of obstruction is usually followed by postobstructive diuresis and may cause fluid and electrolyte imbalance.
4. Kidney stones are caused by supersaturation of the urine with precipitation of stone-forming substances, changes in urine pH, or urinary tract infection. Most stones are unilateral.
5. The most common kidney stone is formed from calcium oxalate and most often causes obstruction by lodging in the ureter.
6. Obstructions of the bladder are a consequence of neurogenic or anatomic alteration of the bladder or both.
7. A neurogenic bladder is caused by a neural lesion that interrupts innervation of the bladder.
8. Upper motor neuron lesions above the pontine micturition center result in detrusor hyperreflexia and uninhibited or reflex bladder.
9. Upper motor neuron lesions between C2 and S1 result in overactive or hyperreflexive bladder function and vesicosphincter dyssynergia (lack of coordinated neuromuscular contraction).
10. Lower motor neuron lesions below S1 result in detrusor areflexia with underactive, hypotonic, or atonic bladder function.
11. OAB syndrome is an uncontrollable or premature contraction of the bladder that results in urgency with or without incontinence, frequency, and nocturia.
12. Anatomic obstructions to urine flow include prostatic enlargement, urethral stricture, and pelvic organ prolapse in women.
13. Partial obstruction of the bladder can result in overactive bladder contractions with urgency. There is deposition of collagen in the bladder wall over time, resulting in decreased bladder wall compliance and ineffective detrusor muscle contraction.
14. Renal cell carcinoma is the most common renal neoplasm. The larger neoplasms tend to metastasize to the lung, liver, and bone.
15. Bladder tumors are commonly composed of transitional cells with a papillary appearance and a high rate of recurrence.

Urinary Tract Infection

1. UTIs are commonly caused by the retrograde movement of bacteria into the urethra and bladder. UTIs are uncomplicated when the urinary system is normal or complicated when there is a defect or abnormality.

SUMMARY REVIEW—cont'd

2. Host defenses that protect against urinary tract infection include high osmolality and acidic pH of urine, mucus, Tamm-Horsfall and other antimicrobial proteins that activate the immune response, sphincters that prevent reflux, and urine flow that washes out bacteria.
3. Virulent uropathogens have pili or fimbriae, or both, that promote binding to the uroepithelium. Formation of biofilms enhances colonization and resists host defenses and antimicrobial therapy.
4. Cystitis is an inflammation of the bladder commonly caused by bacteria and may be acute or chronic. Manifestations of frequency, urgency, and dysuria are caused by inflammation.
5. Painful bladder syndrome/interstitial cystitis includes nonbacterial infectious cystitis (viral, mycobacterial, chlamydial, fungal), noninfectious cystitis (i.e., radiation injury), and interstitial cystitis, which is probably related to autoimmune injury.
6. Pyelonephritis is an acute or chronic inflammation of the renal pelvis often related to ascending infection and obstructive uropathies and may cause abscess formation and scarring with an alteration in renal function.

Glomerular Disorders

1. Glomerular disorders are a group of related diseases of the glomerulus that can be primary and are caused by immune injury, infection, ischemia, toxins or drugs, or vascular disorders or, secondarily, caused by systemic diseases.
2. Acute glomerulonephritis commonly results from inflammatory damage to the glomerulus as a consequence of immune reactions including deposition of circulating immune complexes, antibodies reacting in situ to planted antigens, and antibodies directed against the glomerular basement membrane.
3. The urine sediment may contain large amounts of protein (nephrotic sediment) or have red and white blood cells and protein (nephritic sediment).
4. Acute postinfectious glomerulonephritis is commonly associated with immune complex deposition in the glomerulus or in situ formation.
5. Lupus nephritis is caused by the formation of autoantibodies against double-stranded DNA (dsDNA) and nucleosomes in the glomerulus, causing inflammation and injury.
6. IgA nephropathy is the binding of abnormal IgA to mesangial cells in the glomerulus resulting in injury and mesangial proliferation.
7. Membranous nephropathy is complement-mediated glomerular injury with increased glomerular permeability and glomerulosclerosis.
8. RPGN is associated with injury that results in the proliferation of glomerular capillary endothelial cells and a rapid loss of renal function.
9. Membranous nephropathy is complement-mediated glomerular injury with increased glomerular permeability and glomerulosclerosis.
10. Membranoproliferative glomerulonephritis involves mesangial cell proliferation, complement deposition, and crescent formation.
11. Chronic glomerulonephritis is related to a variety of diseases that cause deterioration of the glomerulus and a progressive loss of renal function over a period of months to years, including diabetic nephropathy and lupus nephritis.
12. Diabetic nephropathy develops from metabolic, inflammatory, and microvascular complications associated with chronic hyperglycemia.
13. Lupus nephritis is caused by the formation of autoantibodies against dsDNA and nucleosomes in the glomerulus, causing inflammation and injury.
14. Nephrotic syndrome is the excretion of at least 3.5 g of protein (primarily albumin) in the urine per day primarily because of glomerular injury with increased capillary permeability and loss of membrane negative charge. The principal signs are hypoproteinemia, hyperlipidemia, and edema. The liver cannot produce enough protein to adequately compensate for urinary loss.

Acute Kidney Injury

1. AKI is the sudden decline in kidney function with decreased glomerular filtration and an increase in serum creatinine and BUN levels.
2. AKI is considered in three categories as prerenal, intrarenal, or postrenal and is usually accompanied by oliguria with elevated plasma BUN and plasma creatinine levels.
3. Prerenal acute renal failure is caused by decreased renal perfusion with a decreased GFR, ischemia, and tubular necrosis.
4. Intrarenal acute renal failure is associated with several systemic diseases but is commonly related to ATN.
5. Postrenal acute renal failure is associated with diseases that obstruct the flow of urine from the kidneys.
6. Oliguria is a urine output of less than 400 ml per day and can be caused by alterations in renal blood flow, tubular obstruction, or tubular fluid backleak, or by a combination of these events.

Chronic Kidney Disease

1. Chronic kidney disease is a progressive loss of renal function. Plasma creatinine levels gradually become elevated as GFR declines, sodium is lost in the urine, potassium is retained, acidosis develops, calcium metabolism and phosphate metabolism are altered, and erythropoietin production is diminished. All organs systems are affected by CRF.
2. Symptomatic changes usually do not become evident until renal function declines to less than 25%.
3. Glomerular hypertension, hyperfiltration, and tubulointerstitial inflammation and fibrosis contribute to the progression of chronic kidney disease. Proteinuria and angiotensin II promote the pathologic changes of chronic renal injury.
4. Uremic syndrome is a proinflammatory state with the accumulation of urea and other nitrogenous compounds as well as toxins and alterations in fluid, electrolyte, and acid-base balance that result from chronic kidney failure. All organ systems are affected and contribute to disease symptoms.

CHAPTER

39

Alterations of Renal and Urinary Tract Function in Children

Patti Ring and Sue E. Huether

evolve WEBSITE

http://evolve.elsevier.com/McCance/
- Review Questions and Answers

CHAPTER OUTLINE

Renal and urinary disorders occur in children as well as adults. In childhood, however, the kidney and genitourinary structures are continuing to develop, so renal dysfunction may be associated with mechanisms and manifestations that are different from those in adults. In addition, some renal and urinary disorders are congenital and involve structural anomalies of the kidney and urinary drainage system.

STRUCTURE AND FUNCTION OF THE URINARY SYSTEM IN CHILDREN

Development of the Urinary System

The embryonic urinary system develops as three sets of sequentially replaced organs: the pronephros, mesonephros, and metanephros. The **pronephros** is a nonfunctional structure that arises at the level of the cervical and upper thoracic regions during the third fetal week and connects the primitive wolffian duct to the cloaca as the foundation for male sexual development (Figure 39-1). The development of the **mesonephros** and **metanephros** is described in Figure 39-1. The Wilms tumor 1 *(WT1)* gene plays an important role at all stages of kidney development and maintenance of kidney function. The wingless type signaling (WNT signaling) transduction pathway also is important for mesenchyme growth and differentiation.[1,2]

After glomeruli and tubules form, the tissues organize and progressively differentiate over approximately 30 days. Initial glomerular development is staggered, so there are glomeruli in various stages. In fact, a few of the first glomeruli formed degenerate and disappear during the later stages of fetal development. Progressive development continues into the ninth fetal month, when all metanephrogenic tissue then disappears.

As the embryo develops and the vertebral column straightens, the kidneys appear to ascend to the sacral area at about 6 weeks, to the third lumbar area by the third month, and to the first lumbar area at term. The kidneys rotate 90 degrees as they ascend so that renal tissue is lateral and the collecting system is medial.

While the kidneys mature, the *cloaca* becomes the urogenital sinus. It then differentiates into the vesicourethral canal, which forms the bladder and the upper urethra, and the urogenital sinus, which forms the main part of the urethra.

At birth the kidneys occupy a large portion of the posterior abdominal wall, and the ureters are proportionately shorter than those of an adult. All the nephrons are present at birth, and their number does not increase as the kidney grows and

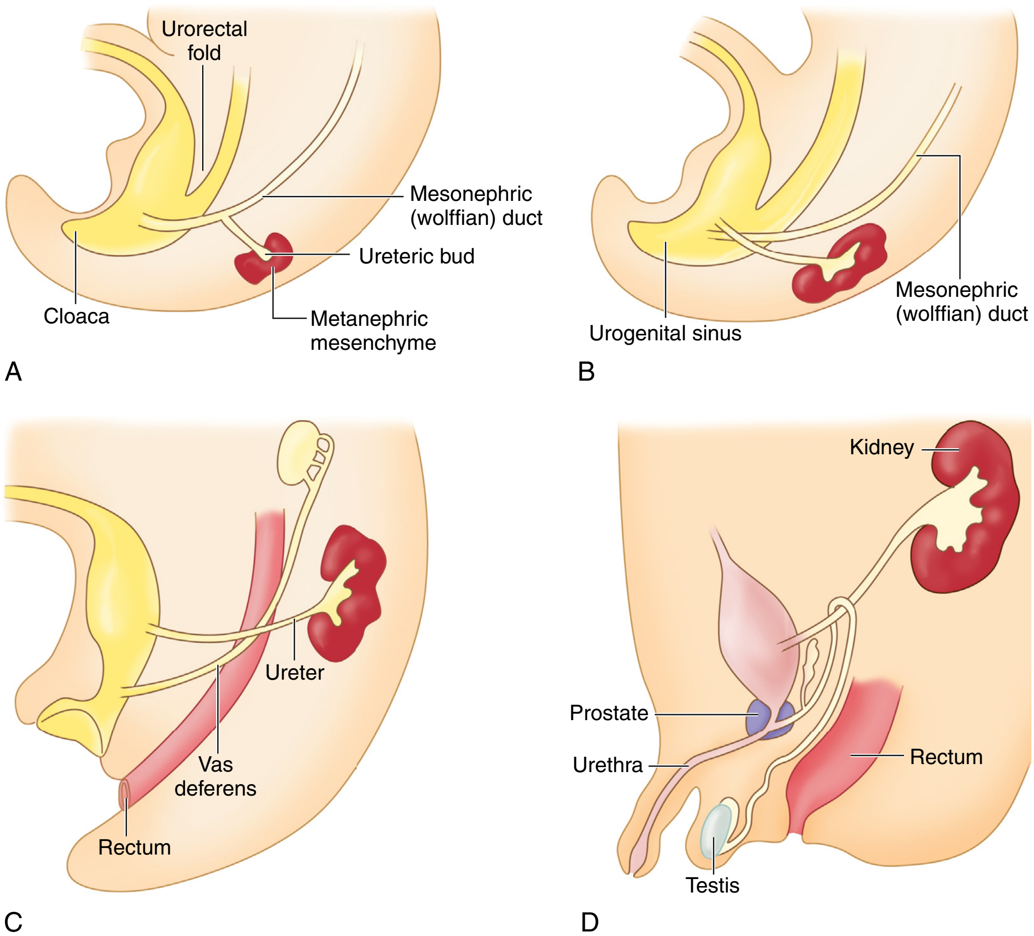

FIGURE 39-1 **Embryonic Development of the Kidneys.** The mesonephros begins development more caudally about the fourth fetal week and begins excretory function in the sixth week. Most of the mesonephros degenerates and disappears by the end of the embryonic period. The metanephros, the permanent kidney, arises distal to the bifurcation of the aorta and develops from two different sources: (1) the *ureteric bud* (metanephric duct) forms as an outgrowth of the mesonephritic (wolffian) duct and grows dorsocranially and starts subdividing to become the collecting system for the kidneys by forming the ureter, renal pelvis, and calyces; by the fifth fetal month it will have progressively branched into the collecting ducts; and (2) the *metanephrogenic mesenchyme* sits atop the terminal branches of the collecting ducts and develops into primitive glomeruli and uriniferous tubules **(A).** Genetic information from the metanephrogenic mesenchyme guides the development of the ureteric bud. Establishing the connection between the uriniferous tubules and the collecting ducts is a vital part of kidney development; errors in this stage can result in polycystic kidneys. As the embryo grows, the definitive kidneys migrate from the caudal position to the lumbar region and the ureters connect with the bladder **(B-D).** In the 8-week male embryo, the wolffian duct begins to give rise to the epididymis, the seminal vesicles, and the caudal part of the vas deferens **(C).** The external genitalia develop between 8 and 16 weeks, and testicular descent begins in month 7 of gestation **(D).** (From Goldman L, Schafer AI: *Goldman's Cecil medicine,* ed 24, Philadelphia, 2012, Saunders.)

matures. The kidney reaches adult size by adolescence and, because of maturation of the tubular system, increases in weight 10-fold from the time of birth.

Urine formation and excretion begin by the third month of gestation, contributing to the amniotic fluid. In infancy the bladder lies close to the abdominal wall, making urinary bladder aspiration for diagnostic purposes a relatively simple procedure. The bladder descends into the pelvis with growth, changing from a cylindrical organ to the adult pyramidal shape. Although small amounts of urine are found in the bladder at birth, the newborn may not void for 12 to 24 hours.

Immediately at birth the renal blood flow and glomerular filtration rate (GFR) increase because of a decrease in vascular resistance and the need to perform excretory functions no longer performed by the placenta. Renal vascular resistance remains higher in newborns and infants, however, which may be attributed to increased levels of circulating renin. The resistance progressively declines during the first year of development, with an increasing fraction of the cardiac output going to the kidney. The GFR continues to increase, achieving adult levels by 2 years of age.

Fluid and Electrolyte Balance in Children

Because the kidney develops from the center toward the periphery, renal distribution of blood flow during the newborn period is primarily to the renal medulla. The result is a preferential flow to

the medullary nephrons, which have comparatively short loops at this stage of development. The combination of higher blood flow and shorter loops produces a more dilute urine—approximately 600 to 700 mOsm (compared with 800 to 1200 mOsm in adults) (see Chapter 3). The immature kidney is also less responsive to the actions of antidiuretic hormone (vasopressin) (see Figure 3-5).[3] The dilute urine is accentuated by a low rate of urea excretion, which is necessary to establish the concentration gradient in the medulla. Urea excretion is low primarily because infants are in a high anabolic state and use their protein for growth.

Because of a high hydrogen ion concentration, limited ability to regulate the internal environment, and lowered osmotic pressure, the infant's renal system has a narrow chemical safety margin. The immaturity and smaller surface area of the tubules also may diminish the water reabsorption response to antidiuretic hormone (ADH). An immature tubular transport capacity means that the ability to excrete a potassium load, reabsorb bicarbonate, or buffer hydrogen with ammonia does not become efficient until approximately 2 years of age. Consequently, any disturbance such as diarrhea, infection, fasting for diagnostic tests, or improper feeding can rapidly lead to severe acidosis and fluid imbalance because the infant can rapidly develop over- or underhydration, or edema (see Chapter 3).[4]

After birth the proportion of total body water to body weight does not change markedly. Considerable change occurs, however, in the location of that body water as the child matures (see Chapter 3). Compared to an adult, the percentage of extracellular fluid volume of the newborn infant is nearly double. Decrease in extracellular fluid volume occurs in two different periods of rapid growth—infancy and adolescence.

An infant has not only a greater content of extracellular fluid but also a greater rate of fluid exchange. The adult consumes and excretes approximately 2000 ml of water daily, representing 5% of the total body fluid and 14% of the extracellular fluid. In contrast, the infant's daily exchange of 600 to 700 ml represents 290% of the total or nearly 50% of the extracellular volume, making control of dehydration and overhydration more difficult.

The composition of body fluids differs slightly with age. The total electrolyte concentration in extracellular fluids is greater in the newborn than in the adult. The concentrations of sodium, chloride, phosphates, and organic acids are also greater. The concentration of bicarbonate ions is lower in the infant than in the older child, with a mild acidosis evidenced by a lowered pH. These variations, combined with a lowered plasma protein level, cause a reduced oncotic pressure of the vascular compartment and favor accumulation of fluid in the tissue spaces and an increased GFR. In the healthy child these differences remain for a few weeks or months. The premature infant and the normal newborn infant are usually in a state of well-compensated acidosis and potential edema.

ALTERATIONS IN RENAL AND BLADDER FUNCTION IN CHILDREN

Congenital Abnormalities

Congenital abnormalities of the kidney and urinary tract occur in about 1 out of 500 newborns.[5] Structural abnormalities range from minor, nonpathologic, or easily correctable anomalies to those that are incompatible with life. For example, the kidneys may fail to ascend from the pelvis to the abdomen, causing ectopic kidneys—which usually function normally. The kidneys also may fuse in the midline as they ascend, causing a single U-shaped **horseshoe kidney,** with an incidence rate of 0.25 to 0.61 per 10,000 births.[6] Approximately one third of individuals with horseshoe kidneys are asymptomatic, and the most common problems are hydronephrosis, infection, stone formation, and tumors.[7] Collectively, structural anomalies of the renal system account for approximately 45% of cases of renal failure in children.

Some anomalies are obvious at birth, whereas others remain silent or become apparent in childhood. The following structural anomalies are commonly associated with urinary tract malformations[8]:

- Low-set, malformed ears
- Chromosomal disorders, especially trisomy 13 (Patau syndrome) and trisomy 18
- Absent abdominal muscles (prune-belly syndrome)
- Anomalies of the spinal cord and lower extremities
- Imperforate anus or genital deviation
- Wilms tumor
- Congenital ascites
- Cystic disease of the liver
- Positive family history of renal disease (e.g., hereditary nephritis or renal cystic disease)

Hypospadias

Hypospadias is a congenital condition in which the urethral meatus is located on the ventral side or undersurface of the penis. The meatus can be located anywhere on the glans, the penile shaft, the base of the penis, the penoscrotal junction, or the perineum (Figure 39-2). This is the most common anomaly of the penis and occurs in about 1 in 125 infant boys. The etiology is multifactorial and related to disruptions in male hormones, including testosterone biosynthesis defects, steroid 5α-reductase type 2 mutations, genes associated with penile and urethral development, hormones administered for in vitro fertilization, advanced maternal age, and other environmental factors.[9] **Chordee,** or penile torsion, may accompany hypospadias. In chordee a shortage of skin on the ventral surface causes the penis to bend or to "bow" ventrally (Figure 39-3). *Penile torsion* is a counterclockwise twist of the penile shaft. Partial absence of the foreskin, inguinal hernia, and cryptorchidism (undescended testes; see Chapter 25) are associated with the anomaly.[10]

The goals for corrective surgery on the child with hypospadias are: (1) a straight penis when erect to facilitate sexual intercourse as an adult, (2) a uniform urethra of adequate caliber to prevent spraying during urinations, (3) a cosmetic appearance satisfactory to the individual, and (4) repair completed in as few procedures as possible. Formerly performed in two or more stages, hypospadias repairs are now done in one stage. Improvements in microsurgical techniques have enhanced outcomes and decreased complications and the need for follow-up surgery. Surgery is usually performed between 4 and 12 months of age.[11]

Epispadias

Epispadias and exstrophy of the bladder are the same congenital defect but expressed to a different degree. The dorsal urethra is not fused in epispadias and has failed to form into a tube. In male epispadias the urethral opening is on the dorsal surface of the penis. In females a cleft along the ventral urethra usually extends to the bladder neck. The incidence of epispadias is about 1 in 40,000 to 118,000 births. About twice as many boys as girls present with this defect.

In boys the urethral opening may be small and situated behind the glans (anterior epispadias), or a fissure may extend the entire length of the penis and into the bladder neck (posterior epispadias). The majority of children with epispadias can achieve urinary continence, although surgical intervention may be necessary.[12]

FIGURE 39-4 Exstrophy of Bladder. (Courtesy H. Gil Rushton, MD, Children's National Medical Center, Washington, DC; from Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children,* ed 9, St Louis, 2011, Mosby.)

Exstrophy of the Bladder

Exstrophy of the bladder is a rare extensive congenital anomaly of herniation of the bladder through the abdominal wall with failure of the abdominal muscles, pelvic ring, and pelvic floor musculature to fuse in the midline (Figure 39-4). The posterior portion of the bladder mucosa is exposed and appears bright red. The prevalence of exstrophy of the bladder is about 2.07 in 100,000 live births. Boys are predominant with a ratio of about 2:1 and this complication is more common in whites.[13]

Exstrophy of the bladder is caused by intrauterine failure of the abdominal wall and the mesoderm of the anterior bladder to fuse. Urine seeps onto the abdominal wall from the ureters, causing a constant odor of urine and excoriation of the surrounding skin. The rectus muscles below the umbilicus are separated, and the pubic rami (bony projections of the pubic bone) are not joined. The clitoris in girls is divided into two halves with the urethra between them. The penis in boys is epispadic. In addition, the posterior aspect of the pelvis is externally rotated, which retroverts the acetabula and causes external rotation of the feet. This causes a waddling gait when the child

first learns to walk, but most children quickly learn to compensate. Surgical intervention may be required.[14] Because the exposed bladder mucosa becomes hyperemic and edematous, it bleeds easily and is painful. It should be covered with Silastic or a plastic dressing (e.g., kitchen plastic wrap) for protection from diaper irritation while permitting urine drainage. The unrepaired exstrophic bladder is cosmetically unacceptable and prone to cancerous changes as soon as 1 year after birth. Ideally the bladder and pubic defect should be closed before the infant is 72 hours old. Surgical reconstruction is usually performed within the first year either as a complete primary repair or as staged procedures. Staged procedures may include bladder augmentation and bladder neck and epispadias repair.[15] Objectives of management include preservation of renal function, attainment of urinary control, prevention of infection, reconstructive repair of the defect, and improvement of sexual function and quality of life.

Cloacal exstrophy is the most rare and severe form of bladder exstrophy. The intestines, genitourinary tract, and spine may be involved, and reconstruction with restored urine and fecal control is difficult.

Ureteropelvic Junction Obstruction

Ureteropelvic junction (UPJ) obstruction is a blockage of the tapered point where the renal pelvis transitions into the ureter.[16] An intrinsic malformation of smooth muscle hypertrophy and fibrosis produces obstruction in 90% of cases.[17] It is the most common cause of hydronephrosis in neonates.[18] Diagnosis is made by ultrasound. Open or endoscopic surgery to relieve the obstruction occurs if there is decline of renal drainage or function.[19] During infancy or childhood, **secondary ureteropelvic junction obstruction** is caused by kinking or secondary scarring in the presence of high-grade vesicoureteral reflux. Children with UPJ obstruction have an increased risk of vesicoureteral reflux. Other defects are sometimes associated with ureteral duplication including complete ureteral duplication (abnormal growth of two ureters and ureteral orifices draining a single kidney), incomplete duplication (bifurcation of the ureter terminates into one ureteral orifice and serves a single kidney), and ureterocele (cystic dilation of the intravesical ureter). Obstruction of the distant ureter (ureterovesical junction obstruction) causes dilation of the entire ureter, renal pelvis, and calyceal system (megaureter). Megaureter can occur when a short acontractile segment of the ureter develops just above the ureterovesical junction or from ureteral reflux.[20]

Bladder Outlet Obstruction

Congenital causes of bladder outlet obstruction are rare and include urethral valves, urethral polyps, and urethral atresia. A **urethral valve** is a thin membrane that occludes the urethral lumen and obstructs urinary outflow in males. It is the most common cause of congenital lower urinary tract obstruction and renal failure. Most valves occur in the posterior urethra, although a few arise from the embryologically distinct anterior urethra.[21] **Urethral polyps** arising from the prostatic urethra are rare. Symptoms of polyps may include hematuria; voiding issues, such as urinary retention or straining to void; and dilation of the upper tracts.[22] **Urethral atresia** is absence of the urethra and is rare.

Congenital urethral valves or polyps can be diagnosed with prenatal ultrasound and treated with prenatal bladder shunting or with resection during the first days of life.[23] Infants with significant renal (and pulmonary) hypoplasia who are unable to undergo primary resection may be managed with a vesicostomy, a small opening created between the bladder wall and the abdomen.[24]

Hypoplastic or Dysplastic Kidneys

During embryologic development the ureteric duct grows into the metanephric tissue, triggering the formation of the kidneys. If this growth does not occur, the kidney is absent—a condition called **renal aplasia.** A **hypoplastic kidney** is small with a decreased number of nephrons. These conditions may be unilateral or bilateral; the occurrence may be incidental or familial.[24] Bilateral hypoplastic kidneys are a common cause of chronic renal failure in children. Segmental hypoplasia (the Ask-Upmark kidney) may be congenital or secondary to vesicoureteral reflux.[25]

Renal dysplasia usually results from abnormal differentiation of the renal tissues; for example, primitive glomeruli and tubules, cysts, and nonrenal tissue (such as cartilage) are found in the dysplastic kidney. Dysplasia may be secondary to antenatal obstruction of the urinary tract from ureteroceles, posterior urethral valves, or prune-belly syndrome (congenital absence of abdominal muscles).

Renal Agenesis

Renal agenesis (the absence of one or both kidneys) may be unilateral or bilateral, and may occur randomly or be hereditary. It may be an isolated entity or associated with anomalies in other organs.[26]

Unilateral renal agenesis occurs in approximately 1 of 1000 live births in the United States. Males are more often affected, and it is usually the left kidney that is absent. The single kidney is often completely normal so that the child can expect a normal, healthy life. The normal solitary kidney grows because of compensatory hypertrophy before[27] and after birth. By the time the child is several years older, the volume of this kidney may approach twice the normal size. In some instances the single kidney is abnormally formed and associated with abnormalities of its collecting system.[28] Extrarenal congenital abnormalities are relatively more common with unilateral renal agenesis.

Bilateral renal agenesis (also called **Potter syndrome**) is a rare disorder incompatible with extrauterine life.[29] Approximately 75% of affected infants are male. Bilateral renal agenesis results from either an abnormal development of the normal progression from pronephros to mesonephros to metanephros or an isolated bilateral failure of development of the ureteral buds. The term *Potter syndrome* refers to the association with a specific group of facial anomalies (wide-set eyes, parrot-beak nose, low-set ears, and receding chin). Oligohydramnios (low amount of amniotic fluid) leads to underdeveloped lungs. Affected infants rarely live more than a few hours because

of pulmonary insufficiency. Approximately 40% of affected infants are stillborn. Renal agenesis can be detected prenatally by ultrasound.

Polycystic Kidneys

Autosomal dominant polycystic kidney disease (ADPKD) is an inherited disorder that occurs in about 1 in 1000 live births in the United States. Mutations of two genes, *PKD-1* (chromosome 16) and *PKD-2* (chromosome 4), account for the disease most often presenting in late childhood or adulthood. The gene products (polycystins) regulate growth and differentiation of the tubular epithelium.[30] Defects in the formation of epithelial cells and their cilium result in cyst formation and obstruction accompanied by destruction of renal parenchyma, interstitial fibrosis, and loss of functional nephrons. Cysts may occur in other organs including the liver, ovaries, and pancreas. Hypertension, heart valve defects, and cerebral and aortic aneurysms may develop. Urinary tract infection, hematuria, and flank pain may occur. Diagnosis is usually confirmed by ultrasound. Individuals may live for decades before developing symptoms of renal disease and not all progress to end-stage disease.[31] Autosomal recessive PKD *(ARPKD)* with cystic changes in the kidney and liver is often first suspected on a prenatal ultrasound. The gene mutation for *ARPKD (PKHD1)* encodes a protein important to maintaining structural integrity and cellular function of the kidneys and liver. Renal replacement therapy is usually required during childhood or adolescence. Biomarkers and therapies to slow the progression of cyst development and renal failure are being studied.[32]

Glomerular Disorders

The most common glomerular disorders in children are glomerulonephritis, nephrotic syndrome, and hemolytic uremic syndrome. Most glomerular diseases are acquired and immunologically mediated. The disease can be acute or chronic. The likelihood of developing renal failure depends on the specific condition. The most common glomerular disorders in children are presented below.

Glomerulonephritis

Acute glomerulonephritis includes a number of renal disorders in which proliferation and inflammation of the glomeruli are secondary to an immune mechanism (Table 39-1). (The major glomerulopathies and their histologic characteristics can be reviewed in Chapter 38 and Table 38-7.) The symptoms usually include the sudden onset of hematuria with red blood cell casts and proteinuria, and can be accompanied by renal salt and water retention, edema, hypertension, and in severe cases azotemia (i.e., decreased glomerular filtration rate). Chronic glomerulonephritis is the causative factor for 30% to 50% of renal failure in children and is the condition responsible for most school-age and teenage children requiring dialysis and kidney transplantation.

TABLE 39-1 PRIMARY GLOMERULONEPHRITIS IN CHILDREN

CLASSIFICATION	FINDINGS
Cause	Poststreptococcal infection Related to other bacterial or viral infection Unknown
Immunologic mechanism	Antigen-antibody complex deposition Planted antigens with immune complex formed in situ Formation of antiglomerular basement membrane antibodies (rare) No immunologic cause established
Histopathology	No lesion Diffuse, focal, or segmented Membranous, proliferative, or combination of types Lobular, exudative, necrotizing, and other types Chronic with glomerular proliferation
Clinical manifestations of disease	Acute glomerulonephritis Persistent (chronic) glomerulonephritis Idiopathic nephrotic syndrome

Acute Poststreptococcal Glomerulonephritis. **Acute poststreptococcal glomerulonephritis (PSGN)** is one of the most common immune complex–mediated renal diseases in children ages 5 to 15 years and it is representative of acute glomerulonephritis. It most commonly occurs after a throat (pharyngitis) or skin (impetigo) infection with nephritogenic strains of group A beta-hemolytic streptococci, although other bacteria (e.g., Staphylococcus) and viruses also may be responsible. Sporadic occurrences of infectious glomerulonephritis have been observed after bacterial endocarditis, which may be associated with streptococcal or staphylococcal microorganisms, or after viral diseases, such as varicella and hepatitides B and C. Glomerulonephritis develops with the deposition of antigen-antibody complexes (immunoglobulin G [IgG], IgA, and C_3 complement) (see Chapter 8) in the glomerulus or the antigen may be trapped within the glomerulus and immune complexes formed in situ.[33] The exact mechanism of immune complex formation is unknown. The immune complexes initiate inflammation and glomerular injury. Immunofluorescence microscopy shows lumpy deposits of immunoglobulin (IgG) and complement (C3) on the glomerular basement membrane (Figure 39-5). The thickened glomerular membrane contributes to decreased GFR. Activated complement, inflammatory cytokines, oxidants, proteases, and growth factors attack epithelial cells, alter membrane permeability, and cause hematuria and proteinuria. More severe renal disease is observed after a prolonged infection and before antibiotic therapy. Hypertension occurs primarily because of fluid retention.[34]

Symptoms usually begin 1 to 2 weeks after an upper respiratory tract infection (more common during cold weather) and up to 6 weeks after skin infections, such as impetigo (more common during warm, humid weather). The onset of symptoms in the child is abrupt, varying with disease severity. The urine is usually smoky brown or cola colored because of the presence of red blood cells. The child may complain of flank or midabdominal pain, irritability, general malaise, and fever. Acute hypertension may cause headache, vomiting,

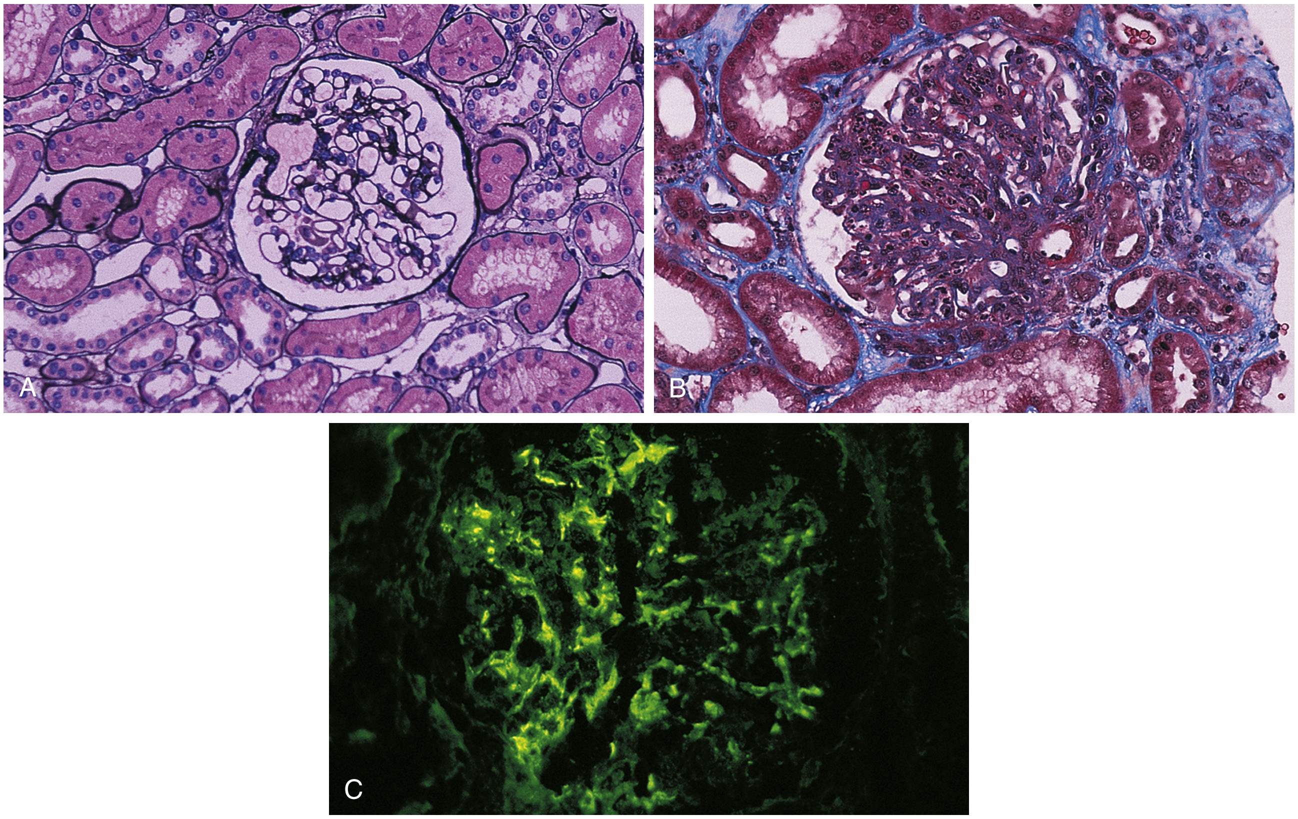

FIGURE 39-5 Glomerulonephritis. **A,** Normal glomerulus; note single-contoured walls, patent capillaries, inconspicuous mesangium, and degree of cellularity. (Periodic acid–methenamine silver stain.) **B,** Acute postinfectious glomerulonephritis. There is considerable increase in cellularity, mainly because of accumulation of numerous polymorphonuclear leukocytes in capillary lumina. Note numerous subepithelial hump-shaped fuchsinophilic deposits in many capillary walls. Protein precipitates (hyalinization) are in the arteriole. (Masson trichrome stain.) **C,** Postinfectious glomerulonephritis. Irregular mesangial and capillary wall immunostaining for C3. (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

somnolence, and other central nervous system (CNS) manifestations, including seizures. Cardiovascular symptoms are related to circulatory overload and are compounded by hypertension. These include dyspnea, tachypnea, and an enlarged, tender liver. The most severely affected children develop acute renal failure with oliguria. As many as half the children affected are asymptomatic. The disease is usually mild and runs its course in 1 month, but urine abnormalities may be found up to 1 year after the onset. Less than 5% of children become oliguric or develop rapidly progressive glomerulonephritis, or progress to chronic glomerulonephritis. Prolonged proteinuria and abnormal GFR indicate an unfavorable prognosis. More than 95% recover completely.

Acute glomerulonephritis (AGN) may be accompanied by a positive throat or skin culture for *Streptococcus*. Antistreptolysin-O titers confirm a recent streptococcal infection. Antihyaluronidase, antideoxyribonuclease B, and antistreptokinase antibody are other diagnostic markers. Serum complement level is decreased, and serum creatinine concentration and blood urea nitrogen level are elevated. The urine usually contains red blood cells and proteins. Treatment is supportive and symptom specific. For severe disease oliguria and hypertension are common, and fluid, sodium, and potassium intakes are restricted. Antihypertensive medication and diuretic agents may be indicated during the acute phase.

Henoch-Schönlein Purpura Nephritis. **Henoch-Schönlein purpura (HSP) nephritis** (**anaphylactoid purpura**) is an immune-mediated IgA vasculitis that affects glomerular blood vessels, causing inflammation and damage to the vessel wall (see Chapter 38 for the pathophysiology of IgA nephropathy). The disease also involves small vessels in the skin and gut. Classic symptoms of HSP include palpable purpura, arthritis, abdominal pain, and renal disease characterized by gross or microscopic hematuria with mild or no proteinuria. Kidney biopsy demonstrates IgA deposition in the mesangium[35] (see Table 38-7 in Chapter 38). The development of interstitial fibrosis and crescent formation from subepithelial immune deposits along the glomeruli increases the risk of chronic renal failure.[36] Most children recover with supportive care, although some progress to kidney failure. Severe symptoms require corticosteroids and other immunosuppressant drugs.[37]

Hemolytic Uremic Syndrome

Hemolytic uremic syndrome (HUS) is an acute disorder characterized by microangiopathic hemolytic anemia, thrombocytopenia, and renal impairment. It is the most common community-acquired cause of acute renal failure in young

children. The disease occurs most frequently in infants and children younger than 4 years of age. The prognosis has improved dramatically in recent years, with more than 90% of children surviving and most regaining normal renal function.

PATHOPHYSIOLOGY. HUS has been associated with both bacterial and viral agents, as well as endotoxins, especially those from *Escherichia coli* 0157:H7 and recently *Escherichia coli* 0104:H4 (Shiga toxins).[38] Potential sources of exposure include animals, unpasteurized beverages, and contaminated meat and vegetables. The disease also occurs with cancer and use of chemotherapeutic agents.[39] In HUS, verotoxin (Shiga toxin) from *E. coli* is absorbed from the intestines into the blood, binds to polymorphonuclear leukocytes, and is transported to the kidney, causing a cascade of effects, including lysis of glomerular capillary endothelial cells, separation of endothelial cells from the basement membrane, activation and aggregation of platelets, and activation of the coagulation cascade. The glomerular arterioles become swollen and occluded with platelets and fibrin clots. There is decreased glomerular filtration, and the damaged glomerular membrane results in hematuria and proteinuria. Oliguria with renal failure occurs in up to 50% of children. Narrowed vessels damage passing erythrocytes. These damaged red blood cells, identified as burr cells, helmet cells, and fragmented red blood cells, are removed by the spleen, causing acute hemolytic anemia. Fibrinolysis, the process of dissolution of a clot, acts on precipitated fibrin, causing the fibrin split products to appear in serum and urine. The platelet clustering within damaged vessels, combined with the damage and removal of platelets, produces thrombocytopenia. Fibrin-rich thrombi can be found throughout the microcirculation.[40] Other tissues, including the brain, liver, heart, and intestines, are often involved, which portends a poorer prognosis.

CLINICAL MANIFESTATIONS. Typical HUS is preceded by a prodromal gastrointestinal (GI) illness with diarrhea (usually caused by Shiga toxin–producing *E. coli*) and is known as D+ HUS. Less frequently atypical or sporadic HUS is preceded by an unknown event or an upper respiratory tract infection and is known as D− HUS. A rare familial form is associated with mutations in complement proteins. P-hemolytic-uremic syndrome is associated with *Streptococcus pneumoniae* respiratory tract infection and is mediated by neuraminidase that injures glomerular epithelial cells. It occurs without diarrhea. The onset of D+ HUS occurs about 1 to 2 weeks after a GI illness with a symptom-free 1- to 5-day period. There is sudden onset of pallor, bruising or purpura, irritability, and oliguria. Slight fever, anorexia, vomiting, diarrhea (with the stool characteristically watery and blood stained—hemorrhagic diarrhea), abdominal pain, mild jaundice, and circulatory overload are accompanying symptoms. Seizures and lethargy indicate CNS involvement. Renal failure is apparent within 2 days to 2 weeks of onset. The renal failure causes metabolic acidosis, uremia, hyperkalemia, and often hypertension.

EVALUATION AND TREATMENT. Clinical evaluation includes history of preexisting illness, presenting symptoms, and urine and blood analysis. Antibiotics are not used in the initial treatment because they increase Shiga toxin release and increase the risk of HUS. Management consists of maintaining nutrition and hydration (to dilute toxins) and controlling hypertension, hyperkalemia, and seizures.[41] When renal failure occurs, dialysis is indicated. Blood transfusions with packed red blood cells are needed to maintain reasonable hemoglobin levels. Most children recover; however, some will develop hypertension, proteinuria, or renal insufficiency or failure. Death usually occurs from complications related to CNS or myocardial involvement.[42] Preventing Shiga toxin–producing bacterial infection (i.e., *E. coli*) prevents HUS.

Nephrotic Syndrome

Nephrotic syndrome is a term used to describe a symptom complex characterized by proteinuria, hypoalbuminemia, hyperlipidemia, and edema. The syndrome is more common in children than adults. When no identifiable cause is found, the condition is termed **primary (idiopathic) nephrotic syndrome.** If it results from a systemic disease or other causes (e.g., drugs, toxins, diabetes mellitus, lupus nephritis) it is called **secondary nephrotic syndrome**. Primary nephrotic syndrome is usually described by histopathologic results (i.e., minimal change nephropathy [MCN], focal segmental glomerulosclerosis [FSGS], membranous nephropathy [MN], or membranoproliferative glomerulonephritis [MPGN]) (see Table 38-7). Secondary nephrotic syndrome has the same patterns of histopathology but is associated with an underlying cause.

Approximately 95% of cases of nephrotic syndrome in children occur in the absence of systemic or preexisting renal disease. Primary nephrotic syndrome is found predominantly in preschool children, with a peak incidence of onset between 2 and 3 years of age. Onset is rare after 8 years of age. Boys are affected more often than girls. No prevalent racial or geographic distributions are evident. The incidence is approximately 2 to 3 per 100,000 children per year.[43]

PATHOPHYSIOLOGY. The cause of nephrotic syndrome in children is usually idiopathic and includes minimal change nephropathy (85%), FSGS (10%), and mesangial proliferative nephropathy (MPN) (5%) (see Chapter 38, Table 38-7).[44] Secondary nephrotic syndrome may develop during the course of several different renal or systemic diseases. The pathophysiology (see Figure 38-10) and common clinical manifestations of nephrotic syndrome in adults are described in Chapter 38 (Table 38-8), and are similar in children. The most common causes of nephrotic syndrome in children are presented here.

Minimal change nephropathy (MCN), also known as *lipoid nephrosis,* is the most common cause of nephrotic syndrome in children ages 2 to 6 years. A systemic immune mechanism is a likely cause of the disease, but the true etiology is unknown. The mechanism of increased glomerular permeability is unknown but is related, in part, to release of permeability factors from abnormal circulating T cells that injure the glomerular epithelial cells. The glomeruli appear normal by light microscopy, and immunoglobulin deposition is usually absent. The only change is *fusion of epithelial cell podocyte foot processes*.[44] There are few other renal structural abnormalities. Loss of the electrical negative charge and increased permeability within the glomerular capillary wall lead to albuminuria.[45] Hyperlipidemia leads to

hyperlipiduria and primarily results from increased hepatic lipid synthesis and decreased plasma lipid catabolism.[46]

Focal segmental glomerulosclerosis (FSGS) is present in approximately 10% to 15% of children with nephrotic syndrome and is more common in blacks. The frequency of FSGS is increasing in children and adults.[47] The primary injury is effacement (thinning or deletion) of epithelial podocytes, with a significant increase in pore size leading to impairment of size selectivity and proteinuria. Progressive disease results in proliferation of endothelial and mesangial cells with occlusion and sclerosis of glomerular capillaries. The more severe the proteinuria, the more likely that end-stage renal disease will occur.[48]

Edema is the classic symptom of nephrotic syndrome. Several factors contribute to edema formation with hypoalbuminemia (decreased plasma oncotic pressure) and sodium retention as major contributors. The movement of fluid from the vascular to the interstitial space can decrease blood volume and increase the activity of aldosterone and antidiuretic hormone (vasopressin), and decrease atrial natriuretic peptide concentration, all of which promote fluid retention.[49]

Hyperlipidemia occurs in inverse proportion to the decrease in plasma proteins, particularly albumin. There are high concentrations of triglycerides, low-density lipoprotein (LDL), and very-low-density lipoprotein (VLDL) cholesterol. High-density lipoprotein (HDL) cholesterol concentration is decreased. Hypoalbuminemia leads to a deficiency in the carrier protein for the transport of fatty acids, and they remain elevated in the serum. There is hepatic compensation for hypoalbuminemia with increased synthesis of lipoproteins to maintain plasma oncotic pressure. Hypoalbuminemia also leads to an increased hepatic stimulus for synthesis of LDL and VLDL cholesterol by the liver. Serum lipids may remain elevated from 1 to 3 months after remission of proteinuria.

Hypercoagulation with risk for arterial or venous thrombosis results from abnormalities in the coagulation pathways during nephrotic syndrome. Although rare, thrombosis can occur in the brain or lung. Family history and predisposing risk factors should be evaluated. Anticoagulants may be required.[50]

Congenital, or **infantile, nephrotic syndrome (Finnish type)** is caused by an autosomal recessive mutation of the *NPHS1* gene that encodes an immunoglobulin-like protein, nephrin, at the podocyte slit membrane. Lack of nephrin causes heavy proteinuria.[51] The disease usually manifests within the first 3 to 12 months of life, and these infants do not respond to corticosteroid treatment.[52]

CLINICAL MANIFESTATIONS. Onset of nephrotic syndrome is often insidious, with periorbital edema as the first sign. The edema is most noticeable in the morning but subsides during the day as fluid shifts to the abdomen and lower extremities (Figure 39-6). Parents may notice diminished, frothy, or foamy urine output; when edema becomes pronounced with ascites, respiratory difficulty from pleural effusion and labial or scrotal swelling may develop.

Edema of the intestinal mucosa may cause diarrhea, anorexia, and poor absorption. Edema often masks the malnutrition caused by malabsorption and protein loss. Because of protein deficiency, changes in the quality of hair indicate a malnourished state. Pallor, with shiny skin and prominent veins, may be present. Blood pressure is usually normal. The child has an increased susceptibility to infection, especially pneumonia, peritonitis, cellulitis, and septicemia. Irritability, fatigue, and lethargy are common. Infants born with congenital nephrotic syndrome have large fontanels and separated cranial sutures.

EVALUATION AND TREATMENT. The diagnosis of nephrotic syndrome is evident from the clinical presentation and findings of proteinuria, hyperlipidemia, and edema. Several diagnostic tests, including kidney biopsy, may be required to determine whether the cause is an intrinsic renal disease or a consequence of systemic disease.

The goals of treatment are to reduce the excretion of protein and to maintain protein-free urine. Prevention or treatment of infection, control of edema, establishment of a balanced nutritional state, and restoration of normal metabolic processes also are important in managing the disorder and avoiding adverse aspects of treatment. Basic management of nephrotic syndrome includes administering glucocorticosteroids (prednisone); adhering to a low-sodium, well-balanced diet; performing good skin care; and, if edema becomes problematic, administering diuretics (furosemide, metolazone).[53] Angiotensin-converting enzyme (ACE) inhibitors inhibit formation of

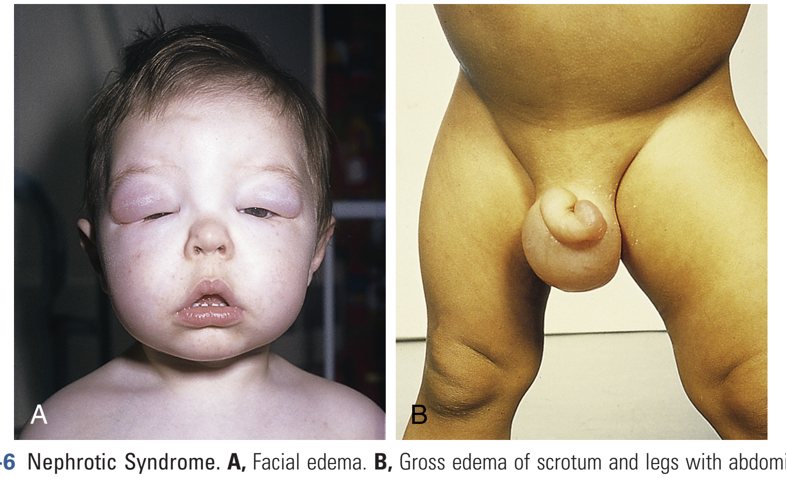

FIGURE 39-6 Nephrotic Syndrome. **A,** Facial edema. **B,** Gross edema of scrotum and legs with abdominal distention from ascites. (From Lissauer T, Clayden G: *Illustrated textbook of paediatrics,* ed 4, London, 2012, Mosby.)

angiotensin II and aldosterone, resulting in decreased blood pressure and decreased renal sodium reabsorption. Nephrotic syndrome is often described by the response to steroid therapy (Table 39-2). **Steroid-sensitive nephrotic syndrome** usually results in complete remission without serious adverse effects. **Steroid-resistant nephrotic syndrome** is described for children (usually infants 3 to 12 months of age or adolescents) who fail to respond to prednisone within 8 weeks. They may be treated with noncorticosteroid immunosuppressive agents (i.e., cyclophosphamide) or combinations of corticosteroids and noncorticosteroid immunosuppressives to prolong remission.[54,55] Children with minimal change disease tend to have a very favorable prognosis, whereas those with other conditions, such as FSGS, may develop end-stage kidney disease.[56]

Kidney Injury

Kidney injury, either acute or chronic, is rare in children. The pathophysiology (see Figure 38-11) and management are similar to those for kidney injury in adults. A modification of the RIFLE criteria (*R* = risk, *I* = injury, *F* = failure, *L* = loss, and *E* = end-stage kidney disease [ESKD]) that was proposed to standardize the definition of acute kidney injury in adults has been used in critically ill children (pRIFLE criteria) (Table 39-3).[57]

TABLE 39-2 CORTICOSTEROID RESPONSE IN CHILDREN WITH NEPHROTIC SYNDROME

RESPONSE TO CORTICOSTEROID	OUTCOMES
Steroid sensitive	May have just one or recurrent episodes.
Steroid dependent (frequently relapsing)	May require low-dose prednisone or treatment with other immunosuppressive agents to prevent recurrence
Steroid resistant	Treatment with immunosuppressive and nonimmunosuppressive medications; risk for development of end-stage kidney disease

Data from Gipson DS et al: *Pediatrics* 124(2):747–757, 2009.

TABLE 39-3 PEDIATRIC-MODIFIED RIFLE (pRIFLE) CRITERIA

RISK CATEGORY	ESTIMATED CCL-GFR CRITERIA	URINE OUTPUT CRITERIA
Risk	eCCl decrease by 25%	<0.5 ml/kg/hr for 8 hr
Injury	eCCl decrease by 50%	<0.5 ml/kg/hr for 16 hr
Failure	eCCl decrease by 75% or eCCl <35 ml/min/1.73 m^2	<0.3 ml/kg/hr for 24 hr or anuric for 12 hr
Loss (of kidney function)	Persistent failure >4 weeks	
End-stage	End-stage renal disease (persistent failure >3 months)

eCCl, Estimated creatinine clearance; *GFR*, glomerular filtration rate; *pRIFLE*, *p*ediatric *r*isk, *i*njury, *f*ailure, *l*oss, and *e*nd-stage renal disease.

The most common causes of *prerenal acute kidney injury* are dehydration, hemorrhage, and sepsis. Glomerulonephritis, hemolytic uremic syndrome, and hypersensitivity reactions to drugs or infectious agents are the most common causes of *intrinsic acute kidney injury*. Obstructive uropathies, such as posterior urethral valves and obstruction of the ureteropelvic junction, are associated with *postrenal acute kidney injury*.[58] Chronic kidney failure in very young children is commonly associated with congenital renal structural abnormalities. In older children the most common cause is glomerulonephropathies.[59,60] Renal replacement modalities available for children with end-stage renal disease include peritoneal and hemodialysis and kidney transplant.[61,62] The use of growth hormone before and after transplant has contributed to normal growth and development, particularly in prepubertal children.[63]

Wilms Tumor

Wilms tumor is an embryonal tumor of the kidney arising from epigenetic and genetic changes that lead to abnormal proliferation of renal stem cells (metanephric blastema). It is also known by the histologic name of **nephroblastoma** and is the most common solid tumor occurring in children.

The incidence of Wilms tumor remains constant in the United States, with approximately 650 children diagnosed each year. Most children are between 1 and 5 years of age when they are diagnosed. The peak incidence occurs between 2 and 3 years of age. Wilms tumor is slightly more common in females and in black than in white children, and is less common in Asian children.[64,65]

Microscopically, Wilms tumor is composed of three cellular components: stromal, epithelial, and blastemic. This occurs because blastemic cells, which are primitive and undifferentiated, may have partially developed into epithelial or stromal tissue. With each of these three cellular components, varying stages of differentiation may be evident within the tumor.

PATHOGENESIS. Wilms tumor (nephroblastoma) has sporadic and inherited origins. The sporadic form occurs in children with no known genetic predisposition. Inherited cases, which are relatively rare (1% to 2% of cases), are transmitted in an autosomal dominant fashion.

A "two-hit" hypothesis for the development of Wilms tumor has been proposed wherein children who inherit a mutation in one allele of a tumor-suppression gene require just one more somatic mutation for a tumor to form[66] (see Figure 16-18). This hypothesis may not apply to all Wilms tumors, however, because a number of genetic abnormalities have been identified in Wilms tumors.[67,68] Wilms tumor-suppressor genes *WT1* and *WT2* are located on chromosome 11. Chromosomal abnormalities, including gains, losses, and rearrangements, are often present in Wilms tumors. Gains in chromosomes 6, 7, 8, 12, 13, and 18 and losses in chromosomes 11, 16, 22, and X are among the most common findings, although multiple other chromosomal abnormalities also have been identified.[69] *WTX* is a tumor-suppressor gene located on the X chromosome.[67] Approximately 10%

of children who have Wilms tumor also have loss of other important genes and therefore have a number of congenital anomalies. These anomalies include aniridia (lack of an iris in the eye), hemihypertrophy (an asymmetry of the body), and genitourinary malformations (i.e., horseshoe kidneys, hypospadias, ureteral duplication, polycystic kidneys, uterine abnormalities).[70,71] Children with congenital anomalies as well as Wilms tumor are more likely to have the inherited bilateral form of the disease.

CLINICAL MANIFESTATIONS. Most Wilms tumors (90%) present as an enlarging asymptomatic upper abdominal mass in a healthy, thriving child. Other presenting complaints include vague abdominal pain, hematuria, fever, and hypertension.[72]

EVALUATION AND TREATMENT. On physical examination the tumor feels firm, nontender, and smooth, and generally is a solitary mass of varying size confined to one side of the abdomen. Diagnostic imaging demonstrates a solid intrarenal mass.

Diagnosis is based on surgical biopsy. Additional laboratory and radiologic studies are used to evaluate the presence or absence of metastasis. The most common sites of metastasis are regional lymph nodes and the lungs and less commonly liver, brain, and bone.

Staging systems for Wilms tumor have been developed and serve as guides to treatment. The most widely accepted system was developed by the National Wilms Tumor Study Group (Table 39-4). The system is based on surgical findings and the extent of disease at diagnosis.[73] Children are further classified as either high or low risk according to favorable or unfavorable histologic presentation (anaplasia).

Primary treatment is usually (1) surgical exploration and resection, or (2) chemotherapy followed by surgical resection. In bilateral disease, surgical intervention may include heminephrectomy of the less involved kidney and nephrectomy of the other. Radiation therapy has been found to be most effective if begun 1 to 3 days after surgery for stages III and IV disease and metastases. Chemotherapy is specific to histologic presentation and stage of disease.[74]

The overall cure rate is as high as 95% for children with stage I through stage III disease (Table 39-5). Prognosis is improving for children with metastases, and this is one of the few tumors for which lung metastases have been cured. Recurrent disease is treated aggressively in children with favorable histologic results.

TABLE 39-4 STAGING OF WILMS TUMOR

STAGE*	TUMOR CHARACTERISTICS
Stage I (40% to 45%)	Tumor limited to the kidney, completely resected
Stage II (20% to 25%)	Tumor ascending beyond the kidney or into vessels of renal sinus, but appearing to be totally resected
Stage III (20% to 25%)	Residual nonhematogenous tumor confined to the abdomen, positive lymph nodes in renal hila
Stage IV (10%)	Hematogenous metastases (e.g., lung, liver, bone, brain)
Stage V (5%)	Bilateral disease either at diagnosis or later, but need to stage each kidney

Data from American Cancer Society: *Wilms tumor,* 2013. Available at www.cancer.org/cancer/wilmstumor/detailedguide/wilms-tumor-staging. Accessed April 2013.

***Note:** Staging system of the Third National Wilms Tumor Study Group (NWTS-3).

Bladder Disorders

Urinary Tract Infections

Urinary tract infection (UTI) is the colonization of a pathogen anywhere along the urinary tract (urethra, bladder, ureter, kidney) and occurs commonly in children.[75] The incidence of UTI is greater in boys up to 1 year of age, particularly among those not circumcised.[76] Girls have a greater incidence after 1 year of age with an increasing incidence at adolescence. UTIs in girls occur as a result of perineal bacteria, especially *E. coli,* ascending the urethra, which lies close to the anus. The incidence of UTI in neonates and infants is low, but the risk is increased because of an immature immune system.

The pathophysiology of UTIs in children is similar to that of adults (see Chapter 38). Although nephrolithiasis can be associated with UTI in adults, nephrolithiasis in children is rare, but is increasing in incidence (see What's New? Kidney Stones in Children). UTIs in children are often clinically categorized as first or recurrent infection. Individual susceptibility, bacterial virulence, and the host's anatomy (presence of reflux, obstruction, stasis, stones, or structural anomalies of the urinary tract) affect the severity of the disease. The recurrence rate is approximately 30% to 40%[77] and is highest in females. Sexually active female adolescents are at increased risk to have a UTI. Similar to adult women, susceptibility is increased when genetically controlled blood group antigens (P1 and Lewis blood group nonsecretor) are present on surface uroepithelial cells and act as receptors for bacterial attachment.[78]

TABLE 39-5 NATIONAL WILMS TUMOR STUDY 4-YEAR SURVIVAL RATES

TUMOR STAGE	FAVORABLE HISTOLOGY	UNFAVORABLE HISTOLOGY (ANAPLASTIC WILMS TUMOR)
I	99%	83%
II	98%	81%
III	94%	72%
IV	86%	38%
V	87%	55%

WHAT'S NEW?

Kidney Stones in Children

Nephrolithiasis in children is rare although the incidence of calcium stones among children is increasing, particularly in adolescents. There are limited data available regarding the pathogenesis of kidney stones in children, but the mechanisms appear different compared to those of adults. Epidemiologic data indicate nephrolithiasis in children is more common in non-Hispanic white adolescent females between ages 13 and 18 years (male to female ratio 1:1.4). Proposed risk factors include obesity; diets high in salt, protein, or fructose, or low in water or calcium; and use of certain antiseizure, diuretic, vitamin, or antibiotic medications. Kidney stones also can be associated with urinary tract malformations (reflux disease and megaureter). Calcium stones are the most common stone type (72% to 88%). Children who form stones have higher supersaturation of calcium oxalate; however, the significance to stone formation is unknown. The most common symptom presentation is pain and gross hematuria. Prevention and treatment are individualized and any metabolic cause needs to be evaluated. Stone inhibitors, magnesium, and citrate have been effective in some groups. Surgical methods include extracorporeal shock wave lithotripsy, ureteroscopy, and percutaneous nephrolithotomy.

Data from Ayoob R, Wang W, Schwaderer A: *Pediatr Nephrol* 26(12):2173–2178, 2011; Bergsland KJ et al: *Kidney Int* 81(11): 1140–1148, 2012; Chahed J et al: *Afr J Paediatr Surg* 8(2):168–171, 2011; Dwyer ME et al: *J Urol* 188(1):247–252, 2012; Granberg CF, Baker LA: *Pediatr Clin North Am* 59(4):897–908, 2012; Sas DJ: *Clin J Am Soc Nephrol* 6(8):2062–2068, 2011; Schissel BL, Johnson BK: *Pediatr Emerg Care.* 27(7):676–681, 2011.

Cystitis, or infection of the bladder, results in mucosal inflammation and congestion. This causes detrusor muscle hyperactivity and a resulting decrease in the bladder capacity. It also can lead to transient reflux of urine up the ureters, sending bacteria all the way to the kidney, causing acute or chronic pyelonephritis and renal abscesses or scarring.

Symptoms of UTI in children are nonspecific, and differentiating whether an infection is in the bladder or kidneys is difficult based on symptoms alone. Infants usually develop vomiting, diarrhea, or jaundice. Infants and young children may present only with fever of undetermined origin and others may present with urinary tract symptoms of frequency; urgency; enuresis or incontinence in a previously dry child; abdominal, flank, or back pain; foul-smelling urine; and sometimes hematuria. **Acute pyelonephritis** usually causes chills, fever, and flank or abdominal pain along with enlarged kidney(s) caused by edema. **Chronic pyelonephritis** may be asymptomatic.

Diagnosis of UTIs is by urine culture of a pathogen before antimicrobial treatment. An accompanying urinalysis can show pyuria, nitrites, and hematuria. The presence of casts in the urine can indicate pyelonephritis. Ultrasound, voiding cystourethrography (VCUG) or radionuclide cystography, or computed tomography (CT) scan may be necessary to rule out obstructions, abscesses, or reflux, particularly in young children who do not respond to antimicrobial therapy.

With treatment, UTI symptoms are usually relieved in 1 to 2 days and the urine becomes sterile. A 2- to 4-day course of oral antibiotics is effective for uncomplicated UTI.[79] Longer treatment may be required if the child has a recurrent UTI, has a complicated UTI including congenital abnormalities of the urinary tract, or is immunosuppressed. Imaging of children after a first UTI is controversial.[80,81] The age of the child and seriousness of the infection should be considered when making imaging decisions. Repeat urine cultures are not needed if a child has responded to treatment.[82]

Management of constipation, promotion of adequate fluid intake, and elimination of dysfunctional voiding patterns are the cornerstones of minimizing the risk of recurrence.[83] Prophylactic antibiotics may be helpful for some children. Educating families about signs and symptoms of UTI allows for early identification and treatment. Surgical correction of vesicoureteral reflux or obstruction may be necessary.

Vesicoureteral Reflux

Vesicoureteral reflux (VUR) is the retrograde flow of bladder urine into the kidney or ureters, or both. Reflux allows infected urine from the bladder to reach the kidneys. Reflux perpetuates infection by preventing complete emptying of the bladder as refluxed urine drains back into the bladder at the end of each void. In addition, the reflux allows the maximal intravesical pressure to be transmitted to the renal calyces and pyramids. The combination of reflux and infection is an important cause of pyelonephritis, especially in children younger than 5 years.

Vesicoureteral reflux occurs more often in girls by a ratio of 10:1 and is less common in blacks. Its incidence is approximately 1 in 1000 children, and siblings of those affected have an approximately 30% chance of developing reflux.[84] Reflux nephropathy in males is associated with congenitally abnormal kidneys.[85] The shortness of the submucosal segment of the ureter during infancy and childhood renders the antireflux mechanism relatively inefficient and delicate. Thus reflux is seen commonly in association with infections during early childhood but rarely in older children and adults. (Among adults with UTIs, the incidence of reflux is approximately 5%.) Reflux may be unilateral or bilateral, and it can be classified or graded (Figure 39-7) for comparative purposes:

Grade I—Reflux into a nondilated distal ureter

Grade II—Reflux into the upper collecting system without dilation

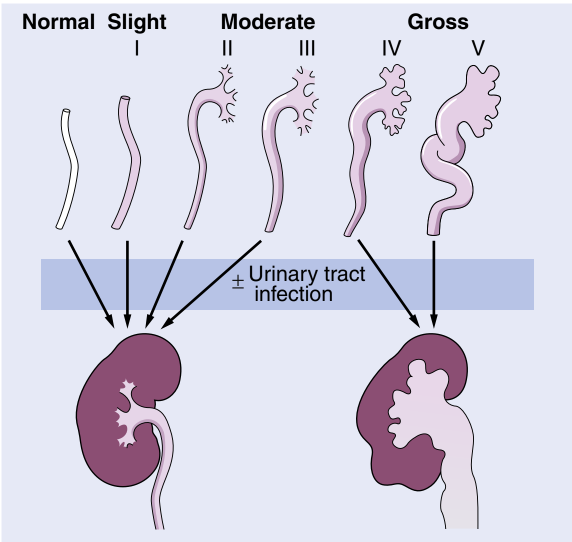

FIGURE 39-7 Grades of Reflux. (From Feehally J, Floege J, Johnson RJ: *Comprehensive clinical nephrology,* ed 3, Philadelphia, 2008, Mosby.)

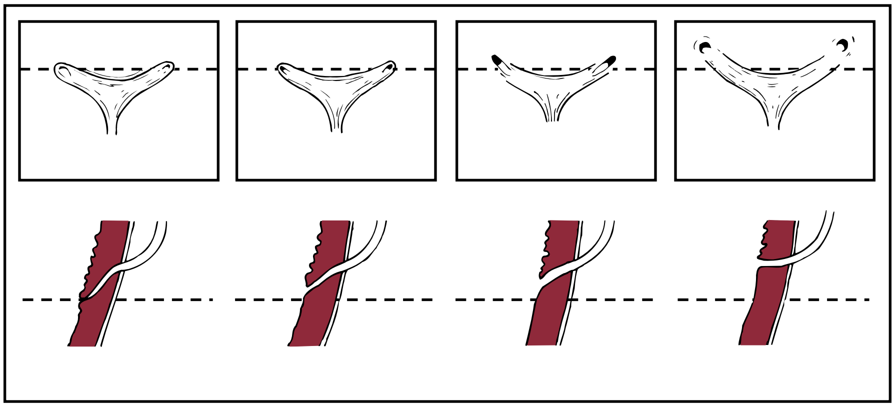

FIGURE 39-8 Normal and Abnormal Configuration of the Ureteral Orifices. *Left to right:* Progressive lateral displacement of the ureteral orifices and shortening of the intramural tunnels. *Top row:* Endoscopic appearance. *Bottom row:* Sagittal view through the intramural ureter. (From Kliegman RM et al, editors: *Nelson textbook of pediatrics,* ed 19, Philadelphia, 2011, Saunders.)

Grade III—Reflux into dilated ureter or blunting of calyceal fornices

Grade IV—Reflux into a grossly dilated ureter

Grade V—Massive reflux with ureteral dilation and tortuosity and effacement of the calyceal details; occurs almost exclusively in male infants[86]

PATHOPHYSIOLOGY. Primary reflux results from a congenitally abnormal or ectopic insertion of the ureter into the bladder. In some infants VUR may be related to inadequate relaxation of the external urethral sphincter.[87] Occasionally the condition is hereditary. Secondary reflux may be transient or persistent. It develops in association with infection, malformations of the ureterovesical (UV) junction, increased intravesical pressures, voiding disorders, or surgery on the UV junction (Figure 39-8). Urinary tract infection associated with VUR may lead to permanent renal scarring, particularly when there is pyelonephritis.[88] The actual cause of renal cell damage and scarring is unknown but contributing factors include inflammatory cytokines activated by bacterial virulence factors.[89]

CLINICAL MANIFESTATIONS. Children with reflux may be asymptomatic or may experience recurrent UTIs or unexplained fever, poor growth and development, irritability, and feeding problems. The family history may reveal VUR or urinary tract infections.

EVALUATION AND TREATMENT. Prompt treatment of UTIs in children with reflux is important to minimize the risk of renal scar development. Some infants may have renal scarring at birth from intrauterine damage caused by reflux. In addition to the history of recurrent UTIs and other symptoms, imaging may be required for diagnosis and assessment of structural change, scarring, urinary tract function, and risk for future infection and renal damage. Most children with vesicoureteral reflux respond to nonoperative management aimed at prevention and treatment of infection. Spontaneous remission of grades I and II reflux may occur in more than 80% of children. Resolution of grades III and IV reflux occurs in 46% and 30%, respectively, over 5 years.[90] The use of prophylactic antibiotics for these children is controversial with concerns regarding efficacy and the development of antibiotic resistance.[91] Recurrent infection or high-grade reflux are possible indications for surgical intervention or endoscopic injection of biomaterials into the bladder wall below the ureteral orifice. Surgical repair of reflux has been shown to decrease the incidence of pyelonephritis but does not decrease the risk of the development or progression of renal damage.[92] The value of screening asymptomatic siblings of children with vesicoureteral reflux is debatable. One current recommendation is to perform a renal ultrasound and consider a VCUG only in children with scarring or otherwise abnormal appearing kidneys.[84]

Urinary Incontinence

Urinary incontinence refers to the involuntary passage of urine by a child who is beyond the age when voluntary bladder control should have been acquired. Nighttime wetting is called **enuresis.** Bladder control is accomplished by most children before the age of 5 years, although this is largely influenced by cultural beliefs and parental toilet training practices. **Functional incontinence** is urinary incontinence in which no structural or neurologic abnormality can be identified. The underlying mechanism may include disorders of both the storage and voiding phases of the bladder cycle. A child may have daytime incontinence or enuresis, or both.

The incidence of incontinence is difficult to determine because it is not a problem that parents readily share with others and because definitions vary according to cultural norms and family practices. The incidence of enuresis in children older than 5 years ranges from 15% to 20%. Boys are more enuretic than girls by a ratio of 2:1. Less than 2% of adults experience enuresis. Daytime incontinence occurs in up to 9% of early school age children.[93]

PATHOGENESIS. Multiple factors are likely responsible for incontinence. All or part of each one might be operating in a given child. A reasonable approach is to eliminate organic, behavioral, or physiologic causes before exploring the psychologic ones.

Organic causes of incontinence account for 2% to 10% of cases. The causes include urinary tract infections; neurologic disturbances; congenital defects of the meatus, urethra, and

bladder neck; allergies; constipation;[94] obesity;[95] or alteration in renal tubular ion and water transport related to prostaglandin secretion. Disorders that increase the normal output of urine, such as diabetes mellitus and diabetes insipidus, or disorders that impair the concentrating ability of the kidney must be considered in the evaluation of enuresis.[96] Enuresis in children may be associated with a maturational lag. Studies have demonstrated that some children with enuresis have smaller functional bladder capacities than nonenuretic children.[97] Children who do not have the normal nocturnal elevation of vasopressin produce a higher volume of urine with a lower osmolality than controls.[98] A number of children experience bladder overactivity with elevated intravesical pressure and spikelike detrusor contractions during bladder filling. Incontinence often spontaneously disappears in children as they get older.

Genetic factors as a cause of enuresis are being investigated. Linkages have been proposed between nocturnal enuresis and chromosomes 8, 12, 13, and 22.[99] Bed-wetting occurs with high frequency among parents, siblings, and other near relatives of symptomatic children. These observations are further supported by a high concordance rate in enuretic monozygotic twins.

Multiple studies have examined the role of sleep architecture on enuresis. Findings have ranged from elevated arousal thresholds[100] to increased light sleep with frequent cortical arousal without complete awakening.[101] Enuresis may be associated with obstructive sleep apnea. Inspiratory effort against a closed airway increases intrathoracic negative pressure, causing cardiac distention and release of atrial natriuretic hormone and decreased levels of vasopressin and renin-angiotensin-aldosterone complex.[102]

A variety of psychosocial factors also have been postulated as explanations of enuresis. Enuresis has been associated with attention-deficit/hyperactivity disorders, anxiety disorders, depression, and opposition defiant disorders.[103,104]

CLINICAL MANIFESTATIONS. **Primary incontinence** refers to a condition in which the child has never been continent. **Secondary incontinence** occurs when a child who has experienced a period of dryness of at least 6 months after toilet training becomes incontinent again. Secondary enuresis may be diurnal, nocturnal, or a combination of both. (Types of incontinence are defined in Table 39-6.)

TABLE 39-6 CLASSIFICATION OF INCONTINENCE

TYPES OF INCONTINENCE	DEFINITION
Daytime voiding frequency	Decreased: 3 or fewer voids per day Increased: 8 or more voids per day
Dysfunctional voiding	Habitual contraction of the urethral sphincter during voiding; observed by uroflow
Enuresis	Intermittent incontinence of urine while sleeping
Incontinence, intermittent	Leakage of urine in discrete episodes during the day and/or night
Incontinence, stress	Leakage of small amounts of urine with exertion or raised intra-abdominal pressure
Urgency	Sudden, unexpected, immediate need to void
Overactive bladder	Child has urgency with or without frequency or incontinence
Underactive bladder	Decreased voiding frequency with use of raised intra-abdominal pressure to void

Data from Nevéus T et al: *J Urol* 176(1):312–324, 2006.

EVALUATION AND TREATMENT. Evaluation of incontinence includes use of questionnaires, drinking and voiding charts, physical examination, and urinalysis. Underlying pathology, including kidney disease, vesicoureteral reflux, urinary tract infection, or neurogenic bladder, is excluded. Radiologic and urodynamic evaluation may be required.[105,106]

Therapeutic management of incontinence or enuresis begins with education. If the child and family understand the probable etiology of the child's condition, they are better able to choose and participate in therapies that are most likely to succeed. Treatment of daytime incontinence includes behavioral therapy, including timed voiding; fluid management; treatment of constipation, urinary tract infections, and other coexisting conditions if present; and medication (anticholinergic, alpha-blocker).[107,108] Enuresis treatment also may include enuresis alarms or other medications (desmopressin acetate tablets).[109,110]

SUMMARY REVIEW

Structure and Function of the Urinary System in Children

1. The Wilms tumor 1 gene and *WNT* signaling are important for kidney development, growth, and differentiation.
2. The kidney develops from three sets of structures: the pronephros (nonfunctional by the end of the embryonic period), mesonephros (nonfunctional), and metanephros (the functional kidney).
3. All nephrons are present at birth. The number does not increase with maturation, but they do increase in weight and function.
4. Urine formation begins by the third gestational month and contributes to the amniotic fluid.
5. Infants have a narrow chemical safety margin because of high hydrogen ion concentration, limited ability to regulate the internal environment, and lowered osmotic pressure.
6. Any disturbance, such as diarrhea, infection, fasting, or feeding alterations, can lead rapidly to severe acidosis and fluid imbalance in infants.
7. The composition of body fluids differs with age, thus making children more vulnerable to pathophysiologic changes.
8. Because the kidney develops from the medulla to the cortex, blood flow to the medullary nephrons is limited in infancy, and infants thus have limited urine-concentrating capacity.

SUMMARY REVIEW—cont'd

Alterations in Renal and Bladder Function in Children

1. Congenital renal disorders affect about 1 out of 500 newborns. These disorders range in severity from minor, easily correctable anomalies to those incompatible with life.
2. Horseshoe kidney is a single U-shaped kidney that develops from fusion of the kidneys as they descend from the midline. The kidney may be asymptomatic or associated with hydronephrosis, stone formation, or infection.
3. Hypospadias is a congenital condition in which the urethral meatus is located on the undersurface of the penis; epispadias is a congenital condition in which the urethral opening is located on the dorsal surface of the penis.
4. Exstrophy of the bladder is a congenital malformation in which the pubic bones are separated, the lower portion of the abdominal wall and anterior wall of the bladder are missing, and the back wall of the bladder is everted through the opening.
5. Ureteropelvic junction obstruction is blockage where the renal pelvis joins the ureter and is often caused by smooth muscle or urothelial malformation or scarring that leads to hydronephrosis.
6. Bladder outlet obstruction is usually caused by urethral valves or polyps.
7. A dysplastic kidney is the result of abnormal differentiation of renal tissues. The hypoplastic kidney is a very small but otherwise normal kidney.
8. Renal agenesis is the failure of a kidney to grow or develop. The condition may be unilateral or bilateral and may occur as an isolated entity or in association with other disorders.
9. Polycystic kidney disease is an autosomal dominant or recessive disorder in which the renal tubule or epithelium proliferates; excessive fluid transport causes cyst formation and obstruction.
10. Glomerulonephritis is an inflammation of the glomeruli secondary to immune mechanisms characterized by hematuria, edema, and hypertension. Poststreptococcal glomerulonephritis may occur after infection, especially of the upper respiratory tract.
11. IgA nephropathies result from deposition of IgA immunoglobulins and other immune products in the mesangium of the glomerular capillaries. It is the most common type of childhood glomerulonephritis.
12. Henoch-Schönlein nephritis is an IgA nephropathy that affects glomerular blood vessels.
13. Hemolytic uremic syndrome is an acute disorder characterized by hemolytic anemia, acute renal failure, and thrombocytopenia and can be associated with *E. coli* verotoxin.
14. Nephrotic syndrome is a term used to describe a symptom complex characterized by proteinuria, hypoalbuminemia, hyperlipidemia, and edema. Metabolic, biochemical, or physiochemical disturbance in the glomerular basement membrane leads to increased permeability to protein. The most common form is minimal change nephropathy.
15. Acute or chronic renal injury is rare in children and the most common cause is prerenal acute renal failure related to dehydration, sepsis, or hemorrhage.
16. Wilms tumor is an embryonal tumor of the kidney that usually presents between birth and 5 years of age as an inherited (5% to 10%) or sporadic form. The tumor can be successfully treated by surgery, with a combination of drugs, and, sometimes, with radiation therapy.
17. Urinary tract infections can result from general sepsis in the newborn but are usually caused by bacteria ascending the urethra in older children. The bladder alone is infected in cystitis. The infection ascends to the kidney or kidneys in pyelonephritis. Urinary tract anomalies may need surgical correction to prevent frequent recurrent infections.
18. Vesicoureteral reflux, which refers to the retrograde flow of bladder urine into the kidney and/or ureters, provides mechanisms for bladder infection in children whose ureters are shorter than those of adults. It can be unilateral or bilateral.
19. Urinary incontinence refers to the involuntary passage of urine beyond the age when normal continence should have occurred. This may occur during the day (incontinence) or night (enuresis). These disorders can have a variety of organic and psychologic causes.

CHAPTER OUTLINE

The digestive system breaks down ingested food, prepares it for uptake by the body's cells, provides body water, and eliminates wastes. This system consists of the gastrointestinal tract and accessory organs of digestion: the liver, gallbladder, and exocrine pancreas.

Food breakdown begins in the mouth with chewing and continues in the stomach, where food is churned and mixed with acid, mucus, enzymes, and other secretions. From the stomach, the fluid and partially digested food pass into the small intestine, where biochemicals and enzymes secreted by the liver, exocrine pancreas, and small intestinal epithelium break it down into absorbable components of proteins, carbohydrates, and fats. These nutrients pass through the small intestinal epithelium into underlying blood vessels and lymphatics that carry them to the liver via the hepatic portal circulation for further processing and storage.

Ingested substances and secretions that are not absorbed in the small intestine pass into the large intestine, where fluid continues to be absorbed. Solid wastes pass into the rectum and are eliminated from the body through the anus.

Except for chewing, swallowing, and defecation of solid wastes, the activities of the digestive system are controlled by hormones and the autonomic nervous system. As ingested substances move through the gastrointestinal tract, they trigger the release of hormones that stimulate or inhibit (1) the muscular contractions (gastrointestinal motility) that mix and propel food from the esophagus to the anus, and (2) the timely secretion of substances that aid in digestion. The autonomic innervation, sympathetic and parasympathetic, is controlled by centers in the brain and by local stimuli that are mediated by neural plexuses within the gastrointestinal walls.

THE GASTROINTESTINAL TRACT

The **gastrointestinal tract** (**alimentary canal**) consists of the mouth, esophagus, stomach, small intestine, large intestine,

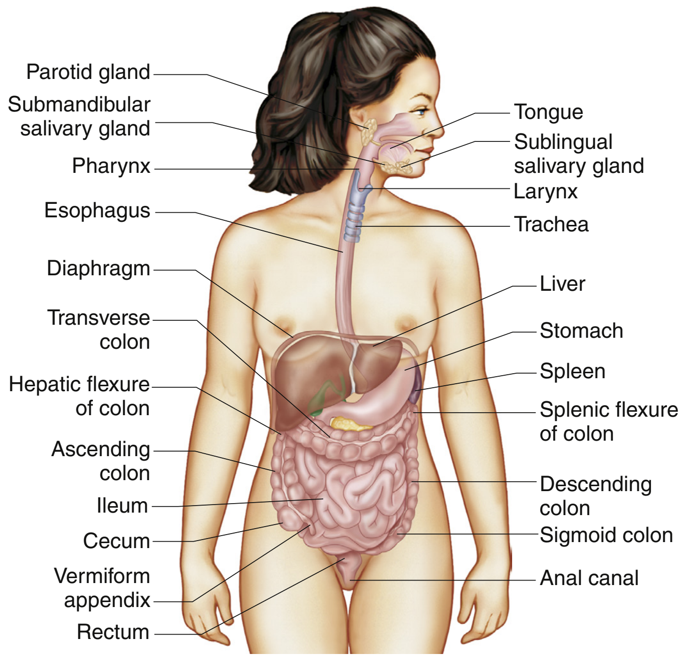

FIGURE 40-1 Structures of the Digestive System.

rectum, and anus (Figure 40-1). It carries out the following digestive processes:

1. Ingestion of food
2. Propulsion of food and wastes from the mouth to the anus
3. Secretion of mucus, water, and enzymes
4. Mechanical digestion of food particles
5. Chemical digestion of food particles
6. Absorption of digested food
7. Elimination of waste products by defecation

Histologically, the gastrointestinal tract consists of four layers. From the inside out, they are the mucosa, submucosa, muscularis, and serosa or adventitia (esophagus only). These concentric layers vary in thickness, and each layer has sublayers (Figure 40-2). Neurons forming the **enteric nervous system** are located solely within the gastrointestinal tract and are controlled by local and autonomic nervous system stimuli. The enteric nervous system comprises three nerve plexuses located in different layers of the gastrointestinal walls. The **submucosal plexus (Meissner plexus)** is located in the muscularis mucosae, the **myenteric plexus (Auerbach plexus)** between the inner circular and outer longitudinal muscle layers in the muscularis, and the **subserosal plexus** just beneath the serosa. The enteric (intramural) plexus neurons regulate motility reflexes, blood flow, absorption, secretions, and immune response.[1]

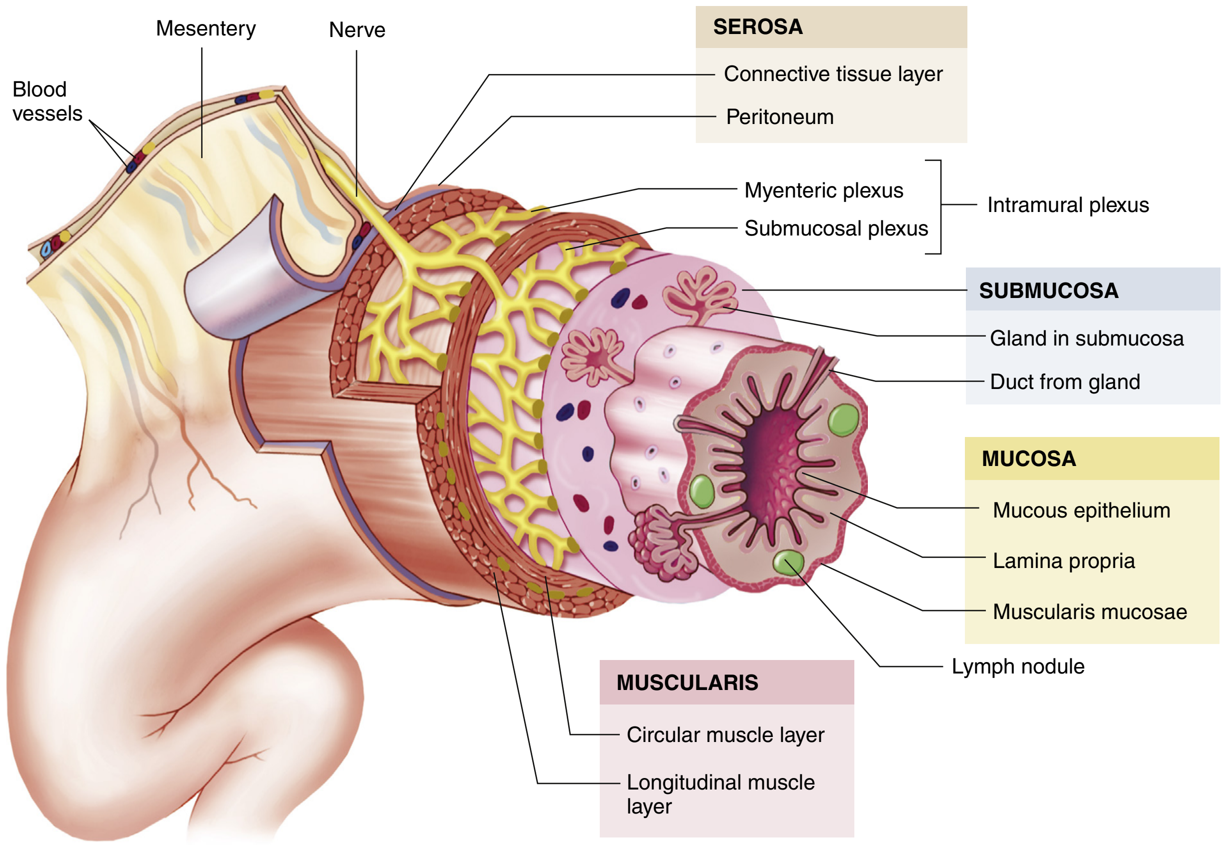

FIGURE 40-2 Wall of the Gastrointestinal (GI) Tract. The wall of the GI tract is made up of four layers with a network of nerves between the layers. Shown here is a generalized diagram of a segment of the GI tract. Note that the serosa is continuous with a fold of serous membrane called a *mesentery.* Note also that digestive glands may empty their products into the lumen of the GI tract by way of ducts. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

Mouth and Esophagus

The **mouth** is a reservoir for the chewing and mixing of food with saliva. As food particles become smaller and move around in the mouth, the taste buds and olfactory nerves are continuously stimulated, adding to the satisfaction of eating. The tongue's surface and soft palate contains thousands of chemoreceptors, or taste buds, that can distinguish salty, sour, bitter, umami, and sweet tastes. Tastes and food odors help initiate salivation and the secretion of gastric juice in the stomach. There are 32 permanent teeth in the adult mouth, and they are important for speech and mastication.

Salivation

The three pairs of **salivary glands** (the submandibular, sublingual, and parotid glands) (Figure 40-3) secrete about 1 L of saliva per day. **Saliva** consists mostly of water that contains varying amounts of mucus, sodium, bicarbonate, chloride, potassium, and **salivary α-amylase (ptyalin),** an enzyme that initiates carbohydrate digestion in the mouth and stomach.

The sympathetic and parasympathetic divisions of the autonomic nervous system control salivation. Because cholinergic parasympathetic fibers stimulate the salivary glands, atropine (an anticholinergic agent) inhibits salivation and makes the mouth dry. β-Adrenergic stimulation from sympathetic fibers also increases salivary secretion. The salivary glands are not regulated by hormones, although hormones are found in saliva.[1a]

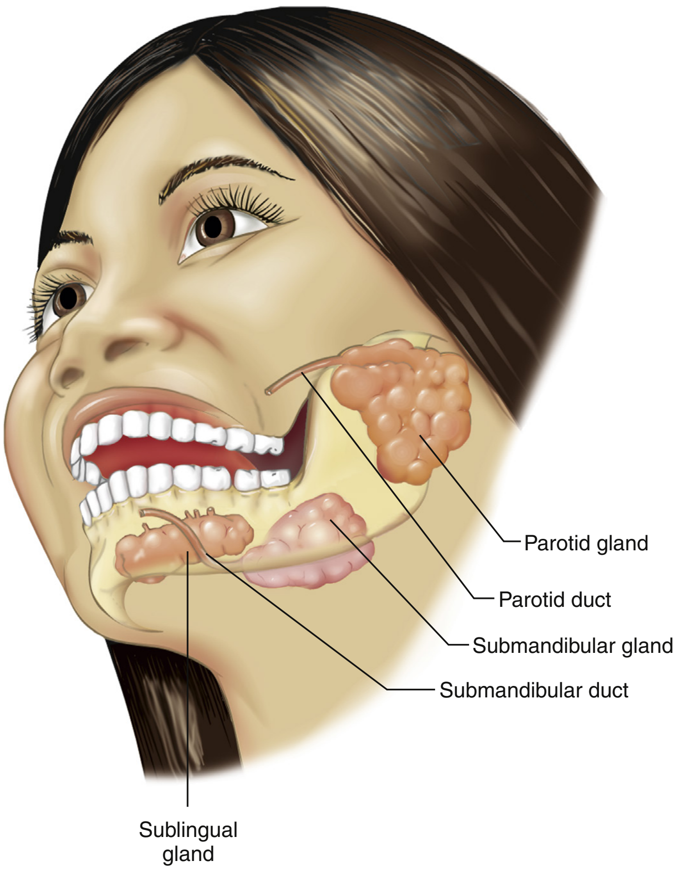

FIGURE 40-3 Salivary Glands. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

The composition of saliva depends on the rate of secretion. Aldosterone can decrease the rate of secretion by increasing an exchange of sodium for potassium. Sodium and water are conserved and potassium is excreted. The bicarbonate concentration of saliva sustains a pH of about 7.4, which neutralizes bacterial acids and prevents tooth decay. Saliva also contains immunoglobulin A (IgA), which helps prevent infection. Exogenous fluoride (e.g., fluoride in drinking water) is absorbed and then secreted in the saliva, providing additional protection against tooth decay.

Swallowing

The **esophagus** is a hollow muscular tube approximately 25 cm long that conducts substances from the oropharynx to the stomach (see Figure 40-1). The pharynx and upper third of the esophagus contain striated muscle that is directly innervated by skeletal motor neurons that control swallowing. The middle third contains a mix of striated and smooth muscle, and the lower third is smooth muscle that is innervated by preganglionic cholinergic fibers from the vagus nerve. Peristalsis is stimulated when afferent fibers distributed along the length of the esophagus sense changes in wall tension caused by stretching as food passes. The greater the tension, the greater the intensity of esophageal contraction. Occasionally, intense contractions cause pain similar to "heartburn" or angina.

Each end of the esophagus is opened and closed by a sphincter. The **upper esophageal sphincter (cricopharyngeal muscle)** prevents entry of air into the esophagus during respiration.[2] The **lower esophageal sphincter (cardiac sphincter)** prevents regurgitation from the stomach. The lower esophageal sphincter is located near the esophageal hiatus—the opening in the diaphragm where the esophagus ends at the stomach.[3]

Swallowing is a complex event mediated by the trigeminal nucleus, nucleus tractus solitarius, and reticular formation of the brainstem and also involves other brain regions, including the insula/claustrum and cerebellum.[4]

Swallowing occurs in two phases: the oropharyngeal (voluntary) phase and the esophageal (involuntary) phase. During the **oral** and **pharyngeal phases of swallowing,** food is segmented into a bolus by the tongue and forced posteriorly toward the pharynx as the tongue pushes upward against the hard palate. The superior constrictor muscle of the pharynx contracts, preventing movement of food into the nasopharynx. At the same time, respiration is inhibited and the epiglottis folds downward to prevent the bolus from entering the larynx and trachea. The movements of the tongue and pharyngeal constrictors propel the food into the esophagus in a series of coordinated events, taking less than 1 or 2 seconds.

During the **esophageal phase of swallowing,** the bolus is transported to the stomach by the coordinated sequential contraction and relaxation of outer longitudinal and inner circular layers of smooth muscle. The wave of relaxation reduces resistance and allows food to pass, after which the wave of contraction pushes food farther along. The terminal 1 to 2 cm portion of the musculature forms the lower esophageal sphincter, which relaxes just before the arrival of a peristaltic wave. The sphincter muscles return to their resting tone after the bolus of food passes into the stomach. The esophageal phase of swallowing

takes 5 to 10 seconds, with the bolus moving 2 to 6 cm/second. Throughout swallowing, the sphincters and esophagus work in concert with the peristaltic wave that moves food from the mouth to the stomach.

Peristalsis that immediately follows the oropharyngeal phase of swallowing is called **primary peristalsis.** If a bolus of food becomes stuck in the esophageal lumen, the distention of the esophageal wall stimulates **secondary peristalsis,** a wave of contraction and relaxation that is independent of voluntary swallowing. This is in response to stretch receptors that are stimulated by increased wall tension, causing an increase in impulses from the swallowing center of the brain.

When it is closed, the lower esophageal sphincter serves as a barrier between the stomach and esophagus. Cholinergic vagal stimulation and the digestive hormone gastrin increase sphincter tone. Nonadrenergic, noncholinergic vagal impulses relax the lower esophageal sphincter, as do the hormones progesterone, secretin, and glucagon. Relaxation during swallowing is mediated by the vagus nerve.[5]

Stomach

The **stomach** is a hollow muscular organ that stores food during eating, secretes digestive juices, mixes food with these juices, and propels partially digested food, called **chyme,** into the duodenum of the small intestine. The anatomy of the stomach is presented in Figure 40-4. Its major anatomic boundaries are the lower esophageal sphincter, where food passes through the **cardiac orifice** at the gastroduodenal junction into the stomach, and the **pyloric sphincter,** which relaxes as food is propelled into the duodenum. Functional areas of the stomach are the **fundus** (upper portion), **body** (middle portion), and **antrum** (lower portion).

The stomach has three layers of smooth muscle: an outer, longitudinal layer; a middle, circular layer; and an inner, oblique layer (the most prominent) (see Figure 40-4). These layers become progressively thicker in the body and antrum, where food is mixed, churned, and pushed into the duodenum. The circular layer is most prominent and the oblique layer is the least complete; the longitudinal layer is absent on the anterior and posterior surfaces. The glandular epithelium is discussed in the section about secretory functions of the stomach (see p. 1398).

Blood is supplied to the stomach by branches of the celiac artery. The blood supply is so abundant that nearly all arterial vessels must be occluded before ischemic changes occur in the stomach wall. A series of small veins (short gastric, left and right gastric, and left and right gastro-omental) drain blood from the stomach towards the hepatic portal vein.

The stomach is innervated by sympathetic and parasympathetic divisions of the autonomic nervous system. Some of the autonomic nerves are extrinsic; that is, they originate in the central nervous system and are controlled by nerve centers in the brain. The vagus nerve provides parasympathetic innervation and branches of the celiac plexus innervate the stomach sympathetically. Other neurons are intrinsic; that is, they originate within the stomach and respond to local stimuli and are components of the enteric nervous system. Extrinsic sympathetic fibers reach the stomach through the celiac plexus (solar plexus), whereas extrinsic parasympathetic fibers enter through the gastric branch of the vagus nerve.

Few substances are absorbed in the stomach. The stomach mucosa is impermeable to water, but the stomach can absorb alcohol and aspirin and other nonsteroidal anti-inflammatory agents.

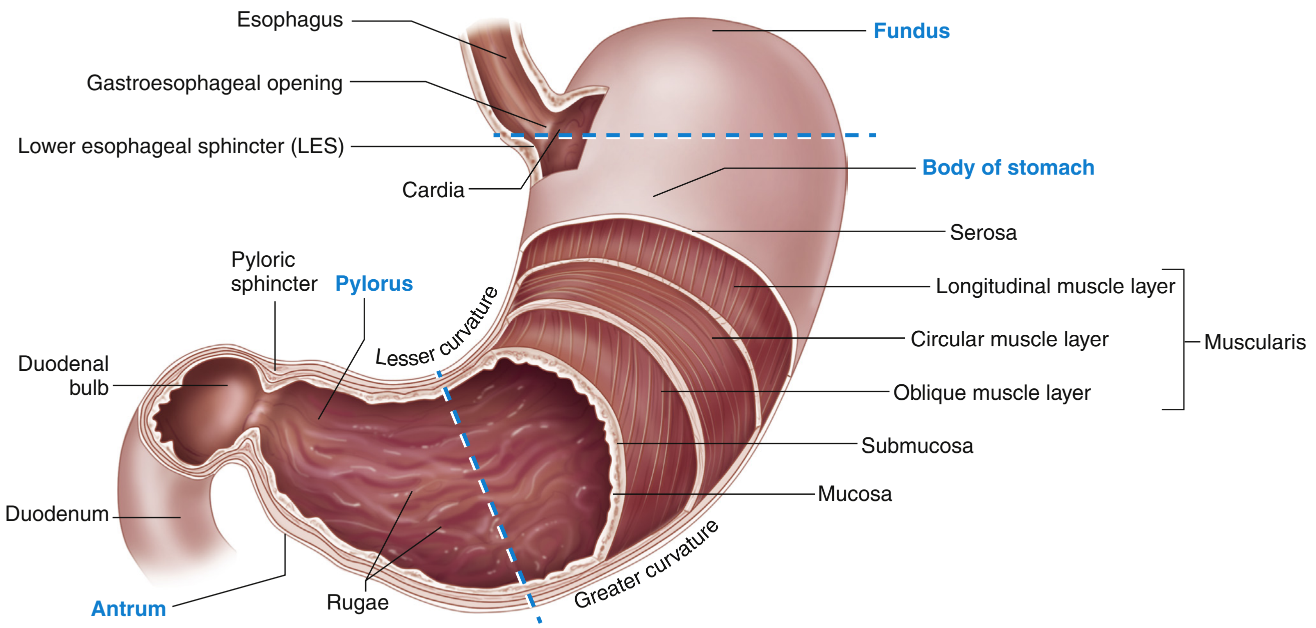

FIGURE 40-4 Stomach. A portion of the anterior wall has been cut away to reveal the muscle layers of the stomach wall. Note that the mucosa lining the stomach forms folds called *rugae.* The dashed lines distinguish the fundus, body, and antrum of the stomach. (Modified from Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

Gastric Motility

In its resting state the stomach is small and contains about 50 ml of fluid. There is little wall tension, and the muscle layers in the fundus contract very little. Swallowing causes the fundus to relax (receptive relaxation) to receive a bolus of food from the esophagus. Relaxation is coordinated by efferent, nonadrenergic, noncholinergic vagal fibers and is facilitated by gastrin and cholecystokinin, two polypeptide hormones secreted by the gastrointestinal mucosa. (The actions of digestive hormones are summarized in Table 40-1.) Food is stored in vertical or oblique layers as it arrives in the fundus, whereas fluids flow relatively quickly down to the antrum.

Gastric (stomach) motility increases with the initiation of peristaltic waves, which sweep over the body of the stomach toward the antrum. The rate of peristaltic contractions is approximately three per minute and is influenced by neural and hormonal activity. **Gastrin** and **motilin** (small intestine hormones) and the vagus nerve increase contraction by making the threshold potential of muscle fibers less negative. (The neural and biochemical mechanisms of muscle contraction are described in Chapter 43.) Sympathetic activity and **secretin** (another small intestine hormone) are inhibitory and make the threshold potential more negative. The rate of peristalsis is mediated by pacemaker cells that initiate a wave of depolarization (basic electrical rhythm), which moves from the upper part of the stomach to the pylorus.

Gastric mixing and subsequent emptying of gastric contents (chyme) from the stomach take several hours (3 to 6 hours depending on the composition and volume of food intake). Mixing occurs as food is propelled toward the antrum. As food approaches the pylorus, the velocity of the peristaltic wave increases, forcing the contents back toward the body of the stomach. This **retropulsion** effectively mixes food with digestive juices, and the oscillating motion breaks down large food particles. With each peristaltic wave a small portion of the chyme passes through the pylorus and into the duodenum. The pyloric sphincter is about 1.5 cm long and is always open about 2 mm. It opens wider during antral contraction. Normally there is no regurgitation from the duodenum into the antrum.

The rate of **gastric emptying** (movement of gastric contents into the duodenum) depends on the volume, osmotic pressure, and chemical composition of the gastric contents. Larger volumes of food increase gastric pressure, peristalsis, and rate of emptying. Solids, fats, and nonisotonic solutions delay gastric emptying.[6] (Osmotic pressure and tonicity are described in Chapters 1 and 3.) Products of fat digestion, which are formed

TABLE 40-1 SELECTED HORMONES AND NEUROTRANSMITTERS OF THE DIGESTIVE SYSTEM*

SOURCE	HORMONE†	STIMULUS FOR SECRETION	ACTION
Mucosa of the stomach	Gastrin	Presence of partially digested proteins in the stomach	Stimulates gastric glands to secrete hydrochloric acid and pepsinogen; growth of gastric mucosa; promotes gastric motility
	Histamine	Gastrin	Stimulates acid secretion
	Somatostatin	Acid in the stomach	Inhibits acid and pepsinogen secretion and release of gastrin
	Acetylcholine	Vagus and local nerves in stomach	Stimulates release of pepsinogen and acid secretion
	Gastrin-releasing peptide (bombesin)	Vagus and local nerves in stomach	Stimulates gastrin and release of pepsinogen and acid secretion
Mucosa of the small intestine	Motilin	Presence of acid and fat in the duodenum	Increases gastrointestinal motility
	Secretin	Presence of chyme (acid, partially digested proteins, fats) in the duodenum	Stimulates pancreas to secrete alkaline pancreatic juice and liver to secrete bile; decreases gastrointestinal motility; inhibits gastrin and gastric acid secretion
	Cholecystokinin	Presence of chyme (acid, partially digested proteins, fats) in the duodenum	Stimulates gallbladder to eject bile and pancreas to secrete alkaline fluid; decreases gastric motility; constricts pyloric sphincter; inhibits gastrin; delays gastric emptying
	Enteroglucagon	Intraluminal fats and carbohydrates	Weakly inhibits gastric and pancreatic secretion and enhances insulin release, lipolysis, ketogenesis, and glycogenolysis; delays gastric emptying
	Entero-oxyntin	Presence of chyme in duodenum	Delays gastric emptying
	Gastric inhibitory peptide (GIP)	Fat and glucose in small intestine	Inhibits gastric secretion and gastric emptying, stimulates insulin release; inhibits intestinal motility
	Peptide YY	Intraluminal fat and bile acids	Inhibits postprandial gastric acid and pancreatic secretion and delays gastric and small bowel emptying
	Pancreatic polypeptide	Protein, fat, and glucose in small intestine	Decreases pancreatic and enzyme secretion
	Vasoactive intestinal peptide	Intestinal mucosa and muscle	Relaxes intestinal smooth muscle, increases blood flow

†Note: The digestive hormones are not secreted into the gastrointestinal lumen but rather into the bloodstream, in which they travel to target tissues. There are more than 30 peptide hormone genes expressed in the gastrointestinal tract and more than 100 hormonally active peptides.

in the duodenum by the action of bile from the liver and enzymes from the pancreas, stimulate the secretion of **cholecystokinin.**[7] This hormone inhibits food intake, reduces gastric motility, and decreases gastric emptying so that fats are not emptied into the duodenum at a rate that exceeds the rate of bile and enzyme secretion. Osmoreceptors in the wall of the duodenum are sensitive to the osmotic pressure of duodenal contents. The arrival of hypertonic or hypotonic gastric contents activates the osmoreceptors, which delays gastric emptying to facilitate formation of an isosmotic duodenal environment. The rate at which acid enters the duodenum also influences gastric emptying. Secretions from the pancreas, liver, and duodenal mucosa neutralize gastric hydrochloric acid in the duodenum. The rate of emptying is adjusted to the duodenum's ability to neutralize the incoming acidity. Peristaltic activity in the stomach is also affected by blood glucose levels. Low blood glucose levels stimulate the vagus nerve and gastric smooth muscles, increasing the rate of contraction.[8]

Gastric Secretion

Stimulated by eating, the stomach produces large volumes of gastric secretions. Specialized cells located throughout the gastric mucosa produce mucus, acid, enzymes, hormones, intrinsic factor, and gastroferrin. Intrinsic factor is necessary for the intestinal absorption of vitamin B_{12} and gastroferrin facilitates small intestinal absorption of iron. The hormones are secreted into the blood and travel to target tissues in the bloodstream. The other gastric secretions are released directly into the stomach lumen under neural and hormonal regulation.[9] Mucus covering the entire mucosa, intercellular tight junctions, bicarbonate secretion, and submucosal acid sensors form a protective barrier against acid and proteolytic enzymes, which otherwise would damage the gastric lining.[10]

In the fundus and body of the stomach the **gastric glands** of the mucosa are the primary secretory units (Figure 40-5). Several of these glands (three to seven) empty into a common duct known as the **gastric pit.** The **parietal cells (oxyntic cells)** within the glands secrete hydrochloric acid, intrinsic factor, and gastroferrin. The **chief cells** within the glands secrete **pepsinogen,** an enzyme precursor that is readily converted to **pepsin** (a proteolytic enzyme) in the gastric fluid. The pyloric gland mucosa in the antrum synthesizes and releases the hormone gastrin from **G cells. Enterochromaffin-like cells** secrete **histamine,** and **D cells** secrete **somatostatin.**

The composition of gastric fluid depends on volume and flow rate (Figure 40-6). Potassium level remains relatively constant, but its concentration is greater in gastric secretions than in plasma. The rate of secretion varies with the time of day; lower in the morning and higher in the afternoon and evening. Loss of gastric secretions through vomiting, drainage, or suction may decrease body stores of sodium, potassium, hydrogen, and chloride.

Acid. The major functions of **gastric hydrochloric acid** are to dissolve food fibers, act as a bactericide against swallowed organisms, and convert pepsinogen to pepsin. The production of acid by the parietal cells requires the transport of hydrogen and chloride from the parietal cells to the stomach lumen. Acid is formed in the parietal cells, primarily through the hydrolysis of water (Figure 40-7). At a high rate of gastric secretion, bicarbonate moves into the plasma, producing an "alkaline tide" in the venous blood, which also may result in a more alkaline urine.[11]

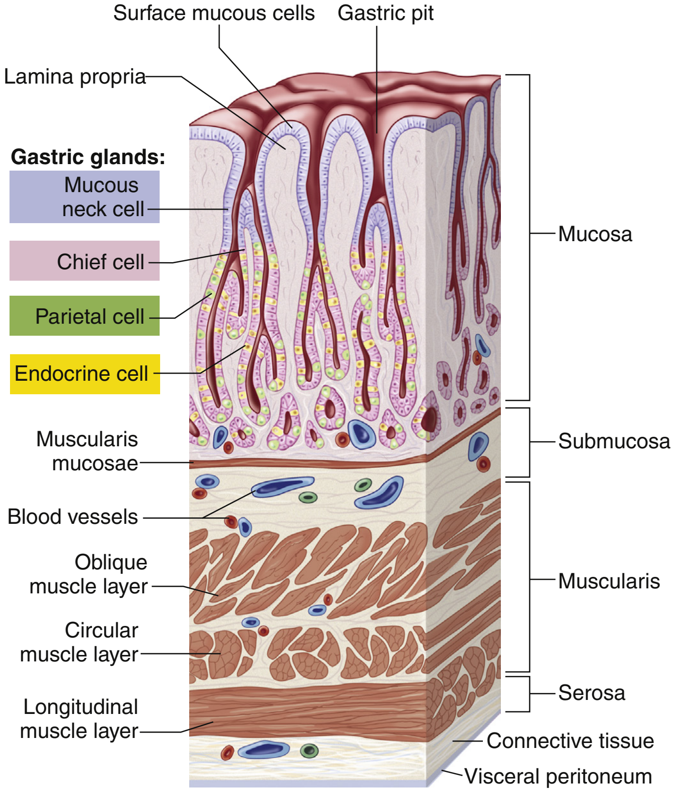

FIGURE 40-5 **Gastric Pits and Gastric Glands.** Gastric pits are depressions in the epithelial lining of the stomach. At the bottom of each pit is one or more tubular gastric glands. Chief cells produce the enzymes of gastric juice, and parietal cells produce stomach acid. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

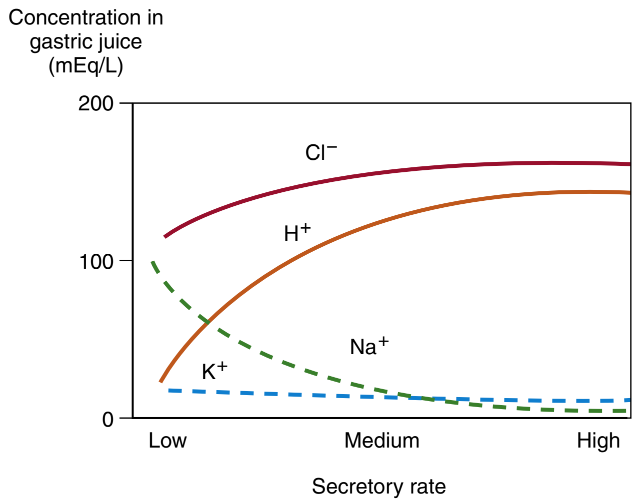

FIGURE 40-6 **Relationship Between Secretory Rate and Electrolyte Composition of the Gastric Secretions.** Sodium *(Na^+)* concentration is lower in the gastric secretions than in the plasma, whereas hydrogen *(H^+),* potassium *(K^+),* and chloride *(Cl^-)* concentrations are higher. Gastric secretions are close to isotonic. Secretory rate increases during the cephalic and gastric phases of digestion.

Acid secretion by parietal cells is stimulated by acetylcholine (ACh) (a neurotransmitter), gastrin (a hormone), and histamine (a biochemical mediator). The vagus nerve releases ACh and stimulates the secretion of histamine and gastrin-releasing peptide (GRP), which stimulates release of gastrin.[12] Histamine secretion is also stimulated by gastrin. Histamine is stored in enterochromaffin cells (mast cells; see Chapter 7) in the gastric mucosa. Histamine receptors in the gastric mucosa are H2 receptors (unlike those in the bronchial mucosa, which are H1 receptors). Gastric lipase is produced by glands in the fundus of the stomach and is most effective in an acidic environment. Caffeine stimulates acid secretion, as does calcium. Prostaglandins, enterogastrones (such as gastric inhibitory peptide), somatostatin, and secretin inhibit acid secretion.[13]

Pepsin. Acetylcholine, through vagal stimulation during the cephalic and gastric phases, is the strongest stimulation for pepsin secretion. The precursor pepsinogen is quickly converted to pepsin at a pH of 2. Acid also stimulates a local cholinergic reflex and stimulates chief cells to secrete pepsin. Gastrin and secretin are weaker pepsinogen secretagogues. **Pepsin** is a proteolytic enzyme that breaks down protein-forming polypeptides in the stomach. Once chyme has entered the duodenum, the alkaline environment of the duodenum inactivates pepsin.

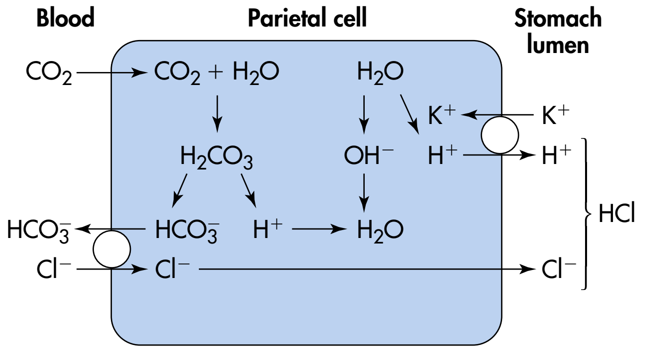

FIGURE 40-7 Hydrochloric Acid Secretion by Parietal Cell.

Mucus. The gastric mucosa is protected from the digestive actions of acid and pepsin by a coating of mucus called the **mucosal barrier.** Gastric mucosal blood flow is important to maintaining mucosal barrier function.[14]

The quality and quantity of mucus and the tight junctions between epithelial cells make gastric mucosa relatively impermeable to acid. Prostaglandins and nitric oxide protect the mucosal barrier by stimulating the secretion of mucus and bicarbonate and by inhibiting the secretion of acid. A break in the protective barrier may occur because of exposure to aspirin or other nonsteroidal anti-inflammatory drugs, *Helicobacter pylori,* ethanol, regurgitated bile, or ischemia. Breaks cause inflammation and ulceration.

Intrinsic factor (IF), a mucoprotein produced by parietal cells, combines with vitamin B_{12} in the stomach. It is required for the absorption of vitamin B_{12} by the ileum. Atrophic gastritis and failure to absorb vitamin B_{12} result in pernicious anemia (see Chapter 28).

Phases of Gastric Secretion. The secretion of gastric juice is influenced by numerous stimuli that together facilitate the process of digestion. The **phases of gastric secretion** are the cephalic phase, gastric phase, and intestinal phase (Figure 40-8).

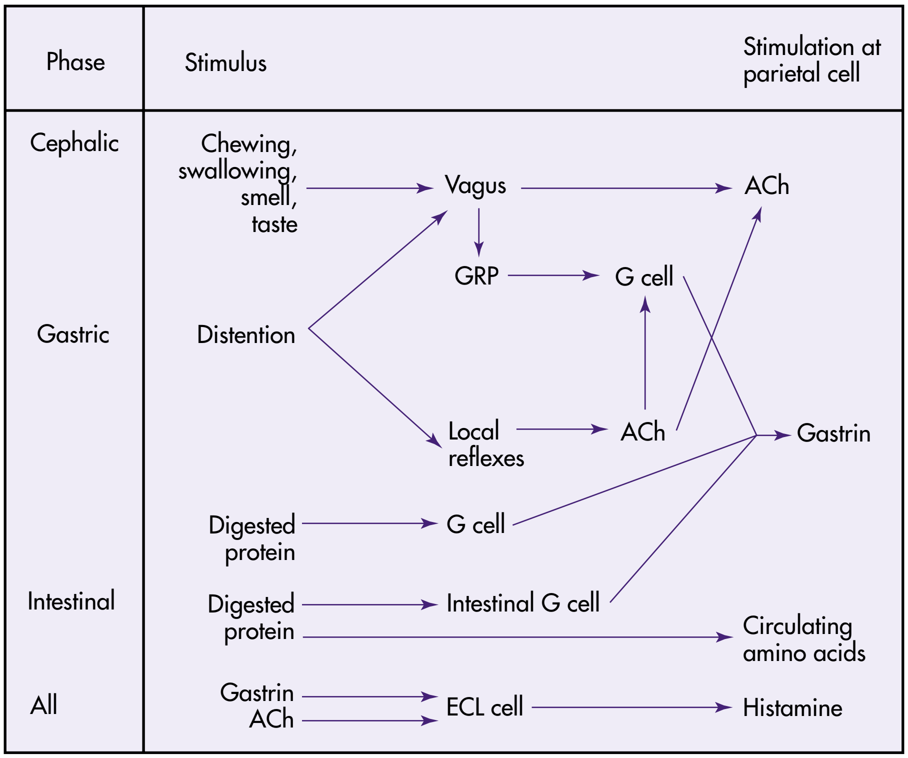

FIGURE 40-8 Mechanisms for Stimulating Acid Secretion. *ACh,* Acetylcholine; *ECL,* enterochromaffin-like cell; *GRP,* gastrin-releasing peptide. (From Johnson LR: *Gastrointestinal physiology,* ed 7, St Louis, 2007, Mosby.)

Cephalic Phase. The anticipatory and sensory experiences of smelling, seeing, tasting, chewing, and swallowing food contribute to the **cephalic phase of secretion.**[15] The cephalic phase of gastric secretion is mediated by the vagus nerve through the myenteric plexus. Acetylcholine stimulates the parietal and chief cells to secrete acid and pepsinogen, respectively. The G cells in the antrum release gastrin, which circulates through the bloodstream to the gastric glands and stimulates acid and pepsinogen secretion.

Insulin secretion by the endocrine pancreas, stimulated by hyperglycemia, also is a strong stimulus for gastric secretion and is mediated by the vagus nerve through sensors located in the hypothalamus. Maintenance of steady serum glucose levels suppresses the gastric response to insulin.

Gastric Phase. The **gastric phase of secretion** begins with the arrival of food in the stomach. Two major stimuli have a secretory effect: (1) distention of the stomach, and (2) the presence of digested protein. The vagus and enteric nerve plexuses are stimulated by distention and contribute to gastric secretion through a local reflex. Both neural reflexes are mediated by ACh and can be blocked by atropine. As digestion proceeds, products of protein break down, stimulating the release of more gastrin from G cells.

Intestinal Phase. The movement of chyme from the stomach into the duodenum initiates the **intestinal phase of secretion.** This phase represents a deceleration of the gastric secretory response; however, the presence of digested protein and amino acids in the duodenum continues to stimulate some gastric secretion.

Concurrently, in response to low duodenal pH and the presence of lipids, inhibitory vagal and enteric reflexes decrease gastric motility when chyme enters the duodenum. The release of secretin and cholecystokinin stimulate pancreatic secretions and inhibit gastric secretions.

Small Intestine

The **small intestine** is about 5 to 6 m long and is functionally divided into three segments: the duodenum, jejunum, and ileum (Figure 40-9). The **duodenum** begins at the pylorus and ends where it joins the **jejunum** at a suspensory ligament called the *Treitz ligament*. The end of the jejunum and beginning of the **ileum** are not distinguished by an anatomic marker. These structures are not grossly different, but the jejunum has a slightly larger lumen. The **ileocecal valve** (**sphincter**) controls the flow of digested material from the ileum into the large intestine and prevents reflux into the small intestine.

The **peritoneum** is the serous membrane surrounding the organs of the abdomen and lining the abdominopelvic cavity. It is analogous to the pericardium and pleura that surround the heart and lungs, respectively. The *visceral peritoneum* lies

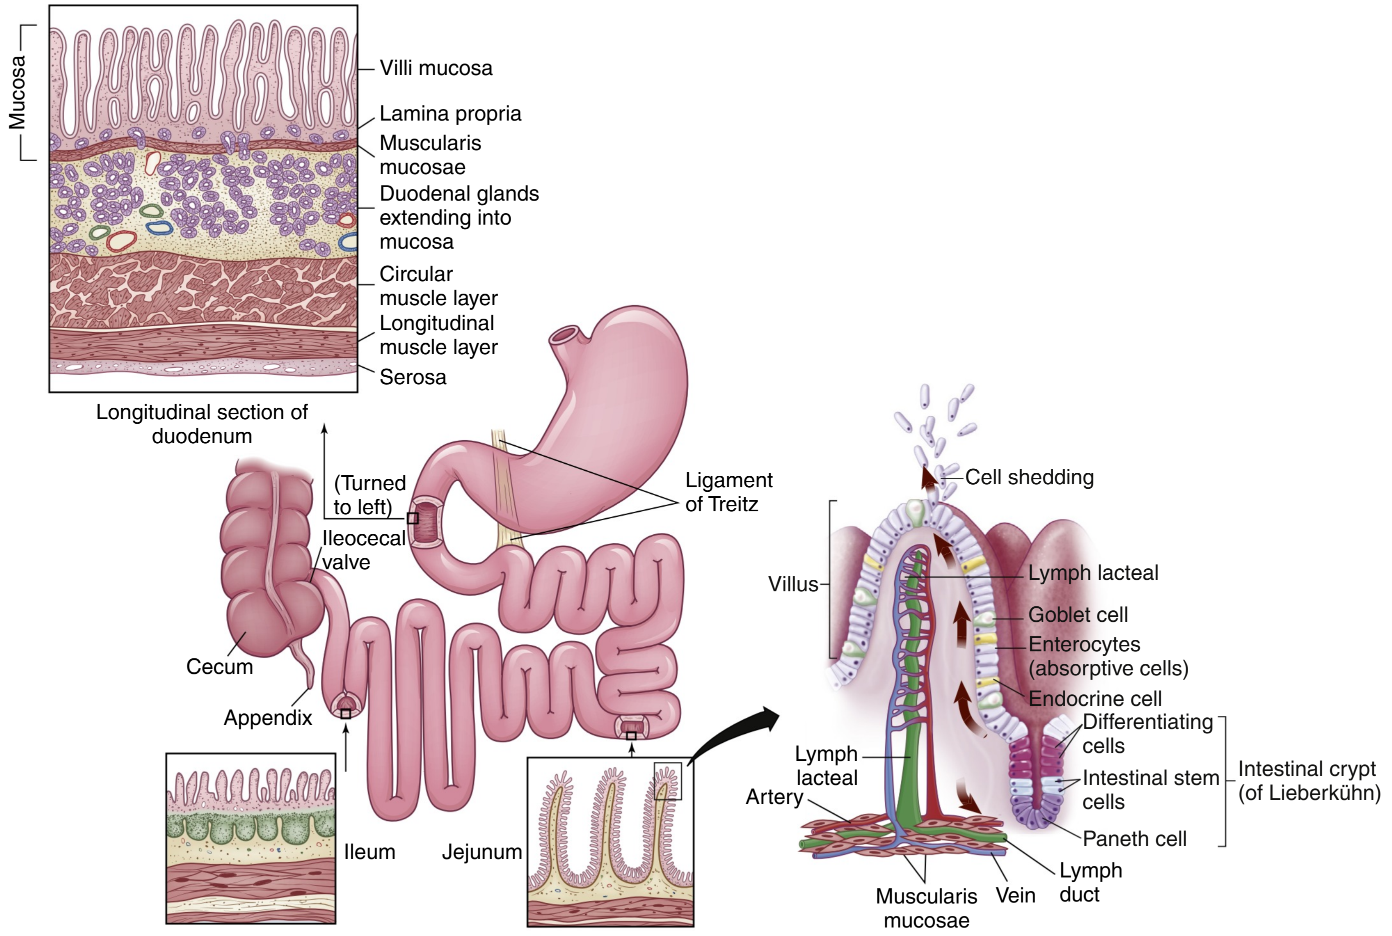

FIGURE 40-9 Small Intestine.

on the surface of the organs, and the *parietal peritoneum* lines the wall of the body cavity. The space between these two layers is called the **peritoneal cavity.** This cavity normally contains just enough fluid to lubricate the two layers and prevent friction during organ movement. Inflammation of the peritoneum, called *peritonitis,* may occur with perforation of the intestine or after abdominal surgery. As the inflammatory process resolves, scar tissue adhesions may form and cause intestinal obstruction.

The duodenum lies behind the peritoneum, or retroperitoneally, and has an essential role in mixing food with digestive juices from the liver and pancreas. The ileum and jejunum are suspended from the posterior abdominal wall by a component of the peritoneum called the **mesentery.** The loose folds of the mesentery facilitate intestinal motility and support blood vessels, nerves, and lymphatics.

The arterial supply to the duodenum arises primarily from the gastroduodenal artery, a small branch of the celiac artery. The jejunum and ileum are supplied by branches of the superior mesenteric artery. Blood flow increases significantly during digestion. The superior mesenteric vein drains blood from the entire small intestine and empties into the hepatic portal circulation. The regional lymphatics drain into the thoracic duct. Both divisions of the autonomic nervous system innervate the small intestine. Secretion, motility, and intestinal reflexes (e.g., relaxation of the lower esophageal sphincter) are mediated parasympathetically by the vagus nerve. Sympathetic activity inhibits motility and produces vasoconstriction. Intrinsic reflexive activity is mediated by the myenteric plexus (Auerbach plexus) and the submucosal plexus (Meissner plexus) of the enteric nervous system.

The smooth muscles of the small intestine are arranged in two layers: a longitudinal, outer layer; and a thicker, inner circular layer (see Figure 40-9). Circular folds of the small intestine mucosa slow the passage of food, thereby providing more time for digestion and absorption. The folds are most numerous and prominent in the jejunum and upper ileum.

Absorption occurs through **villi,** which cover the circular folds and are the functional units of the intestine (see Figure 40-9). A villus is composed of absorptive columnar epithelial cells (enterocytes) and mucus-secreting goblet cells of the mucosa. Each villus secretes some of the enzymes necessary for digestion and absorbs nutrients. Near the surface, columnar cells closely adhere to each other at sites called *tight junctions.* Water and electrolytes are absorbed through these intercellular spaces. The surface of each columnar epithelial cell on the villus contains tiny projections called **microvilli** (see Figure 40-9). Together the microvilli create a mucosal surface known as the **brush border.** The villi and microvilli greatly increase the surface area available for absorption. Coating the brush border is an "unstirred" layer of fluid that is important for the absorption of substances other than water and electrolytes. The **lamina propria** (a connective tissue layer of the mucosa) lies beneath the epithelial cells of the villi and contains lymphocytes; plasma cells, which produce immunoglobulins; and macrophages.

Central arterioles ascend within each villus and branch into a capillary array that extends around the base of the columnar cells and cascades down to the venules that lead to the hepatic portal circulation. The opposing ascending and descending blood flow provides a countercurrent exchange system for absorbed substances and blood gases. A central **lacteal,** or lymphatic capillary, is also contained within each villus and is important for the absorption and transport of fat molecules. Contents of the lacteals flow to regional nodes and channels that eventually drain into the thoracic duct[16] (see Figure 40-9).

Between the bases of the villi are the **crypts of Lieberkühn** (intestinal glands), which extend to the submucosal layer. Undifferentiated (**stem cells**) and secretory cells and Paneth epithelial cells are located here. The stem cells are precursors of columnar epithelial and goblet cells. These premature cells produce alkaline fluids containing electrolytes, mucus, and water. These cells arise from the base of the crypt and move toward the tip of the villus, maturing in shape and function as they progress. After becoming columnar cells and completing their migration to the tip of the villus, they function for a few days and then are shed into the intestinal lumen and digested. The entire epithelial population is replaced about every 4 to 7 days. Many factors can influence this process of cellular proliferation. Starvation, vitamin B_{12} deficiency, and cytotoxic drugs or irradiation suppress cell division and shorten the villi. The decreased absorption that results can cause diarrhea and malnutrition. Nutrient intake and intestinal resection stimulate cell production. The **Paneth cells** located at the base of the crypts produce defensins and other antibiotic peptides and proteins.[17] Other secretory cells produce digestive enzymes.

Intestinal Digestion and Absorption

The process of intestinal digestion is initiated in the stomach by the actions of gastric hydrochloric acid and pepsin, which break down food fibers and proteins. The chyme that passes into the duodenum is a liquid that contains small particles of undigested food. Digestion is continued in the proximal portion of the small intestine by the action of pancreatic enzymes, intestinal brush-border enzymes, and bile salts (Box 40-1). Here carbohydrates are broken down to monosaccharides and disaccharides; proteins are degraded further to amino acids and peptides; and fats are emulsified and reduced to fatty acids and monoglycerides (Figure 40-10). These nutrients, along with water, vitamins, and electrolytes, are absorbed across the intestinal mucosa and into the blood by active transport, diffusion, or facilitated diffusion. Products of carbohydrate and protein breakdown move into villus capillaries and then to the liver through the hepatic portal vein. Digested fats move into the lacteals and eventually reach the liver through the systemic circulation. Intestinal motility exposes nutrients to a large mucosal surface area by mixing chyme and moving it through the lumen. Different segments of the gastrointestinal tract absorb different nutrients. Digestion and absorption of all major nutrients occur in the small intestine. Sites of absorption are shown in Figure 40-11.

Water and Electrolyte Transport by the Small Intestine. The epithelial cell membranes of the small intestine are formed of lipids and therefore are hydrophobic, or tend to repel water. (The properties of cell membranes are described in Chapter 1.) Therefore, water and electrolytes are transported in both directions (toward the capillary blood or toward the intestinal lumen) through the tight junctions and intercellular spaces

rather than across cell membranes. Water diffuses passively across hydrostatic pressure and osmotic gradients established by the active transport of sodium and other substances. Approximately 85% to 90% of the water that enters the gastrointestinal tract each day is absorbed in the small intestine. The remaining water and electrolytes are absorbed at a constant rate in the large intestine.[18] Sodium passes through the tight junctions and is actively transported across cell membranes. Sodium and glucose share a common active transport carrier (sodium-glucose ligand transporter1 [SGLT1]) so that sodium absorption is enhanced by glucose transport[18a] (Figure 40-12). Potassium moves passively across the tight junctions with changes in the electrochemical gradient. Chloride is actively secreted throughout the large and small intestines.

Carbohydrates. Carbohydrate (starch, table sugar [sucrose], milk sugar [lactose], cereal sugar [maltose]) accounts for at least 50% of the American diet. Because only monosaccharides (ribose, galactose, glucose, fructose) are absorbed by the intestinal mucosa, the complex carbohydrates (polysaccharides and oligosaccharides) must be hydrolyzed to their simplest form (see Figure 40-10). Salivary and pancreatic amylases break down starches to oligosaccharides by splitting α-1,4-glucosidic linkages of long-chain molecules. The major disaccharides are sucrose (glucose-fructose), maltose (glucose-glucose), and lactose (glucose-galactose). Approximately half of starch hydrolysis occurs in the stomach and about half in the duodenum. In the small intestine, disaccharides are hydrolyzed by brush-border enzymes (sucrase, maltase, and lactase) to their respective monosaccharides.

The sugars are absorbed primarily in the duodenum and upper jejunum. The monosaccharides pass through the unstirred layer by diffusion. At the cell membrane, glucose and galactose are actively transported with a sodium carrier (SGLT1) and fructose absorption is facilitated by glucose transporter 5 (GLUT5) and GLUT7.[19] Transport of all three monosaccharides from the cytosol to the bloodstream is facilitated by GLUT2[20] (see Figure 40-12). Insulin facilitates glucose transport into fat and muscle cells via glucose transporter 4 (GLUT4).

Insulin is not required for the intestinal absorption of glucose. Cellulose is a glucose polysaccharide found in plants. Humans lack enzymes to digest cellulose, and the undigested fiber contributes to stool volume and stimulates large intestine motility.

Proteins. Adults require 44 to 56 g of protein per day. Approximately 20 to 30 g of protein is derived endogenously from shed epithelial cells and small amounts of plasma proteins. Most ingested protein is absorbed; only 5% to 10% is eliminated in the stool.

The site of digestion of protein depends on the source of the protein. For example, casein from bovine milk precipitates in the stomach and is digested by gastric pepsin and acid, whereas the soluble proteins whey and soy pass rapidly through the stomach and are digested by pancreatic enzymes.[21] Major protein hydrolysis is accomplished in the small intestine by the pancreatic enzymes trypsin, chymotrypsin, and carboxypeptidase (see Figure 40-10). **Trypsin** and **chymotrypsin** (endopeptidase) hydrolyze the interior bonds of the large molecules, and **carboxypeptidases** cleave the end amino acids (exopeptidase). Hydrolysis of proteins is also carried out by the brush-border enzymes and enzymes in the epithelial cytosol (intracellular fluid). The brush-border enzymes hydrolyze the large oligopeptides (proteins composed of three to six amino acids) into smaller peptides, which can cross cell membranes. Enzymes in the cytosol then break them down to amino acids. Amino acids are actively transported from the cytosol into the bloodstream by a sodium-dependent carrier in the basolateral membrane. There also are free amino acids that can be absorbed directly from the intestinal lumen using a membrane transport protein. Like the sugars, proteins are absorbed primarily in the proximal area of the small intestine.

Fats

Approximately 90 to 100 g of fat is consumed daily by the average American. **Fat** is an important source of calories and is a primary structural component of cell membranes and organelles. Sources of dietary fat are reviewed in Box 40-2. Although triglycerides are the major dietary lipids, cholesterol, phospholipids, and fat-soluble vitamins also have nutritional importance. The digestion and absorption of fat occur in four phases: (1) emulsification and lipolysis, (2) micelle formation, (3) fat absorption, and (4) resynthesis of triglycerides and phospholipids.

The mechanical action of the stomach and small intestine disperses the triglyceride droplets into small particles.

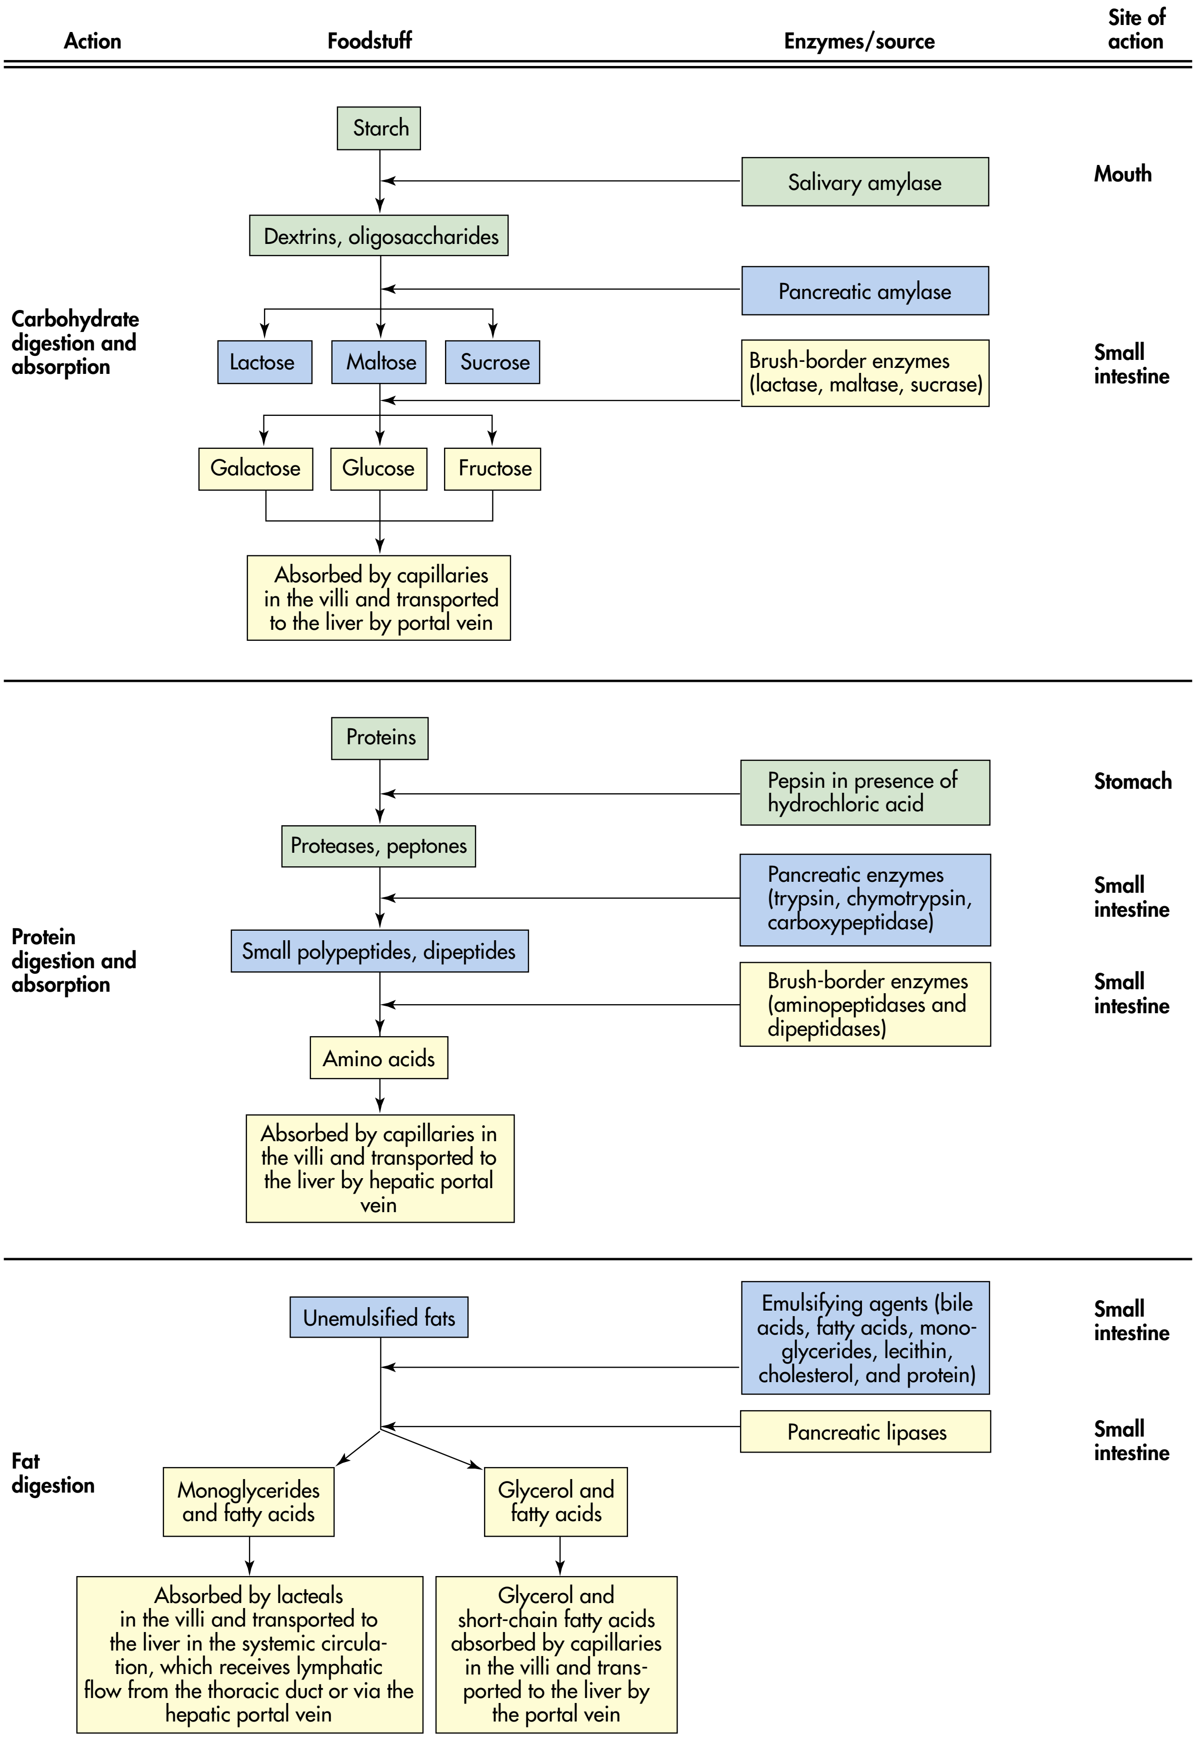

FIGURE 40-10 Digestion and Absorption of Foodstuffs.

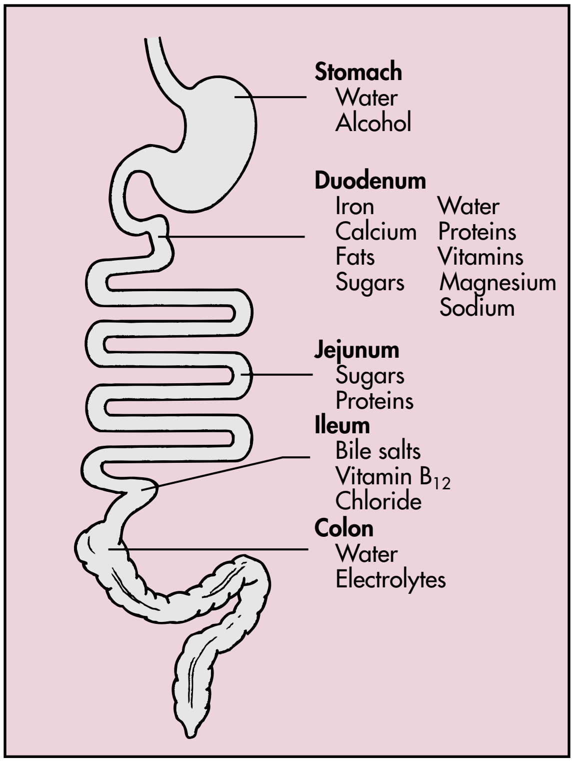

FIGURE 40-11 Sites of Absorption of Major Nutrients.

Emulsification is the process by which emulsifying agents (fatty acids, monoglycerides, lecithin, cholesterol, protein, bile salts) in the small intestinal lumen cover the small fat particles and prevent them from re-forming into fat droplets. Emulsified fat is then ready for **lipolysis** (lipid hydrolysis) by pancreatic lipase, phospholipase, and hydrolase. **Lipase** breaks down triglycerides to diglycerides, monoglycerides, free fatty acids, and glycerol (see Figure 40-10). The action of lipase requires the presence of **colipase,** a pancreatic enzyme that allows lipase to penetrate the triglyceride molecule. **Phospholipase** cleaves fatty acids from phospholipids, and **cholesterol esterase** breaks cholesterol esters into fatty acids and glycerol.

The products of lipid hydrolysis must be made water soluble if they are to be absorbed efficiently from the intestinal lumen. This is accomplished by the formation of water-soluble molecules known as **micelles** (Figure 40-13). Micelles are formed of bile salts (see p. 1411), the products of fat hydrolysis, fat-soluble vitamins, and cholesterol. The fats form the core of the micelle, and the polar bile salts form an outer shell, with the hydrophobic (“water-hating”) side facing the interior and the hydrophilic (“water-loving”) side facing the aqueous (water-like) content of the intestinal lumen. Because the unstirred layer of the brush border is aqueous, the micelles readily diffuse through it. The micelles maintain the fat molecules in the dissolved or solubilized form, which allows them to move more rapidly from the micelle toward the absorbing surface of the intestinal epithelium. The fat products of the micelle then readily diffuse through the epithelial cell membrane, while the bile salts remain in the lumen and proceed to the ileum, where they are absorbed into

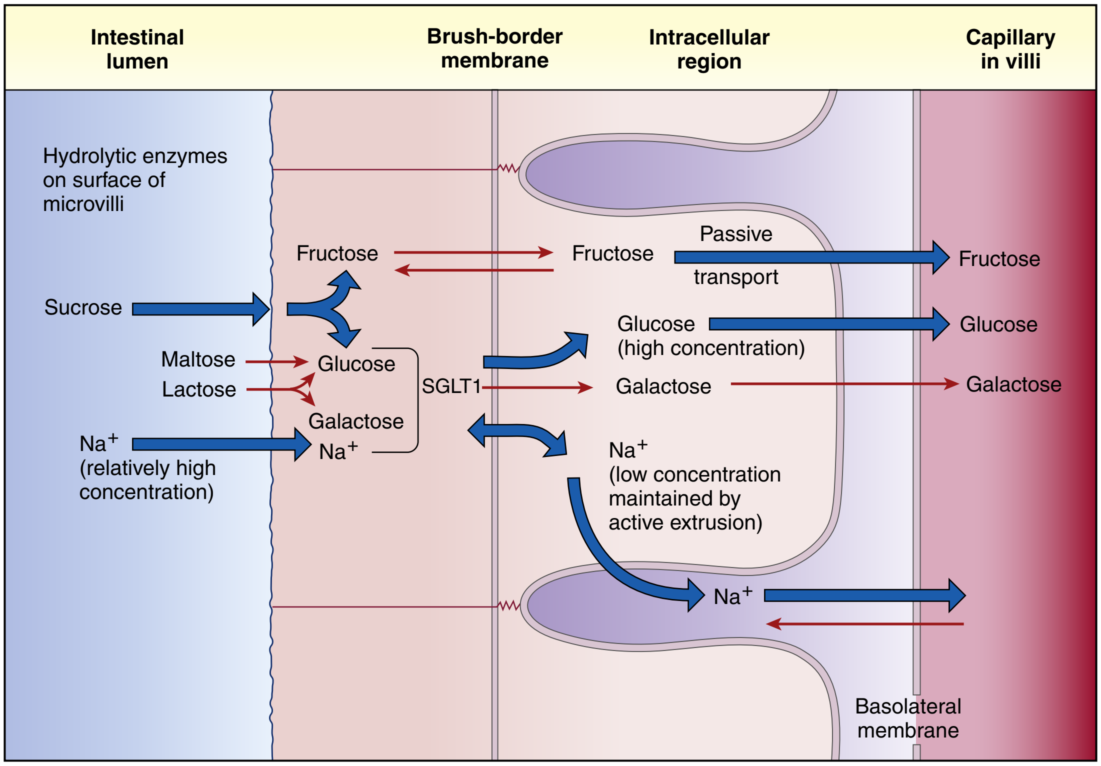

FIGURE 40-12 Monosaccharides and Sodium Transport. Schematic showing monosaccharides and sodium *(Na^+)* transport through the small intestinal epithelium. Glucose, galactose, and sodium are transported into the epithelial cell by sodium-glucose ligand transporter 1 *(SGLT1)*. See text for details.

BOX 40-2 DIETARY FAT

Saturated Fatty Acid (Palmitic Acid [$C_{16}H_{32}O_2$])

Each carbon atom in the chain is linked by single bonds to adjacent carbon and hydrogen atoms; atoms are solid at room temperature and found in animal fat and tropical oils (coconut and palm oils); they increase low-density lipoprotein (LDL) cholesterol ("bad" cholesterol) blood levels and increase the risk of coronary artery disease.

Unsaturated Fatty Acid

Unsaturated fatty acids are soft or liquid at room temperature; omega-6 fatty acids are found in plants and vegetables (olive, canola, and peanut oils), and omega-3 fatty acids are found in fish and shellfish.

1. Monounsaturated fatty acids (e.g., oleic acid [$C_{18}H_{34}O_2$]): Contain one double bond in the carbon chain and are found in plants and animals; may be beneficial in reducing blood cholesterol, glucose levels, and systolic blood pressure; do not lower high-density lipoprotein (HDL) cholesterol ("good" cholesterol) level; low HDL levels have been associated with coronary heart disease.
2. Polyunsaturated fatty acids (e.g., linoleic acid [$C_{18}H_{32}O_2$]): Contain two or more double bonds in the carbon chain and are found in plants and fish oils; omega-6 fatty acids lower total and LDL cholesterol blood levels; high levels of polyunsaturated fatty acids may lower LDL level; omega-3 fatty acids lower blood triglyceride levels, reduce platelet aggregation and blood-clotting tendency, are necessary for growth and development, and may prevent coronary artery disease, hypertension, cancer, and inflammatory and immune disorders.

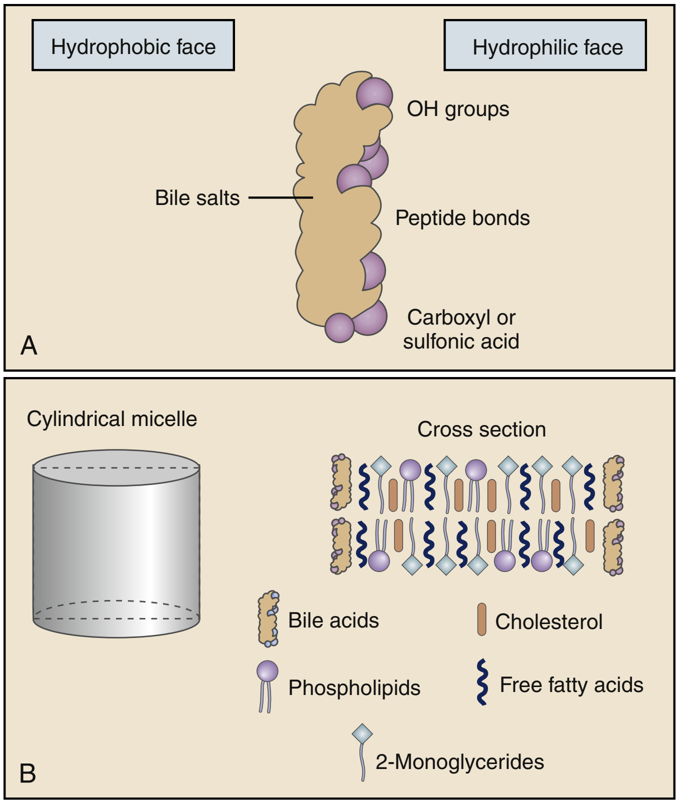

FIGURE 40-13 Structure of Bile Acid and Micelle. **A,** A bile salt molecule in solution. The molecule is amphipathic in that it has a hydrophilic face and a hydrophobic face. The amphipathic structure is key in the ability of the bile salts to emulsify lipids and form micelles. **B,** A model of the structure of a bile salt–lipid mixed micelle, an emulsified fat. (From Levy MN, Koeppen BM, Stanton BA: *Principles of physiology,* ed 4, St Louis, 2006, Mosby.)

the circulation and returned to the liver via the enterohepatic circulation (Figure 40-14 and Figure 40-20, p. 1411). Almost all of the bile salts are recycled in this way.

When the fat products reach the inside of the epithelial cell, they are resynthesized into triglycerides and phospholipids. The triglycerides are covered with phospholipids, lipoproteins, and cholesterol to become particles called **chylomicrons.** The chylomicrons travel to the basolateral membrane of the columnar epithelial cells, where they are extruded into the intercellular spaces of the villus. From here they enter the lacteals and lymphatic channels and, eventually, the systemic circulation.

Minerals and Vitamins. The recommended intake of calcium ranges from 1000 to 1500 mg/day. Between 500 and 600 mg is secreted or shed into the lumen with desquamated epithelial cells. Not all of this calcium is absorbed. Daily absorption of **calcium** is approximately 600 mg. This amount increases with increased intake. When its concentration in the lumen is greater than 5 mmol/L, calcium is absorbed by passive diffusion. At concentrations less than 5 mmol/L, calcium is transported actively across cell membranes, bound to a carrier protein. The carrier formation requires the presence of the active form of vitamin D_3 (1,25-dihydroxy-vitamin D). The calcium-protein complex moves into the epithelial cell, where the calcium binds to proteins or other substances. Then these complexes move through the basolateral membrane to the interstitial fluid by diffusion or active transport. Calcium is absorbed throughout the small intestine, but primarily in the ileum. Increased serum calcium concentration inhibits parathyroid hormone, which in turn decreases the formation of vitamin D_3 by the kidney, thus regulating calcium absorption.

Increased demand for calcium results in increased uptake, as evidenced by the fact that calcium is absorbed more rapidly in children and pregnant or lactating women. Bile salts enhance calcium absorption indirectly by facilitating the absorption of vitamin D, which is fat soluble. In addition, bile salts promote the absorption of free fatty acids that, at high concentrations, bind calcium and form soaps in the intestinal lumen. In older individuals calcium is absorbed less readily because of inadequate amounts of the active form of vitamin D.[22]

The recommended intake of **magnesium** for adults is 300 to 350 mg/day. Approximately 50% of it is absorbed by active transport or passive diffusion in the jejunum and ileum. **Phosphate** is also absorbed in the small intestine by passive diffusion and active transport.

The levels of **iron** in the body are regulated primarily by intestinal absorption and secretion. The average intake ranges from 15 to 30 mg/day. Of this amount, menstruating women absorb 1 to 1.5 mg and men absorb 0.15 to 1 mg. Generally the amount of iron absorbed is equal to the amount required. Iron is absorbed more rapidly if a deficiency exists. A primary source of iron is heme from animal protein. This iron is rapidly absorbed by the epithelial cells primarily in the duodenum. Inorganic iron (e.g., iron in fruits, cereals, eggs, vegetables) is also readily absorbed. The presence of vitamin C reduces ferric iron to ferrous iron, which is the form more easily absorbed. Calcium phosphate and phosphoproteins (milk and antacids) in the intestinal lumen bind iron and reduce absorption. Tea also binds iron and inhibits its absorption by forming iron tannate complexes.

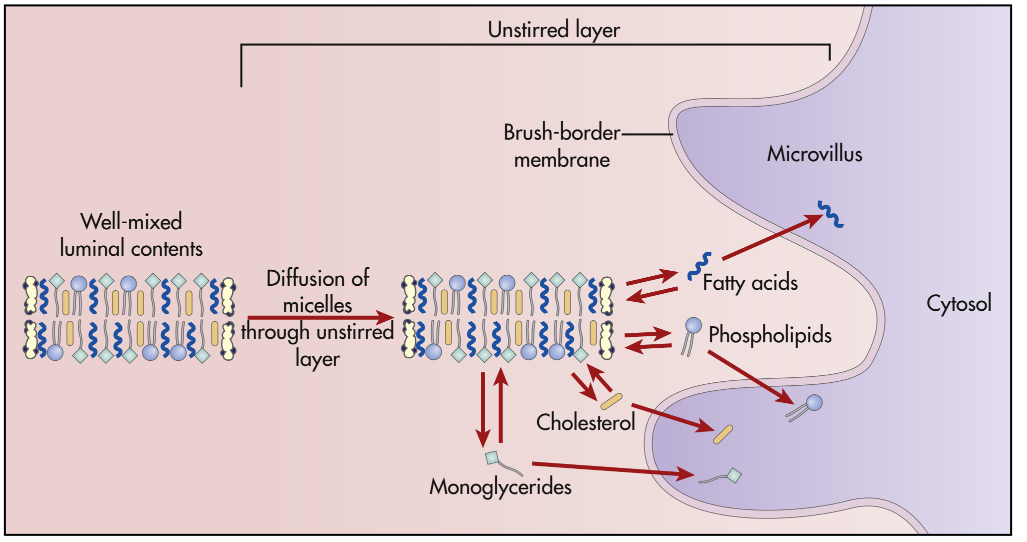

FIGURE 40-14 **Lipid Absorption in the Small Intestine.** Micelles of bile salts and products of lipid digestion diffuse through the unstirred layer and among the microvilli. As digestive products are absorbed from free solution by epithelial cells of the villi, more digestive products dissociate from the micelles. (From Levy MN, Koeppen BM, Stanton BA: *Principles of physiology,* ed 4, St Louis, 2006, Mosby.)

TABLE 40-2 INTESTINAL ABSORPTION OF VITAMINS

VITAMIN	MECHANISMS OF ABSORPTION	SITE OF ABSORPTION
Fat-Soluble Vitamins	Micelle formation with bile salts; lipid diffusion	Ileum
A (retinal)		
D_3 (1,25-dihydroxy-vitamin D)		
E (α-tocopherol)		
K		
Water-Soluble Vitamins		
B_1 (thiamine)	Active transport (sodium dependent)	Duodenum and jejunum
B_2 (riboflavin)	Unknown	Duodenum and jejunum
Niacin (nicotinic acid)	Passive diffusion	Jejunum
C (ascorbic acid)	Passive diffusion; active transport (sodium dependent)	Ileum
Folic acid	Active transport (sodium dependent)	Jejunum
B_{12} (cobalamin)	Active transport (intrinsic factor dependent)	Terminal ileum
B_6 (pyridoxine, pyridoxamine, pyridoxal phosphate)	Passive diffusion	Jejunum
Pantothenic acid	Passive diffusion	Duodenum and jejunum
Biotin	Unknown	Unknown

Iron is bound to *intestinal transferrin* in the lumen and is absorbed and bound to the protein *ferritin* and to amino acid chelates in the cytosol of the enterocytes. Transport of iron across the basolateral membrane is determined by the amount of iron in the circulation. It is transported in the blood by *plasma transferrin,* a glycoprotein, and is carried to body tissues. When there is less need for iron, it remains in the enterocyte as ferritin and is carried into the lumen when the cell is sloughed from the end of the villus. Following hemorrhage, the intestinal cells require 3 days to increase their rate of iron absorption. This is because the need for iron is perceived by the precursor stem cells in the crypts of Lieberkühn, and they take 3 days to mature and migrate to the tips of the villi, where they absorb more iron. **Hepcidin** is a protein synthesized by the liver that inhibits apical uptake of iron by enterocytes and modulates iron trafficking.[23]

The absorption of **vitamins** is summarized in Table 40-2. Most of the water-soluble vitamins are absorbed passively or by sodium-dependent active transport. Most vitamin B_{12} (cobalamin) is bound to intrinsic factor (making it resistant to digestion) and absorbed in the terminal ileum, although a small amount of the vitamin is absorbed in its free (unbound) form.

Intestinal Motility

The movements of the small intestine facilitate digestion and absorption. Chyme coming from the stomach stimulates intestinal movements that mix in secretions from the liver, pancreas, and intestinal glands. A churning motion brings the luminal content into contact with the absorbing cells of the villi. Propulsive movements then advance the chyme toward the large intestine.

Intestinal motility is regulated by the enteric nervous system, vagal stimulation, and hormones (see Table 40-1). Two movements promote motility: segmentation and peristalsis. **Segmentation** consists of localized rhythmic contractions of the circular smooth muscles and occurs more frequently than peristalsis.[24] The contraction waves occur at different rates in different parts of the small intestine in segments of 1 to 4 cm. Frequency is greatest (12 per minute) in the upper small intestine and least (8 per minute) in the distal part of the ileum. Segmentation divides and mixes the chyme, bringing it into contact with the absorbent mucosal surface. It also helps to propel the chyme toward the large intestine. The frequency of the segmentation is regulated intrinsically by the frequency of the basic electrical rhythm (BER), which arises in the myenteric plexus of longitudinal smooth muscle and is controlled by the interstitial cells of Cajal, the pacemaker cells of the gastrointestinal (GI) tract. Although the basic rate of contraction is controlled intrinsically, the force of contraction can be enhanced extrinsically by vagal stimulation.[25]

Intestinal peristalsis involves short segments (about 10 cm) of longitudinal smooth muscle and propels chyme through the intestine. The wave of contraction moves slowly (1 to 2 cm/second) to allow time for digestion and absorption.

Peptide hormones, including motilin, gastrin, secretin, and cholecystokinin, facilitate intestinal motility. Neural reflexes along the length of the small intestine facilitate motility, digestion, and absorption. Through reflex action, receptors in one part of the intestine transmit signals that influence the function of another part. The **ileogastric reflex** inhibits gastric motility when the ileum becomes distended. This prevents the continued movement of chyme into an already distended intestine. The **intestinointestinal reflex** inhibits intestinal motility when one part of the intestine is overdistended. Both of these reflexes require extrinsic innervation. The **gastroileal reflex,** which is activated by an increase in gastric motility and secretion, stimulates an increase in ileal motility and relaxation of the ileocecal sphincter. This empties the ileum and prepares it to receive more chyme. The gastroileal reflex is probably regulated by the hormones gastrin and cholecystokinin or through the autonomic nerves.

During prolonged fasting or between meals, particularly overnight, slow waves sweep along the entire length of the intestinal tract from the stomach to the terminal ileum. This is known as the *interdigestive myoelectric complex,* and it appears to propel residual gastric and intestinal contents, including bacteria, into the colon.

The intestinal villi move with contractions of the muscularis mucosae, a very thin layer of muscle that separates the mucosa and submucosa. Absorption is promoted by the swaying of villi in the luminal contents. Contractile activity also helps to empty the central lacteals, which contain products of fat digestion.

The **ileocecal valve (sphincter)** marks the junction between the terminal ileum and the large intestine. This valve is intrinsically regulated and is normally closed. The arrival of peristaltic waves from the last few centimeters of the ileum causes the ileocecal valve to open, allowing a small amount of chyme to pass through. Distention of the upper large intestine causes the sphincter to constrict, preventing further distention or retrograde flow of intestinal contents.

Large Intestine

The **large intestine** is approximately 1.5 m long and consists of the cecum, appendix, colon, rectum, and anal canal (Figure 40-15). The **cecum** is a pouch that receives chyme from the ileum. Attached to the cecum is the **vermiform appendix,** an appendage having little or no physiologic function. From the cecum, chyme enters the **colon,** a four-part length of intestine that loops upward, traverses the abdominal cavity, and descends to the anal canal. The four parts of the colon are the **ascending colon, transverse colon, descending colon,** and **sigmoid colon.** Two sphincters control the flow of intestinal contents through the cecum and colon: the ileocecal valve, which admits chyme from the ileum to the cecum, and the **rectosigmoid (O'Beirne) sphincter,** which controls the movement of wastes from the sigmoid colon into the rectum. A thick (2.5 to 3 cm) portion of smooth muscle surrounds the anal canal, forming the **internal anal sphincter.** Overlapping it distally is the striated skeletal muscle of the **external anal sphincter.**

In the cecum and colon the longitudinal muscle layer consists of three longitudinal bands called **teniae coli** (see Figure 40-15). The teniae coli are shorter than the colon, giving the colon its "gathered" appearance. The circular muscles of the colon separate the gathers into outpouchings called **haustra.** The haustra become more or less prominent with the contractions and relaxations of the circular muscles. The mucosal surface of the colon has rugae (folds), particularly between the haustra, and Lieberkühn crypts but no villi. Columnar epithelial cells and mucus-secreting goblet cells form the mucosa throughout the large intestine. The columnar epithelium absorbs fluid and electrolytes, and the mucus-secreting cells lubricate the mucosa.

The enteric nervous system regulates motor and secretory activity independently of extrinsic nervous system control. Extrinsic parasympathetic innervation occurs through the vagus nerve and extends from the cecum up to the first part of the transverse colon. Vagal stimulation increases rhythmic contraction of the proximal colon. Extrinsic parasympathetic fibers reach the distal colon through the sacral parasympathetic splanchnic nerves. The internal anal sphincter is usually in a state of contraction, and its reflex response is to relax when the rectum is distended. The myenteric plexus provides the major innervation of the internal anal sphincter, but responds to sympathetic stimulation to maintain contraction and parasympathetic stimulation that facilitates relaxation when the rectum is full. Sympathetic innervation of this sphincter arises from the celiac and superior mesenteric ganglia and the sphincter nerve. The external anal sphincter is innervated by the pudendal nerve arising from sacral levels of the spinal cord. Voluntary control of the external anal sphincter is paralyzed after injury of the lower spinal cord, but the internal sphincter is still functional. Sympathetic activity in the entire large intestine modulates intestinal reflexes, conveys somatic sensations of fullness and pain, participates in the defecation reflex, and constricts blood vessels. The blood supply of the large intestine and rectum is derived primarily from branches of the superior and inferior mesenteric artery.[26]

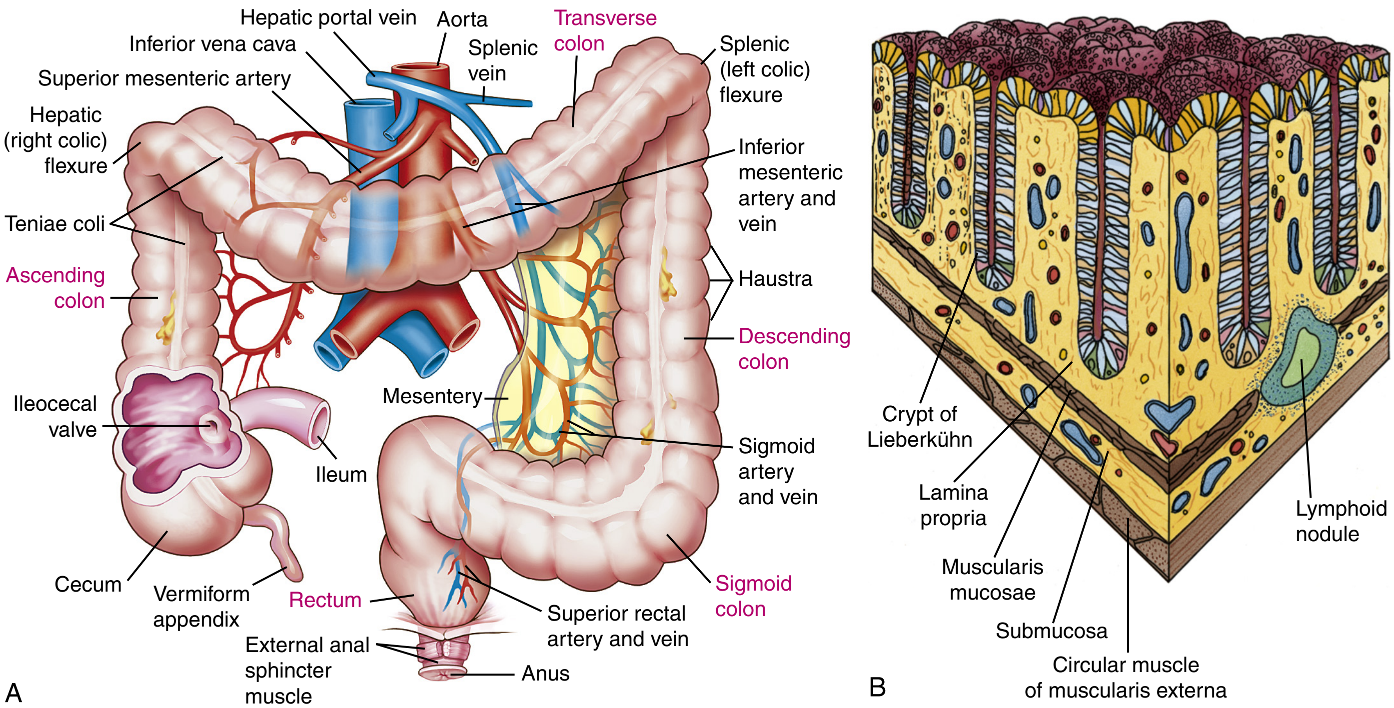

FIGURE 40-15 **Large Intestine. A,** Structure of the large intestine. **B,** Microscopic cross section illustrating cellular structures of the large intestine. The wall of the large intestine is lined with columnar epithelium in contrast to the villi characteristics of the small intestine. The longitudinal layer of muscularis is reduced to become the teniae coli. (**A** modified from Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby; **B** from Gartner LP, Hiatt JL: *Color textbook of histology,* Philadelphia, 2007, Saunders.)

The primary type of colonic movement is segmental. The circular muscles contract and relax at different sites, shuttling the intestinal contents back and forth between the contracting and relaxing haustra. The movements massage the intestinal contents, then called the **fecal mass,** and facilitate the absorption of water. Propulsive movement occurs with the proximal-to-distal contraction of several haustral units. **Peristaltic movements** also occur and promote the emptying of the colon. The **gastrocolic reflex** initiates propulsion in the entire colon, usually during or immediately after eating, when chyme enters from the ileum. The gastrocolic reflex causes the fecal mass to pass rapidly into the sigmoid colon and rectum, stimulating defecation. Gastrin and cholecystokinin participate in stimulating this reflex. Epinephrine inhibits contractile activity.

Approximately 500 to 700 ml of chyme flows from the ileum to the cecum per day. Most of the water is absorbed in the colon by diffusion and active transport. The electrochemical gradient established by sodium movement enhances the diffusion of serum potassium from the capillaries in the lumen. Aldosterone increases colon membrane permeability to sodium, thereby increasing both the diffusion of sodium into the cell and the active transport of sodium across the basolateral membrane to the interstitial fluid. (See Chapters 3, 21, and 37 for a discussion of aldosterone secretion.) This increases the cell-to-lumen diffusion gradient for potassium. Potassium moves outward, and chloride is absorbed with sodium as the complementary anion. Chloride also enters the cell in exchange for bicarbonate.

By the time the fecal mass enters the sigmoid colon, the mass consists entirely of wastes and is called the feces. **Feces,** or excrement, consists of food residue, unabsorbed gastrointestinal secretions, shed epithelial cells, and bacteria. The movement of feces into the sigmoid colon and rectum stimulates the **defecation reflex (rectosphincteric reflex).** The rectal wall stretches and the tonically constricted internal anal sphincter relaxes, creating the urge to defecate. The defecation reflex can be overridden voluntarily by contraction of the external anal sphincter and muscles of the pelvic floor. The rectal wall gradually relaxes, reducing tension, and the urge to defecate passes. Retrograde contraction of the rectum may displace the feces out of the rectal vault until a more convenient time for evacuation. Pain or fear of pain associated with defecation (e.g., rectal fissures or hemorrhoids) can inhibit the defecation reflex. The defecation reflex is regulated by parasympathetic and cholinergic fibers. Voluntary inhibition or facilitation of defecation is mediated from cortical projections onto the medulla and down to sacral segments of the cord.

Defecation is facilitated by squatting or sitting because these positions straighten the angle between the rectum and anal canal and increase the efficiency of straining (increasing intra-abdominal pressure). Intra-abdominal pressure is increased by initiating the **Valsalva maneuver.** This maneuver consists of inhaling and forcing the diaphragm and chest muscles against the closed glottis. This increases both intrathoracic and intra-abdominal pressure, which is transmitted to the rectum.

Intestinal Bacteria

The type and number of bacterial flora vary greatly throughout the normal gastrointestinal tract, with an increasing number

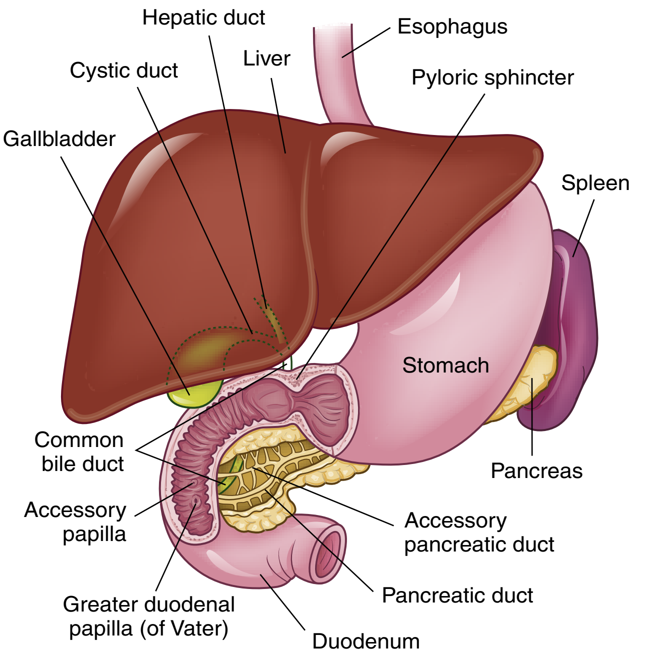

FIGURE 40-16 Locations of the Liver, Gallbladder, and Exocrine Pancreas, Which Are the Accessory Organs of Digestion.

of bacteria from the stomach to the distal colon. The stomach is relatively sterile because of the secretion of acid that kills ingested pathogens or inhibits bacterial growth. Bile acid secretion, intestinal motility, and antibody production suppress bacterial growth in the duodenum, and in the duodenum and jejunum there is a low concentration of aerobes (10^{-1} to 10^{-4}/ml), primarily streptococci, lactobacilli, staphylococci, enterobacteria, and *Bacteroides.* Anaerobes are only found distal to the ileocecal valve. They constitute about 95% of the fecal flora in the colon and contribute one third of the solid bulk of feces. *Bacteroides,* clostridia, anaerobic lactobacilli, and coliforms are the most common microorganisms from the ileum to the cecum.[27]

The intestinal tract is sterile at birth but becomes colonized with *Escherichia coli, Clostridium welchii,* and *Streptococcus* within a few hours. Within 3 to 4 weeks after birth, the normal flora are established. The normal flora do not have the virulence factors associated with pathogenic microorganisms, thus permitting immune tolerances. The intestinal mucosal environment also produces a broad spectrum of protective antimicrobial agents.[28] The intestinal bacteria play a role in the metabolism of bile salts (contributing to the intestinal reabsorption of bile and the elimination of toxic bile metabolites); the metabolism of estrogens, androgens, and lipids and conversion of unabsorbed carbohydrates to absorbable organic acids; the synthesis of vitamin K_2 and B vitamins; and the metabolism of various nitrogenous substances and drugs.[29]

ACCESSORY ORGANS OF DIGESTION

The liver, gallbladder, and exocrine pancreas all secrete substances necessary for the digestion of chyme. These secretions are delivered to the duodenum through ducts (Figure 40-16). The liver produces bile, which contains salts necessary for fat digestion and absorption. Between meals bile is stored in the gallbladder. The exocrine pancreas produces enzymes needed for the complete digestion of carbohydrates, proteins, and fats. The exocrine pancreas also produces an alkaline fluid that neutralizes chyme, creating a duodenal pH that supports enzymatic action. The liver receives nutrients absorbed by the small intestine and metabolizes or synthesizes these nutrients into forms that can be absorbed by the body's cells. It then releases the nutrients into the bloodstream or stores them for later use.

Liver

The **liver,** which weighs 1200 to 1600 g, is the largest solid organ in the body. It is located under the right diaphragm and is divided into right and left lobes. The larger, right lobe is divided further into the caudate and quadrate lobes (Figure 40-17). The *falciform ligament* separates the right and left lobes and attaches the liver to the anterior abdominal wall. A fibrous cord called the *round ligament (ligamentum teres)* extends along the free edge of the falciform ligament. The round ligament is the remnant of the umbilical vein and extends from the umbilicus to the inferior surface of the liver. The *coronary ligament* branches from the falciform ligament and extends over the superior surface of the right and left lobes, adhering the liver to the inferior surface of the diaphragm. The liver is covered by a fibroelastic capsule called the *Glisson capsule.* When the liver is diseased or swollen, distention of the capsule causes pain because it is innervated by afferent neurons.

The metabolic functions of the liver require a large amount of blood. The liver receives blood from both arterial and venous sources. The **hepatic artery** branches from the celiac artery and provides oxygenated blood at the rate of 400 to 500 ml/minute (about 25% of the cardiac output). The **hepatic portal vein,** which receives deoxygenated blood from the inferior and superior mesenteric veins and the splenic vein, delivers about 1000 to 1200 ml/minute of blood to the liver. The hepatic portal vein, which carries 70% of the blood supply to the liver, is rich in nutrients that have been absorbed from the digestive tract (Figure 40-18).

Within the liver lobes are multiple, smaller anatomic units called **liver lobules** (Figure 40-19). The lobules are formed of cords or plates of **hepatocytes,** which are the functional cells of the liver. These cells are capable of regeneration; therefore, damaged or resected liver tissue can regrow. Hepatocytes secrete electrolytes, lipids, lecithin, bile acids, and cholesterol into the canaliculi. Plasma proteins are also synthesized and released into the bloodstream. **Lipocytes** are star-shaped cells that store lipids, including vitamin A. Small capillaries, or **sinusoids,** are located between the plates of hepatocytes. The sinusoids receive a mixture of venous and arterial blood from branches of the hepatic artery and hepatic portal vein. Blood from the sinusoids drains into a central vein in the middle of each liver lobule. Venous blood from all the lobules then flows into the **hepatic vein,** which empties into the inferior vena cava. The sinusoids of the liver lobules are lined with highly permeable endothelium. This permeability enhances the transport of nutrients from the sinusoids into the hepatocytes, where they are metabolized.[30] The sinusoids are also lined with phagocytic

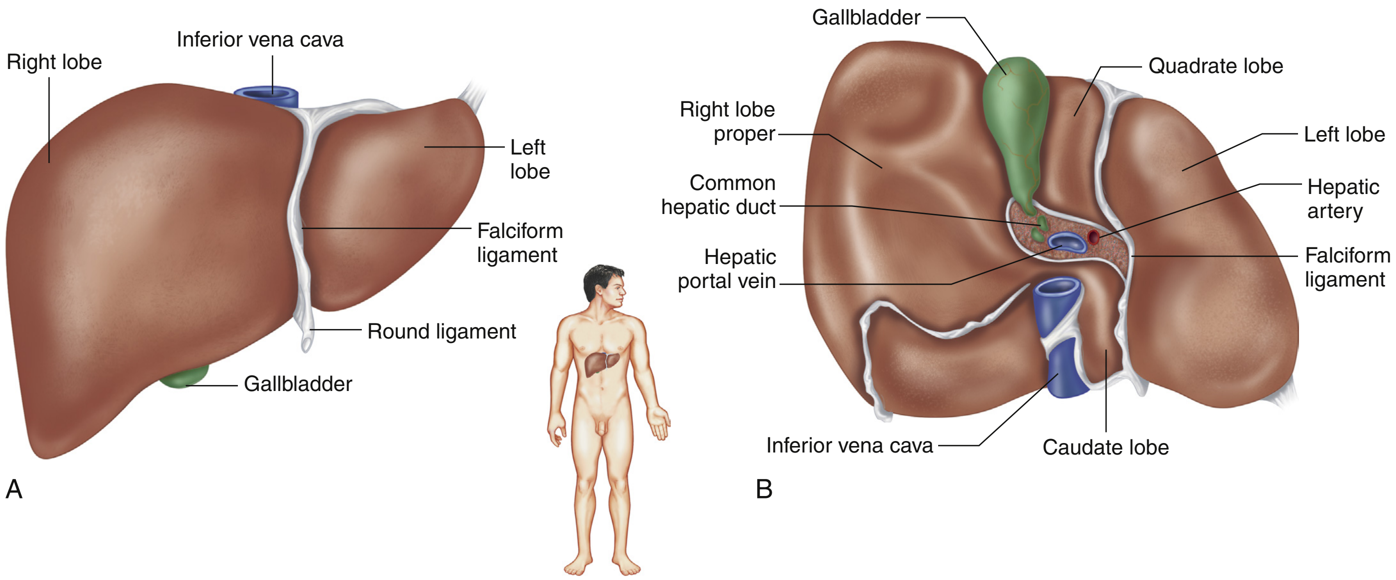

FIGURE 40-17 Gross Structure of the Liver. **A,** Anterior view. **B,** Inferior view. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

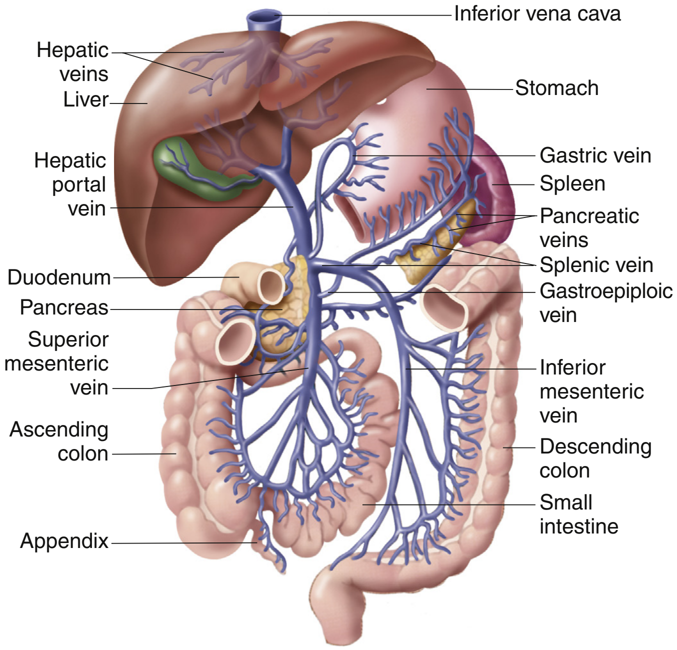

FIGURE 40-18 Hepatic Portal Circulation. In this unusual circulatory route, a vein is located between two capillary beds. The hepatic portal vein collects blood from capillaries in visceral structures located in the abdomen and empties into the liver for distribution to the hepatic capillaries. Hepatic veins return blood to the inferior vena cava. (Organs are not drawn to scale.) (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

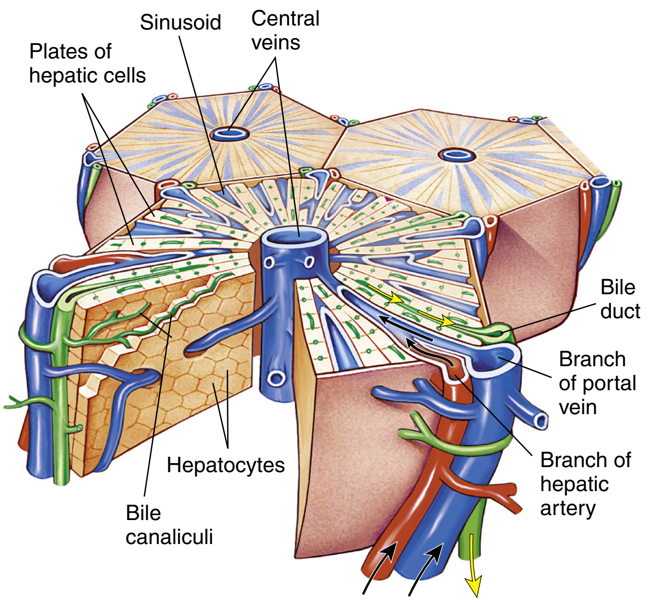

FIGURE 40-19 Diagrammatic Representation of a Liver Lobule. A central vein is located in the center of the lobule, with plates of hepatocytes disposed radially. Branches of the portal vein and hepatic artery are located on the periphery of the lobule, and blood from both vessels perfuses the sinusoids. Peripherally located bile ducts drain the bile canaliculi that run between the hepatocytes. (Modified from Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

cells, known as **Kupffer cells,** which are part of the mononuclear phagocyte system (see Chapters 7 and 27) and are the largest population of tissue macrophages in the body. They are bactericidal and central to innate immunity.[31] **Stellate cells** contain retinoids (vitamin A), are contractile in liver injury, regulate sinusoidal blood flow, may proliferate into myofibroblasts, and participate in liver fibrosis.[32] They remove foreign substances from the blood and trap bacteria. **Pit cells** are natural killer cells found in the sinusoidal lumen; they produce interferon-γ and are important in tumor defense.[33] Between the endothelial lining of the sinusoid and the hepatocyte is the **Disse space,** which drains interstitial fluid into the hepatic lymph system.

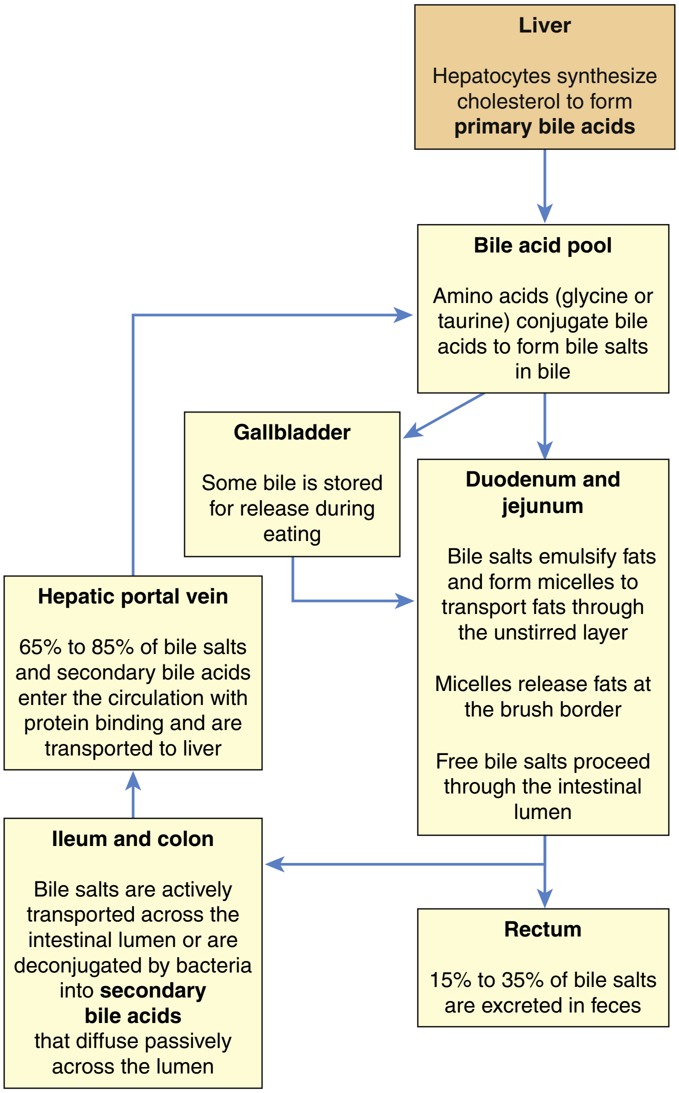

FIGURE 40-20 The Enterohepatic Circulation of Bile Salts.

Secretion of Bile

The liver assists intestinal digestion by secreting 700 to 1200 ml of bile per day. **Bile** is an alkaline, bitter-tasting yellowish green fluid that contains bile salts (conjugated bile acids), cholesterol, bilirubin (a pigment), electrolytes, and water. It is formed by hepatocytes and secreted into the canaliculi, which are small channels adjacent to hepatocytes. **Bile salts,** which are conjugated bile acids, are required for the intestinal emulsification and absorption of fats. The **bile canaliculi** empty into hepatic bile ducts and eventually drain into the **common bile duct** (see Figure 40-19). The union of the common bile duct and pancreatic duct is at the papilla or **ampulla of Vater,** which empties into the duodenum through an opening called the **major duodenal papilla** and is surrounded by the **sphincter of Oddi.**[34] Having facilitated fat emulsification and absorption in the small intestine, most bile salts are actively absorbed in the terminal ileum and returned to the liver through the portal circulation for resecretion. The pathway for recycling of bile salts is termed the **enterohepatic circulation** (Figure 40-20).[35]

Bile has two fractional components: the acid-dependent fraction and the acid-independent fraction. Hepatocytes secrete the **bile acid–dependent fraction** of the bile. This fraction consists of bile acids, cholesterol, lecithin (a phospholipid), and bilirubin (a bile pigment). The **bile acid–independent fraction** of the bile, which is secreted by the hepatocytes and epithelial cells of the bile canaliculi, is a bicarbonate-rich aqueous fluid that gives bile its alkaline pH.

Bile salts are conjugated in the liver from primary and secondary bile acids. The **primary bile acids** are cholic acid and chenodeoxycholic (chenic acid or chenodiol) acid. These acids are synthesized from cholesterol by the hepatocytes. The **secondary bile acids** are deoxycholic acid and lithocholic acid. These acids are formed in the small intestine by the action of intestinal bacteria, after which they are absorbed and flow to the liver (see Figure 40-20). Both forms of bile acids are conjugated with amino acids (glycine or taurine) in the liver to form bile salts. Conjugation makes the bile acids more water soluble, thus restricting their diffusion from the duodenum and ileum. The primary and secondary bile acids together form the **bile acid pool.**

Bile secretion is called **choleresis.** A **choleretic agent** is a substance that stimulates the liver to secrete bile. One strong stimulus is a high concentration of bile salts. Other choleretics include secretin, which increases the rate of bile flow by promoting the secretion of bicarbonate from canaliculi and other intrahepatic bile ducts; cholecystokinin; and vagal stimulation.

Metabolism of Bilirubin

Bilirubin is a byproduct of destruction of aged red blood cells. It gives bile a greenish black color and produces the yellow tinge of jaundice. Aged red blood cells are taken up and destroyed by macrophages of the mononuclear phagocyte system, primarily in the spleen and liver. (In the liver these macrophages are Kupffer cells.) Within these cells, hemoglobin is separated into its component parts—heme and globin (Figure 40-21). The globin component is further degraded into its constituent amino acids, which are recycled to form new protein. The heme moiety is converted to **biliverdin** by the enzymatic (heme oxygenase) cleavage of iron. The iron attaches to transferrin in the plasma and can be stored in the liver or used by the bone marrow to make new red blood cells. The biliverdin is enzymatically converted to bilirubin in the macrophage of the mononuclear phagocytic system and then is released into the plasma. In the plasma, bilirubin binds to albumin and is known as **unconjugated bilirubin,** or free bilirubin, which is lipid soluble. Bilirubin also may have a role as an antioxidant and provide cytoprotection.[36,37]

In the liver, unconjugated bilirubin moves from plasma in the sinusoids into the hepatocyte. Within hepatocytes it joins with glucuronic acid to form **conjugated bilirubin,** which is water soluble. Conjugation transforms bilirubin from a lipid-soluble substance that can cross biologic membranes to a water-soluble substance that can be excreted in the bile. When conjugated bilirubin reaches the distal ileum and colon, it is deconjugated by bacteria and converted to

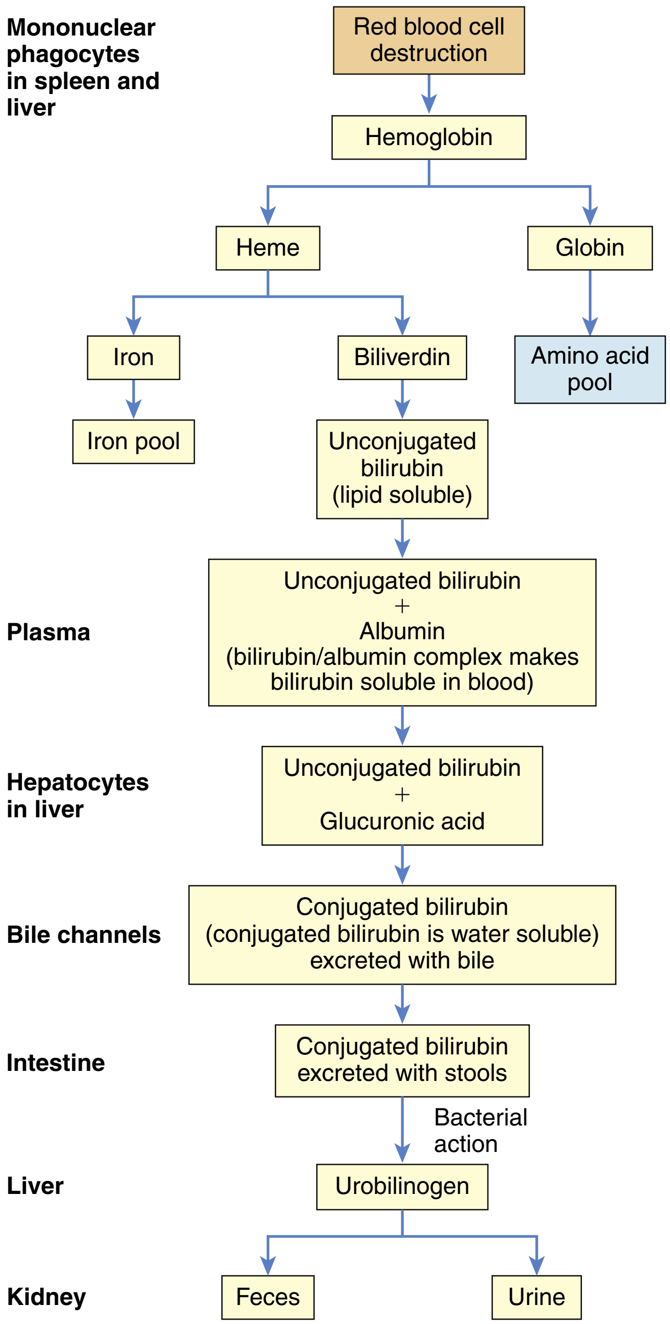

FIGURE 40-21 **Bilirubin Metabolism.** See text for further explanation.

urobilinogen. Urobilinogen is then reabsorbed in the intestines and transported to the kidney where it is excreted in the urine as urobilin, giving urine its yellow color. A small amount of urobilin is recirculated back into the liver and eliminated in feces as stercobilin, which contributes to the stool's brown pigmentation.

Vascular and Hematologic Functions

Because of its extensive vascular network, the liver can store a large volume of blood. The amount stored at any one time depends on pressure relationships in the arteries and veins. The liver also can release blood to maintain systemic circulatory volume in the event of hemorrhage.

TABLE 40-3 PROTEINS IN THE BODY

ROLE	EXAMPLE
Contraction	Actin and myosin enable muscle contraction.
Energy	Proteins can be metabolized for energy.
Fluid balance	Albumin is a major source of plasma oncotic pressure.
Protection	Antibodies and complement protect against infection and foreign substances.
Regulation	Enzymes control chemical reactions; hormones regulate many physiologic processes.
Structure	Collagen fibers provide structural support to many parts of the body; keratin strengthens skin, hair, and nails.
Transport	Hemoglobin transports oxygen and carbon dioxide in the blood; plasma proteins serve as transport molecules; proteins in cell membranes control movement of materials into and out of cells.
Coagulation	Hemostasis is regulated by proteins that balance coagulation and anticoagulation.

Kupffer cells (macrophages) in the sinusoids of the liver remove bacteria and foreign particles from blood in the hepatic circulation. Because the liver receives all of the venous blood from the gut and pancreas, the Kupffer cells play an important role in destroying intestinal bacteria and preventing infections.

The liver also has hemostatic functions. It synthesizes most of the clotting factors (see Chapters 7 and 27). Vitamin K_1 (synthesized by plants and ingested in the diet) and vitamin K_2 (synthesized by intestinal bacteria) are fat-soluble vitamins essential for the synthesis of clotting factors (prothrombin and factors VII, IX, and X). Because bile salts are needed for absorption of fats, vitamin K absorption depends on adequate bile production in the liver. Impairment of vitamin K absorption diminishes production of clotting factors and increases risk of bleeding.

Metabolism of Nutrients

Fats. Ingested fat absorbed by lacteals in the intestinal villi enters the liver through the lymphatics, primarily as triglycerides. In the liver the triglycerides can be hydrolyzed to glycerol and free fatty acids and used to produce metabolic energy (ATP), or they can be released into the bloodstream bound to proteins (lipoproteins). The lipoproteins are carried by the blood to adipose cells for storage. The liver also synthesizes phospholipids and cholesterol, which are needed for the hepatic production of bile salts, steroid hormones, components of plasma membranes, and other special molecules.

Proteins. Protein synthesis requires the presence of all the essential amino acids (obtained only from food), as well as nonessential amino acids. Proteins perform many important roles in the body and are summarized in Table 40-3.

Within hepatocytes, amino acids are converted to carbohydrates by the removal of ammonia (NH_3), a process known as **deamination.** The ammonia is converted to urea by the liver and passes into the blood to be excreted by the kidneys. The plasma proteins, including albumins and globulins (with the exception of gamma globulin, which is formed in lymph nodes and lymphoid tissue), are synthesized by the liver. The liver also

synthesizes several nonessential amino acids and serum enzymes that become elevated with liver injury (and other diseases):

- **Aspartate aminotransferase (AST)** (previously called serum glutamate-oxaloacetate transaminase [SGOT]): also present in red blood cells and skeletal muscle; AST transfers an α-amino group between aspartate and glutamate.
- **Alanine aminotransferase (ALT)** (previously called serum glutamate-pyruvate transaminase [SGPT]): also present in small amounts in the kidneys, heart, skeletal muscle, and pancreas; ALT transfers an amino group from alanine to α-ketoglutarate to form pyruvate and glutamate.
- **Lactate dehydrogenase (LDH):** catalyzes the conversion of lactate to pyruvate; LDH is widely distributed throughout the body and different isoenzymes are found in different tissues.
- **Alkaline phosphatase:** removes phosphate groups, particularly in an alkaline environment.
- **Gamma-glutamyltransferase:** transfers the gamma-glutamyl moiety of glutathione to an acceptor to form glutamate and is a pro-oxidant.

Reference values for the above enzymes can be reviewed in Table 40-6 and are summarized on the inside back book cover.

Carbohydrates. The liver contributes to the stability of blood glucose levels by releasing glucose during states of hypoglycemia (low blood glucose levels) and taking up glucose during states of hyperglycemia (high blood glucose levels) and storing it as glycogen (glyconeogenesis) or converting it to fat. When all glycogen stores have been used, the liver can convert amino acids and glycerol to glucose.

Metabolic Detoxification

The liver alters exogenous and endogenous chemicals (e.g., drugs), foreign molecules, and hormones to make them less toxic or less biologically active. This process, called **metabolic detoxification (biotransformation),** diminishes intestinal or renal tubular reabsorption of potentially toxic substances and facilitates their intestinal and renal excretion. In this way alcohol, barbiturates, amphetamines, steroids, and hormones (including estrogens, aldosterone, antidiuretic hormone, and testosterone) are metabolized or detoxified, preventing excessive accumulation and adverse effects.

Although metabolic detoxification is usually protective, sometimes the end products of metabolic detoxification become toxins. Those of alcohol metabolism, for example, are acetaldehyde and hydrogen. Excessive intake of alcohol over a prolonged period causes these end products to damage hepatocytes. Acetaldehyde damages cellular mitochondria, and the excess hydrogen promotes fat accumulation. This is how alcohol impairs the liver's ability to function (see Chapter 2).

Storage of Minerals and Vitamins

The liver stores certain vitamins and minerals, including iron and copper, in times of excessive intake and releases them in times of need. The liver can store vitamins B_{12} and D for several months and vitamin A for several years. The liver also stores vitamins E and K. Iron is stored in the liver as ferritin, an iron-protein complex, and is released as needed for red blood cell production.

Gallbladder

The **gallbladder** is a saclike organ that lies on the inferior surface of the liver (Figures 40-17 and 40-22). The wall of the gallbladder is composed of the mucous membrane, muscularis, and serosa. The primary function of the gallbladder is to store and concentrate bile between meals. During the interdigestive period, bile flows from the liver through the right or left hepatic duct into the common bile duct and meets resistance at the closed **sphincter of Oddi,** which controls flow into the duodenum and prevents reflux of duodenal contents into the pancreatobiliary system. Bile then flows into the gallbladder through the **cystic duct** where it is concentrated and stored. The mucosa of the gallbladder wall readily absorbs water and electrolytes, leaving a high concentration of bile salts, bile pigments, and cholesterol. The gallbladder holds about 90 ml of bile.

Within 30 minutes after eating, the gallbladder begins to contract, forcing stored bile through the cystic duct and into the common bile duct. The sphincter of Oddi relaxes, and bile flows into the duodenum through the major duodenal papilla. During the cephalic and gastric phases of digestion, gallbladder contraction is mediated by cholinergic branches of the vagus nerve. Hormonal regulation of gallbladder contraction is derived primarily from the release of *cholecystokinin* secreted by the duodenal and jejunal mucosa in the presence of fat. Vasoactive intestinal peptide, pancreatic polypeptide, and sympathetic nerve stimulation relax the gallbladder.

Exocrine Pancreas

The **pancreas** is approximately 20 cm long, with its head tucked into the curve of the duodenum and its tail touching the spleen. The body of the pancreas lies deep in the abdomen, behind the stomach (see Figure 40-16). The pancreas is unique in that it has endocrine as well as exocrine functions. The endocrine pancreas secretes insulin, glucagon, somatostatin, and pancreatic polypeptide (see Chapter 21).

The **exocrine pancreas** is composed of acinar cells that secrete enzymes and networks of ducts that secrete alkaline fluids with important digestive functions. The acinar cells are organized into spherical lobules (acini) around small secretory ducts (see Figure 40-22). Secretions drain into a system of ducts that leads to the **pancreatic duct (Wirsung duct),** which empties into the common bile duct at the **ampulla of Vater** and then through the duodenal papilla into the duodenum. In some individuals an accessory duct (the duct of Santorini) branches off the pancreatic duct and drains directly into the duodenum at an opening called the *minor duodenal papilla* (see Figure 40-22).

Arterial blood is supplied to the pancreas by branches of the celiac and superior mesenteric arteries. Venous blood leaves the head of the pancreas through the tributaries to the hepatic portal vein, with the body and tail being drained through the splenic vein. All hormonal pancreatic secretions also pass through the hepatic portal vein into the liver.

Pancreatic innervation arises from parasympathetic neurons of the vagus nerve, which stimulate enzymatic and hormonal

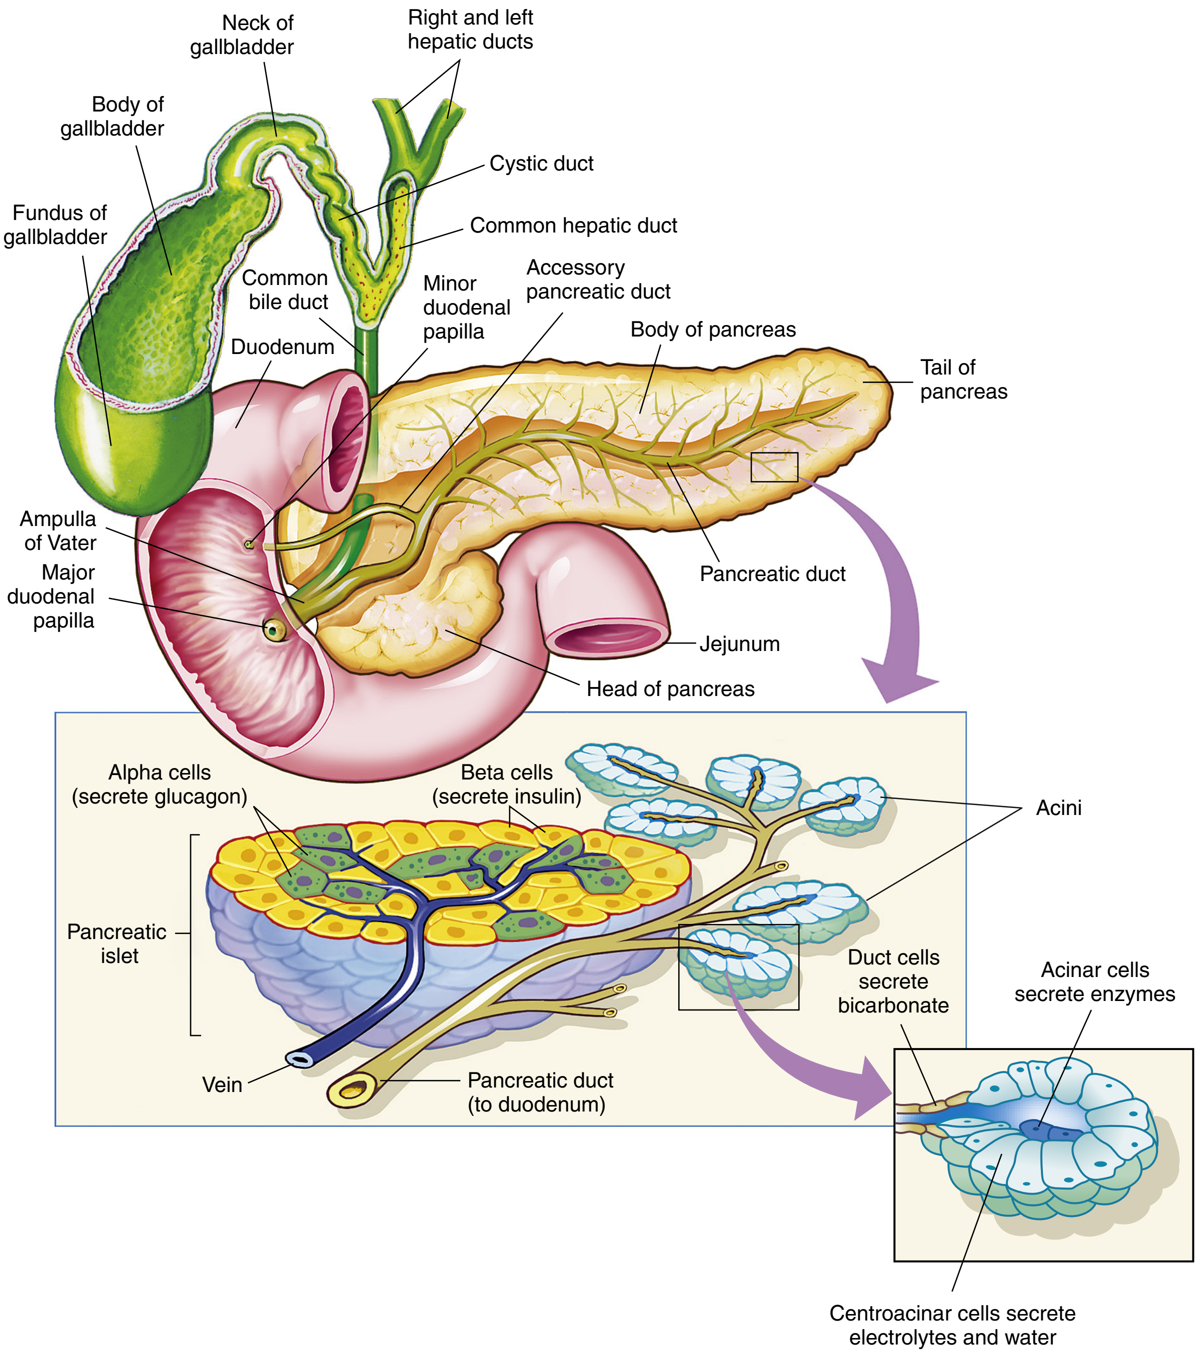

FIGURE 40-22 Associated Structures of the Gallbladder, Pancreas, and Pancreatic Acinar Cells and Duct. (Modified from Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 6, St Louis, 2007, Mosby.)

secretion. Sympathetic postganglionic fibers from the celiac and superior mesenteric plexuses innervate the blood vessels and cause vasoconstriction and inhibit pancreatic secretion.[38]

The aqueous secretions of the exocrine pancreas are isotonic and contain potassium, sodium, bicarbonate, magnesium, calcium, and chloride. Sodium and potassium concentrations are about equal to those in the plasma. The concentration of bicarbonate in pancreatic juice varies directly with the secretory flow rate. As bicarbonate secretion increases, chloride secretion decreases to maintain a constant anionic concentration. The highly alkaline pancreatic juice neutralizes the acidic chyme that enters the duodenum from the stomach and provides the alkaline medium needed for the actions of digestive enzymes and the absorption of fat in the intestine.

In the pancreas, transport of water and electrolytes through the ductal epithelium involves active and passive mechanisms. The ductal cells actively transport hydrogen into the blood and bicarbonate into the duct lumen. Potassium and chloride are secreted by diffusion according to changes in electrochemical potential gradients. As the secretion flows down the duct, water is osmotically transported into the juice until it becomes isosmotic. At low flow rates, bicarbonate is exchanged passively for chloride, but at higher flow rates there is less time for this exchange and bicarbonate concentration increases. Because

TABLE 40-4 **SELECTED STUDIES OF GASTROINTESTINAL STRUCTURE**

TEST	DESCRIPTION	APPLICATION
Plain roentgenograms	Use of high-energy electromagnetic radiation to evaluate tissue structure by radiopacity or radiolucency	Visualization of the position, size, and structure of abdominal contents
Air or barium contrast roentgenograms	Introduction of radiopaque substances into the upper or lower gastrointestinal tract	Enhanced visualization of the contours, position, and size of the gastrointestinal tract to detect umbilical hernia, ulcers, diverticula, congenital anomalies, polyps, tumors, strictures, obstructions
Endoscopy Esophagoscopy (esophagus) Gastroscopy (stomach) Duodenoscopy (duodenum) Colonoscopy (large intestine) Sigmoidoscopy (sigmoid colon)	Passage of rigid or flexible (fiberoptic) endoscope into the gastrointestinal tract for visualization or biopsy	Visualization or biopsy of inflamed hernias, polyps, ulcers, strictures, varices, tumors, sites of bleeding, mucosal or neoplastic lesions and for culture of *Helicobacter pylori* from stomach
Ultrasound	Use of piezoelectric crystal to generate sound waves that are reflected from tissue interfaces to provide an image	Imaging of abdominal organs (gallbladder, liver, pancreas, spleen), masses, stones, abscesses, structural abnormalities
Computed tomography (CT)	Use of a computer to integrate differences in absorption of a large number of x-rays to produce a cross-sectional image; may be done with contrast agents	Imaging of gallbladder, liver, pancreas, spleen, cysts, hematomas, abscesses, stones, extrahepatic bile ducts, and portal vein
Magnetic resonance imaging (MRI)	Projection of differences in magnetic properties of molecules within different cells and tissues, using the field of a large magnet	Same applications as CT scan; also can detect blood flow and vessel patency

eating stimulates the flow of pancreatic juice, the juice is most alkaline when it needs to be—during digestion. Secretion of the aqueous and enzymatic components of pancreatic juice is controlled by hormonal and vagal stimuli.

The *pancreatic enzymes* hydrolyze proteins (proteases), carbohydrates (amylases), and fats (lipases). The proteases include trypsin, chymotrypsin, carboxypeptidase, and elastase. These enzymes are secreted in their inactive forms—that is, as trypsinogen, chymotrypsinogen, and procarboxypeptidase—to protect the pancreas from the digestive effects of its own enzymes. For further protection the pancreas produces **trypsin inhibitor,** which prevents the activation of proteolytic enzymes while they are in the pancreas. Once in the duodenum, the inactive forms (proenzymes) are activated by **enterokinase,** an enzyme secreted by the duodenal mucosa. Trypsinogen is the first proenzyme to be activated. Its conversion to trypsin stimulates the conversion of chymotrypsinogen to chymotrypsin and procarboxypeptidase to carboxypeptidase. Each of these enzymes cleaves specific peptide bonds to reduce polypeptides to smaller peptides.

Pancreatic α-amylase is secreted in active form and digests intestinal carbohydrate by cleaving interior α-1,4-glucosidic bonds to yield glucose and maltose at an optimum pH of approximately 6.9. **Pancreatic lipases** hydrolyze triglycerides, cholesterol, and phospholipids to free fatty acids in the intestine. *Secretin* stimulates the acinar and duct cells to secrete the bicarbonate-rich fluid that neutralizes chyme and prepares it for enzymatic digestion. As chyme enters the duodenum, its acidity (pH of 4.5 or less) stimulates the **S cells** of the duodenum to release secretin, which is absorbed by the intestine and delivered to the pancreas in the bloodstream. In the pancreas, secretin causes ductal and acinar cells to release alkaline fluid. Secretin also inhibits the actions of gastrin, thereby decreasing gastric hydrochloric acid secretion and motility. The overall effect is to neutralize the contents of the duodenum.

Enzymatic secretion follows, stimulated by **cholecystokinin,** which activates ACh from the vagus nerve and release of ACh from pancreatic stellate cells.[39] Cholecystokinin is released in the duodenum in response to the essential amino acids and fatty acids already present in chyme. Once in the small intestine, activated pancreatic enzymes inhibit the release of more cholecystokinin and ACh. This feedback mechanism inhibits the secretion of more pancreatic enzymes. Pancreatic polypeptide is released after eating and inhibits postprandial pancreatic exocrine secretion. (Table 40-1 summarizes hormonal stimulation of pancreatic secretions.)

TESTS OF DIGESTIVE FUNCTION

Gastrointestinal Tract

Although important diagnostic information can be obtained from the patient's medical history and presenting symptoms, numerous disease-specific tests must be performed to evaluate the structure and function of the gastrointestinal tract. A description of selected studies is presented in Tables 40-4 and 40-5. Radiography and imaging techniques—including radionuclide, positron emission tomography (PET), magnetic resonance (MR), computed tomography (CT) scanning, and ultrasound—are procedures for evaluating structure and function. Plain radiographs using contrast media such as barium- or iodine-containing compounds can be used to outline the gastrointestinal lumen, biliary tree and pancreatic ducts, fistulae, and arteriovenous systems. CT scanning is particularly useful for diagnosis of intestinal lesions and pancreatic or hepatic tumors or cysts. Ultrasonic scanning is a safe, simple, and relatively inexpensive technique used to detect gallstones and intra-abdominal masses, particularly abscesses.

TABLE 40-5 SELECTED TESTS OF GASTROINTESTINAL FUNCTION

TEST	NORMAL FINDINGS	CLINICAL SIGNIFICANCE OF ABNORMAL FINDINGS
Stool studies	Resident microorganisms: clostridia, enterococci, *Pseudomonas,* a few yeasts	Detection of *Salmonella typhi* (typhoid fever), *Shigella* (dysentery), *Vibrio cholerae* (cholera), *Yersinia* (enterocolitis), *Escherichia coli* (gastroenteritis), *Staphylococcus aureus* (food poisoning), *Clostridium botulinum* (food poisoning), *Clostridium perfringens* (food poisoning), *Aeromonas* (gastroenteritis)
	Fat: 2-6 g/24 hr	Steatorrhea (increased values) can result from intestinal malabsorption or pancreatic insufficiency
	Pus: none	Large amounts of pus are associated with chronic ulcerative colitis, abscesses, and anorectal fistula
	Occult blood: none (orthotolidine or guaiac test)	Positive tests associated with bleeding
	Ova and parasites: none	Detection of *Entamoeba histolytica* (amebiasis), *Giardia lamblia* (giardiasis), and worms
D-Xylose absorption	5-hr urinary excretion: 4.5 g/L Peak blood level: >30 mg/dl	Differentiation of pancreatic steatorrhea (normal D-xylose absorption) from intestinal steatorrhea (impaired D-xylose absorption)
Gastric acid stimulation	11-20 mEq/hr after stimulation	Detection of duodenal ulcers, Zollinger-Ellison syndrome (increased values), gastric atrophy, gastric carcinoma (decreased values)
Manometry (use of water-filled catheters connected to pressure transducers passed into the esophagus, stomach, colon, or rectum to evaluate contractility)	Values vary at different levels of the intestine	Inadequate swallowing, motility, sphincter function
Culture and sensitivity of duodenal contents	No pathogens	Detection of *Salmonella typhi* (typhoid fever)
Breath tests		
Glucose or D-xylose breath test	Negative for hydrogen or CO_2	May indicate intestinal bacterial overgrowth
Urea breath test	Negative for isotopically labeled CO_2	Presence of *Helicobacter pylori* infection
Lactose breath test	Negative for exhaled hydrogen	Lactose intolerance

Fiberoptic endoscopy, using flexible endoscopes, allows direct visualization of the gastrointestinal tract. A biopsy channel allows tissue sampling, and suction can be applied to remove gastrointestinal secretions or blood. Analysis of stool, gastric secretions, tissue, and plasma provides important clues to infection, malabsorption syndromes, ulcerative lesions, and tumor growth.

Liver

A variety of diagnostic tests can be performed to evaluate liver function[40,41] (Table 40-6). Imaging techniques similar to those described for the gastrointestinal tract also are useful for evaluating liver structure and function. Nuclear imaging is useful after liver transplant.[42] Elevated plasma levels of liver enzymes are associated with many liver diseases because of the release of cytoplasmic enzymes into the circulation when there is damage to the hepatocyte. Of particular importance are elevations of aminotransferases and lactate dehydrogenase (LDH). Obstruction of bile canaliculi or ducts results in regurgitation of bile back into the hepatic sinusoids and into the circulation, manifesting with elevation of conjugated bilirubin levels. Prothrombin times (a measure of clotting tendency) are often prolonged with both hepatitis and chronic liver disease. In severe disease, other plasma proteins, such as albumin and globulins, may be diminished as a result of hepatocyte damage. Liver biopsies are often performed to evaluate the extent of liver involvement or degeneration with cirrhosis, hepatitis, or fatty liver disease.

Gallbladder

Evaluation of structural alterations in the gallbladder may be achieved by the use of various imaging techniques. Table 40-7 summarizes these techniques. Obstruction of the bile ducts from stones, tumors, or inflammation prevents the flow of bile from the liver and gallbladder from reaching the gastrointestinal tract. Both the conjugated and total serum bilirubin values are elevated, urine urobilinogen level is increased, stools are clay colored, and jaundice develops. Fat absorption can be impaired and the prothrombin time prolonged if vitamin K is not absorbed. With inflammation of the gallbladder, the white cell count is elevated.

Exocrine Pancreas

Tests of pancreatic function are summarized in Table 40-8. Evaluation of serum lipase and urinary amylase provides particularly significant measures of pancreatic injury. Inflammation or obstruction of the pancreas results in an early increase in serum amylase levels. Serum lipase level remains elevated after serum amylase has returned to normal levels and provides greater sensitivity with delayed presentation of pancreatitis. Elevation of urine amylase level also occurs later (after 48 hours) when serum amylase may have returned to normal levels. Urinary trypsinogen 2 (available as dipstick) is used to diagnose acute pancreatitis and is comparable to serum amylase and lipase.[43] Increased stool fat can reflect pancreatic insufficiency caused by decreased lipase secretion when biliary function is normal.

TABLE 40-6 COMMON LIVER FUNCTION TESTS

TEST	NORMAL VALUE	INTERPRETATION
Serum Enzymes		
Alkaline phosphatase	13-39 units/L	Increases with biliary obstruction and cholestatic hepatitis
Gamma-glutamyltranspeptidase (GGT)	Male 12-38 units/L Female 9-31 units/L	Increases with biliary obstruction and cholestatic hepatitis
Aspartate aminotransferase (AST; previously serum glutamate-oxaloacetate transaminase [SGOT])	5-40 units/L	Increases with hepatocellular injury (and injury in other tissues, i.e., skeletal and cardiac muscle)
Alanine aminotransferase (ALT; previously serum glutamate-pyruvate transaminase [SGPT])	5-35 units/L	Increases with hepatocellular injury and necrosis
Lactate dehydrogenase (LDH)	90-220 units/L	Isoenzyme LD_5 is elevated with hypoxic and primary liver injury
5′-Nucleotidase	2-11 units/L	Increases with increase in alkaline phosphatase and cholestatic disorders
Bilirubin Metabolism		
Serum bilirubin		
Unconjugated (indirect)	<0.8 mg/dl	Increases with hemolysis (lysis of red blood cells)
Conjugated (direct)	0.2-0.4 mg/dl	Increases with hepatocellular injury or obstruction
TOTAL	<1.0 mg/dl	Increases with biliary obstruction
Urine bilirubin	0	Increases with biliary obstruction
Urine urobilinogen	0-4 mg/24 hr	Increases with hemolysis or shunting of portal blood flow
Serum Proteins		
Albumin	3.5-5.5 g/dl	Reduced with hepatocellular injury
Globulin	2.5-3.5 g/dl	Increases with hepatitis
TOTAL	6-7 g/dl	
Albumin/globulin (A/G) ratio	1.5:1 to 2.5:1	Ratio reverses with chronic hepatitis or other chronic liver disease
Transferrin	250-300 mcg/dl	Liver damage with decreased values, iron deficiency with increased values
Alpha fetoprotein (AFP)	6-20 ng/ml	Elevated values in primary hepatocellular carcinoma
Blood-Clotting Functions		
Prothrombin time (PT)	11.5-14 sec or 90-100% of control	Increases with chronic liver disease (cirrhosis) or vitamin K deficiency
Partial thromboplastin time (PTT)	25-40 sec	Increases with severe liver disease or heparin therapy
Bromsulphthalein (BSP) excretion	<6% retention in 45 min	Increased retention with hepatocellular injury

TABLE 40-7 DIAGNOSTIC EVALUATION OF THE GALLBLADDER

TEST	APPLICATION
Plain roentgenogram of the abdomen	Visualization of calcified gallstones
Oral cholecystogram (use of an oral contrast medium such as iopanoic acid, which is excreted with bile and concentrated in the gallbladder for visualization by radiography; may be administered as a double dose)	Visualization of gallstones; evaluation of filling and emptying of gallbladder
Intravenous cholangiography (use of intravenous contrast agents for visualization of gallbladder and bile ducts)	Diagnosis of acute gallbladder inflammation (cholecystitis) or disease of bile ducts
Cholecystography (ultrasound imaging of gallbladder and bile ducts)	Preferred method for detecting gallstones; differentiation of hepatic disease from biliary obstruction; diagnosis of chronic cholecystitis
Cholescintigraphy (radioisotope imaging of gallbladder)	Diagnosis of cholecystitis in individuals allergic to iodine-containing contrast agents; diagnosis of cystic duct obstruction
Endoscopic retrograde cholangiography (instillation of contrast medium through cannulation of ampulla of Vater with a duodenoscope)	Differentiation of intrahepatic or extrahepatic obstructive jaundice
Computed tomography (CT)	Diagnosis of biliary obstruction or malignancy when ultrasound is not successful

AGING AND THE GASTROINTESTINAL SYSTEM

Age-related changes in gastrointestinal function can begin to occur before 50 years of age.[44] Tooth enamel and dentin wear down, making the teeth vulnerable to cavities. Teeth are lost, often as a result of periodontal (gum) disease, recession of the gums, osteoporotic bone changes, and more brittle roots that fracture easily. Taste buds decline in number, and the sense of smell diminishes.[45] Together these losses decrease the sense of taste. Salivary secretion decreases and contributes to dry mouth and loss of taste.[46] In very old adults these oral and sensory changes make eating less pleasurable and reduce appetite. Food may not be chewed or lubricated sufficiently, making

TABLE 40-8 SELECTED TESTS OF PANCREATIC FUNCTION

TEST	NORMAL VALUE	CLINICAL SIGNIFICANCE
Serum amylase	60-180 Somogyi units/ml	Elevated levels with pancreatic inflammation
Serum lipase	1.5 Somogyi units/ml	Elevated levels with pancreatic inflammation (may be elevated with other conditions; differentiates with amylase isoenzyme study)
Urine amylase	35-260 Somogyi units/hr	Elevated levels with pancreatic inflammation
Secretin test	Volume 1.8 ml/kg/hr Bicarbonate concentration: >80 mEq/L Bicarbonate output: >10 mEq/L/30 sec	Decreased volume with pancreatic disease as secretin stimulates pancreatic secretion
Stool fat	2-5 g/24 hr	Measures fatty acids; decreased pancreatic lipase increases stool fat

swallowing difficult. The esophagus develops decreased motility, and changes in the upper esophageal sphincter, history of stroke, and dementia may affect swallowing and contribute to gastroesophageal reflux.[47]

Age also diminishes gastric motility and volume, including secretion of bicarbonate and gastric mucus in some individuals. Acid content of gastric juice is related to gastric atrophy, which results in hypochlorhydria (insufficient hydrochloric acid), delayed gastric emptying, and compromise of the gastric mucosal barrier.[48] Decreased production of intrinsic factor leads to inadequate small intestinal absorption of vitamin B_{12} and pernicious anemia.[49] Aging may be associated with a change in the composition of the intestinal microflora and increased susceptibility to disease.[50] The ileal villi of the small intestine may become broader and shorter, perhaps because of a decrease in cell turnover. Intestinal absorption, motility, and blood flow decrease, impairing nutrient absorption.[51] Proteins, fats, minerals (including iron and calcium), and vitamins are absorbed more slowly and in lesser amounts, and absorption of carbohydrates is decreased. Intestinal transit time is delayed. Constipation is often described as a condition of old age, but it is probably caused by lifestyle factors (e.g., diet, lack of fluid intake) rather than physiologic decline although studies demonstrate there can be alterations in intestinal innervation.[52]

The rate of liver regeneration decreases with advancing age but the volume of the liver can be maintained.[53] Alterations in liver function in older individuals are usually a sign of a pathologic condition. Liver blood flow and enzyme activity decrease with age and can influence the efficiency of drug and alcohol metabolism.[54] However, liver function test results often remain within relatively normal ranges. Alterations in liver function in older individuals are usually a sign of a pathologic condition. The pancreas undergoes structural changes, such as fibrosis, fatty acid deposits, and atrophy. Pancreatic secretion decreases, but there is usually no observable dysfunction.[55] Aging does not cause apparent changes in the structure and function of the gallbladder and bile ducts, but the incidence of gallstones increases.[56]

SUMMARY REVIEW

The Gastrointestinal Tract

1. The major functions of the gastrointestinal tract are the mechanical and chemical breakdown of food and the absorption of digested nutrients.
2. The gastrointestinal tract is a hollow tube that extends from the mouth to the anus.
3. The walls of the gastrointestinal tract have several layers: mucosa, muscularis mucosa, submucosa, muscularis (circular muscle and longitudinal muscle), and serosa (adventitia in the esophagus).
4. Except for swallowing and defecation, which are controlled voluntarily, the functions of the gastrointestinal tract are controlled by extrinsic autonomic nerves (vagus, parasympathetic splanchnic, and sympathetic nerves) and intrinsic autonomic nerves (enteric nervous system) and intestinal hormones.
5. Digestion begins in the mouth, with chewing and salivation. The digestive component of saliva is α-amylase, which initiates carbohydrate digestion.
6. The esophagus is a muscular tube that transports food from the mouth to the stomach. The muscularis in the upper part of the esophagus is striated muscle, and that in the lower part is smooth muscle.
7. Swallowing is controlled by the swallowing center in the reticular formation of the brain. The two phases of swallowing are the oropharyngeal phase (voluntary swallowing) and the esophageal phase (involuntary swallowing).
8. Food is propelled through the gastrointestinal tract by peristalsis: waves of sequential relaxations and contractions of the muscularis.
9. The lower esophageal sphincter opens to admit swallowed food into the stomach and then closes to prevent regurgitation of food back into the esophagus.
10. The stomach is a baglike structure that secretes digestive juices, mixes and stores food, and propels partially digested food (chyme) into the duodenum. The smooth muscles of the stomach include the outer longitudinal, middle circular, and internal oblique.
11. The vagus nerve stimulates gastric (stomach) secretion and motility.
12. The hormones gastrin and motilin stimulate gastric emptying; the hormones secretin and cholecystokinin delay gastric emptying.
13. Gastric glands in the fundus and body of the stomach secrete intrinsic factor, which is needed for vitamin B_{12} absorption,

SUMMARY REVIEW—cont'd

and hydrochloric acid, which dissolves food fibers, kills microorganisms, and activates the enzyme pepsin.

14. Chief cells in the stomach secrete pepsinogen, which is converted to pepsin in the acidic environment created by hydrochloric acid.
15. Acid secretion is stimulated by the vagus nerve, gastrin, and histamine and inhibited by sympathetic stimulation and cholecystokinin. Acetylcholine stimulates pepsin secretion.
16. Mucus is secreted throughout the stomach and protects the stomach wall from acid and digestive enzymes.
17. The three phases of acid secretion by the stomach are the cephalic phase (anticipation and swallowing), the gastric phase (food in the stomach), and the intestinal phase (chyme in the intestine).
18. The small intestine is 5 m long and has three segments: the duodenum, jejunum, and ileum. Digestion and absorption of all major nutrients and most ingested water occur in the small intestine.
19. The peritoneum is a double layer of membranous tissue. The visceral layer covers the abdominal organs, and the parietal layer extends along the abdominal wall.
20. Blood flow to the small intestine is primarily provided by the superior mesenteric artery.
21. The duodenum receives chyme from the stomach through the pyloric valve. The presence of chyme stimulates the liver and gallbladder to deliver bile and the pancreas to deliver digestive enzymes and alkaline secretions. Bile and enzymes flow through an opening guarded by the sphincter of Oddi.
22. Bile is produced by the liver and is necessary for fat digestion and absorption. Bile's alkalinity helps neutralize chyme, thereby creating a pH that enables the pancreatic enzymes to digest proteins, carbohydrates, and sugars.
23. Enzymes secreted by the small intestine (maltase, sucrase, lactase), pancreatic enzymes (proteases, amylase, and lipase), and bile salts act in the small intestine to digest proteins, carbohydrates, and fats.
24. Digested substances are absorbed across the intestinal wall and then transported to the liver through the hepatic portal vein, where they are metabolized further.
25. The ileocecal valve connects the small and large intestines and prevents reflux into the small intestine.
26. Villi are small fingerlike projections that extend from the small intestinal mucosa and increase its absorptive surface area.
27. Carbohydrates, amino acids, and fats are absorbed primarily by the duodenum and jejunum; bile salts and vitamin B_{12} are absorbed by the ileum. Vitamin B_{12} absorption requires the presence of intrinsic factor.
28. Bile salts emulsify and hydrolyze fats and incorporate them into water-soluble micelles that transport them through the unstirred layer to the brush border of the intestinal mucosa. The fat content of the micelles readily diffuses through the epithelium into lacteals (lymphatic ducts) in the villi. From there fats flow into the lymphatics and into the systemic circulation, which delivers them to the liver.
29. Minerals and water-soluble vitamins are absorbed by active and passive transport throughout the small intestine.
30. Peristaltic movements created by longitudinal muscles propel the chyme along the intestinal tract, whereas contractions of the circular muscles (segmentation) mix the chyme and promote digestion.
31. The ileogastric reflex inhibits gastric motility when the ileum is distended.
32. The intestinointestinal reflex inhibits intestinal motility when one intestinal segment is overdistended.
33. The gastroileal reflex increases intestinal motility when gastric motility increases.
34. The large intestine consists of the cecum, appendix, colon (ascending, transverse, descending, and sigmoid), rectum, and anal canal.
35. The teniae coli are three bands of longitudinal muscle that extend the length of the colon.
36. Haustra are pouches of colon that are formed with alternating contraction and relaxation of the circular muscles.
37. The mucosa of the large intestine contains mucus-secreting cells and mucosal folds, but no villi.
38. The large intestine massages the fecal mass and absorbs water and electrolytes.
39. Distention of the ileum with chyme causes the gastrocolic reflex, or the mass propulsion of feces to the rectum.
40. Defecation is stimulated when the rectum is distended with feces. The conically contracted internal anal sphincter relaxes and, if the voluntarily regulated external sphincter relaxes, defecation occurs.
41. The largest numbers of intestinal bacteria are in the colon. They are anaerobes consisting of *Bacteroides,* clostridia, coliforms, and lactobacilli.
42. The intestinal tract is sterile at birth and becomes totally colonized within 3 to 4 weeks.
43. Endogenous infections of the gastrointestinal tract occur by excessive proliferation of bacteria, perforation of the intestine, or contamination from neighboring structures.

Accessory Organs of Digestion

1. The liver is the largest organ in the body. It has digestive, metabolic, hematologic, vascular, and immunologic functions.
2. The liver is divided into the right and left lobes and is supported by the falciform, round, and coronary ligaments.
3. Liver lobules consist of plates of hepatocytes, which are the functional cells of the liver.
4. The hepatic artery supplies blood to the liver. The portal vein receives blood from the inferior and superior mesenteric veins.
5. Hepatocytes synthesize 700 to 1200 ml of bile per day and secrete it into the bile canaliculi, which are small channels between the hepatocytes. The bile canaliculi drain bile into the common bile duct and then into the duodenum through an opening called the *major duodenal papilla (sphincter of Oddi).*

SUMMARY REVIEW—cont'd

6. Sinusoids are capillaries located between the plates of hepatocytes. Blood from the hepatic portal vein and hepatic artery flows through the sinusoids to a central vein in each lobule and then into the hepatic vein and inferior vena cava.
7. Kupffer cells, which are part of the mononuclear phagocyte system, line the sinusoids and destroy microorganisms in sinusoidal blood.
8. The primary bile acids are synthesized from cholesterol by the hepatocytes. The primary acids are then conjugated to form bile salts. The secondary bile acids are the product of bile salt deconjugation by bacteria in the intestinal lumen.
9. Most bile salts and acids are recycled. The absorption of bile salts and acids from the terminal ileum and their return to the liver are known as the enterohepatic circulation of bile.
10. Bilirubin is a pigment liberated by the lysis of aged red blood cells in the liver and spleen. Unconjugated bilirubin is fat soluble and can cross cell membranes. Unconjugated bilirubin is converted to water-soluble, conjugated bilirubin by hepatocytes and is secreted with bile.
11. Fats are synthesized by the liver from protein and carbohydrates and include glycerol, free fatty acids, phospholipids, and cholesterol. Fat absorbed by intestinal lacteals is primarily triglyceride, which is hydrolyzed to glycerol and free fatty acid.
12. Protein synthesis by the liver requires all essential amino acids. The liver synthesizes albumin, globulin, and several serum enzymes and can convert amino acids to carbohydrates by removal of ammonia.
13. Carbohydrates can be released as glucose, stored as glycogen, or converted to fat.
14. The liver performs many metabolic functions including detoxification of exogenous and endogenous chemicals and hormones.
15. The gallbladder is a saclike organ located in the inferior surface of the liver. The gallbladder stores bile between meals and ejects it when chyme enters the duodenum.
16. Stimulated by cholecystokinin, the gallbladder contracts and forces bile through the cystic duct and into the common bile duct. The sphincter of Oddi relaxes, enabling bile to flow through the major duodenal papilla into the duodenum.
17. The pancreas is a gland located behind the stomach. The endocrine pancreas produces hormones (glucagon and insulin) that facilitate the formation and cellular uptake of glucose. The exocrine pancreas secretes an alkaline solution and the enzymes (trypsin, chymotrypsin, carboxypeptidase, α-amylase, lipase) that digest proteins, carbohydrates, and fats.
18. Secretin stimulates pancreatic secretion of alkaline fluid, and cholecystokinin and ACh stimulate secretion of enzymes. Pancreatic secretions originate in acini and ducts of the pancreas and empty into the duodenum through the common bile duct or an accessory duct that opens directly into the duodenum.

Tests of Digestive Function

1. Numerous diagnostic tests can evaluate structure and function (digestion, secretion, absorption) of the gastrointestinal tract. Radiographs and scans are most commonly used to evaluate structure, in addition to direct observation by endoscopy. Gastric and stool analysis and blood studies provide important information about digestion, absorption, and secretion.
2. Plasma chemistry levels and imaging procedures are commonly used to diagnose alterations in liver function. Of particular importance are the enzymes LDH, AST, and ALT. Plasma bilirubin levels reflect alterations in bilirubin and bile metabolism, and prothrombin times are prolonged in hepatitis and chronic liver disease.
3. Obstructive diseases of the gallbladder are evident by elevated serum bilirubin levels, elevated urine urobilinogen levels, and increased stool fat. The serum leukocyte levels become elevated with inflammation of the gallbladder.
4. The most significant indicators of pancreatic dysfunction are serum amylase and stool fat. Both values are increased with diseases of the pancreas.

Aging and the Gastrointestinal System

1. Advancing age is often associated with the loss or deterioration of teeth, diminished senses of taste and smell, and diminished salivary secretions, all of which may make eating difficult and reduce appetite.
2. Aging reduces gastric motility and secretions, particularly of hydrochloric acid. These changes slow gastric digestion and emptying.
3. Intestinal motility and absorption of carbohydrates, proteins, fats, and minerals decrease with age.
4. Efficiency of drug and alcohol metabolism decreases with age and can be related to decreased liver perfusion and decreased liver enzymes.

CHAPTER OUTLINE

Disorders of the gastrointestinal tract disrupt one or more of its functions. Structural and neural abnormalities can slow, obstruct, or accelerate the movement of intestinal content at any level of the gastrointestinal tract. Inflammatory and ulcerative conditions of the gastrointestinal wall disrupt secretion, motility, and absorption. Inflammation or obstruction of the liver, pancreas, or gallbladder can alter metabolism and result in local or systemic symptoms, or both. Many clinical manifestations of gastrointestinal tract disorders are nonspecific and can be caused by a variety of impairments. These manifestations are described in the section below.

DISORDERS OF THE GASTROINTESTINAL TRACT

Clinical Manifestations of Gastrointestinal Dysfunction

Anorexia

Anorexia is lack of a desire to eat despite physiologic stimuli that would normally produce hunger. Anorexia is a nonspecific symptom that is often associated with nausea, abdominal pain, diarrhea, and psychologic distress. Side effects of drugs and disorders of other organ systems, including cancer,

heart disease, and renal disease, are often accompanied by anorexia.

Vomiting

Vomiting is the forceful emptying of stomach and intestinal contents through the mouth. The vomiting center lies in the medulla oblongata and includes the reticular formation and tractus solitarius nucleus. Stimulation of the vomiting center occurs directly by irritants or indirectly. Indirect stimulation includes the cerebral cortex and thalamus (anxiety and pain); the vestibular system through the eighth cranial nerve (motion sickness); several types of intestinal, vagal, or sympathetic input, including the presence of ipecac or copper salts in the duodenum; side effects of many drugs; distention of the stomach or duodenum; or torsion or trauma affecting the ovaries, testes, uterus, bladder, or kidney. Serotonin (5-hydroxytryptamine [5-HT]) stimulates the vomiting center and appears to be released from enterochromaffin cells in the intestinal wall, which activate vagal afferents leading to the chemoreceptor trigger zone (CTZ).[1] Activation of the CTZ, which lies in the area postrema between the medulla and floor of the fourth ventricle, leads to vomiting by triggering receptors for substances such as dopamine (D_2), opioids, acetylcholine, substance P, serotonin (5-hydroxytryptamine type 3), and neurokinin-1. Serotonin and neurokinin-1 antagonists are effective antiemetics and have been used to treat nausea and vomiting associated with postoperative vomiting and cancer chemotherapy. Apomorphine, levodopa, and bromocriptine are dopamine D_2 agonists that cause nausea and vomiting. Metoclopramide, domperidone, and haloperidol are D_2 antagonists and are effective antiemetics.[2]

Nausea and retching usually precede vomiting although they are distinct entities. **Nausea** is a subjective experience that is associated with many different conditions, including visceral pain, labyrinthine stimulation (i.e., motion), and use of opiate medications. Specific neural pathways have not been identified for nausea. Hypersalivation and tachycardia are common associated symptoms.

With vomiting, the duodenum and antrum of the stomach produce retrograde peristalsis while the body of the stomach and the esophagus relax. When the stomach is full of gastric contents, the diaphragm is forced high into the thoracic cavity by strong contractions of the abdominal muscles. The higher intrathoracic pressure forces the upper esophageal sphincter to open, and chyme is expelled from the mouth. Then the stomach relaxes and the upper part of the esophagus contracts, forcing the remaining chyme back into the stomach. The lower esophageal sphincter then closes. The cycle is repeated if there is a volume of chyme remaining in the stomach.

Retching is the muscular event of vomiting without the expulsion of vomitus. Retching begins with deep inspiration. The glottis then closes, intrathoracic pressure falls, and the esophagus becomes distended. Simultaneously, the abdominal muscles contract creating a pressure gradient from abdomen to thorax. The lower esophageal sphincter and body of the stomach relax, but the duodenum and antrum of the stomach spasm. The reverse peristalsis and pressure gradient force chyme from the stomach and duodenum up into the esophagus. Because the upper esophageal sphincter is closed, chyme does not enter the mouth. As the abdominal muscles relax, the contents of the esophagus drop back into the stomach. This process may be repeated several times before vomiting occurs. A diffuse sympathetic discharge causes the tachycardia, tachypnea, and sweating that accompany retching and vomiting. The parasympathetic system mediates copious salivation, increased gastric motility, and relaxation of the upper and lower esophageal sphincters.

Projectile vomiting is spontaneous vomiting that is not preceded by nausea or retching. Projectile vomiting is caused by direct stimulation of the vomiting center by neurologic lesions (e.g., increased intracranial pressure, tumors, or aneurysms involving the brainstem [see Chapters 17 and 20]). The metabolic consequences of vomiting are fluid, electrolyte, and acid-base disturbances, including hyponatremia, hypokalemia, hypochloremia, and metabolic alkalosis (see Chapter 3).

Constipation

Constipation is difficult or infrequent defecation and is estimated to affect 2% to 28% of the population. Constipation must be individually defined because patterns of bowel evacuation differ greatly among individuals. Normal bowel habits range from two or three evacuations per day to one per week. Constipation is not significant until it causes health risks (e.g., severe abdominal distention or fecal impaction) or impairs quality of life.[3]

PATHOPHYSIOLOGY. Primary constipation is generally classified into three categories. *Normal transit (functional) constipation* involves a normal rate of stool passage but there is difficulty with stool evacuation. Functional constipation is most common and is associated with low-residue diet (the habitual consumption of highly refined foods) or low fluid intake, which decreases the volume and number of stools and can contribute to constipation. Physical activity stimulates peristalsis; therefore, a sedentary lifestyle and lack of regular exercise are common causes of constipation. Lack of access to toilet facilities, consistent suppression of the urge to empty the bowel, and dehydration are other causes. *Slow-transit constipation* involves impaired colonic motor activity with infrequent bowel movements, straining to defecate, mild abdominal distention, and palpable stool in the sigmoid colon. *Pelvic floor dysfunction* (pelvic floor dyssynergia-anismus) is difficulty expelling stool because of failure of the pelvic floor muscles or anal sphincter to relax with defecation.

Secondary constipation can be caused by neurogenic disorders (e.g., stroke, Parkinson disease, spinal cord injury, multiple sclerosis) in which neurotransmitters are altered or neural pathways are diseased or degenerated, resulting in delayed colon transit time. Opiates, particularly codeine, antacids containing calcium carbonate or aluminum hydroxide; anticholinergics; iron; and bismuth tend to inhibit bowel motility. Endocrine or metabolic disorders associated with constipation include hypothyroidism, diabetes mellitus, hypokalemia, and hypercalcemia. Pelvic hiatal hernia (herniation of the bowel through the floor of the pelvis), diverticuli, irritable bowel syndrome–constipation predominant, and pregnancy also can be associated with constipation. Aging can result in constipation caused from decreased motility related to the degeneration of neurons

in the myenteric plexus, decreased neurotransmitter function, use of medications, and comorbid medical conditions.[4] Constipation as a notable change in bowel habits can be an indication of colorectal cancer.

Many mechanical conditions can slow intestinal transit time. The abdominal muscles are normally used to create the intra-abdominal pressure required to evacuate the rectum. Weakness or pain can interfere with the generation of adequate intra-abdominal pressure. Lesions of the anus, such as inflamed hemorrhoids, fissures, or fistulae, make defecation painful because of stretching. With the urge to defecate, the sphincter becomes hypertonic and the stool is not eliminated. Depression often impairs bowel evacuation, partly because depressed individuals tend to be sedentary and lack the motivation to eat a healthy diet. The problem is made worse if antidepressant drugs (e.g., anticholinergics) are used to treat the depression.

CLINICAL MANIFESTATIONS. Indicators of constipation include two of the following for at least 3 months: (1) straining with defecation at least 25% of the time, (2) lumpy or hard stools at least 25% of the time, (3) sensation of incomplete emptying at least 25% of the time, (4) manual maneuvers to facilitate stool evacuation for at least 25% of defecations, and (5) fewer than three bowel movements per week.[5] Changes in bowel evacuation patterns, such as less frequent defecation, smaller stool volume, hard stools, difficulty passing stools (straining), or a feeling of bowel fullness and discomfort or blood in the stools, require investigation. Fecal impaction (hard, dry stool retained in the rectum) is associated with rectal bleeding, abdominal or cramping pain, nausea and vomiting, weight loss, and episodes of diarrhea. Straining to evacuate stool may cause engorgement of the hemorrhoidal veins and hemorrhoidal disease or thrombosis with rectal pain, bleeding, and itching. Passage of hard stools can cause painful anal fissures.

EVALUATION AND TREATMENT. The history, current use of medications, physical examination, and stool diaries provide precise clues regarding the nature of constipation. Sudden-onset constipation can accompany the development of colorectal cancer and requires careful evaluation. The individual's description of frequency, stool consistency, associated pain, and presence of blood or whether evacuation was stimulated by enemas or cathartics (laxatives) is significant. Cramping abdominal pain may be symptomatic of partial bowel obstruction. Palpation discloses colonic distention, masses, and tenderness. Blood may be caused by bleeding hemorrhoids or a neoplastic lesion of the colon.

Digital examination of the rectum and anorectal manometry are performed to assess sphincter tone and detect anal lesions. Proctosigmoidoscopy and colonoscopy are used to visualize the lumen directly. Colonic transit studies and imaging techniques can assist in identifying the etiology of constipation.

The treatment for constipation is to manage the underlying cause or disease for each individual. Management usually consists of bowel retraining, in which the individual establishes a satisfactory bowel evacuation routine without becoming preoccupied with bowel movements. Moderate exercise, increased fluid and fiber intake, stool softeners, and laxative agents are useful for some individuals. Enemas can be used to establish bowel routine, but they should not be used habitually. Biofeedback training can be effective for dyssynergic defecation.[6] Drugs used to treat constipation include the colonic secretagogues lubiprostone and plecanatide and the 5-HT_4 agonist prucalopride. Methylnaltrexone is a peripherally acting μ-opioid receptor antagonist approved for opioid-induced constipation in terminally ill individuals.[7]

Diarrhea

Diarrhea is an increase in the frequency of defecation and the fluid content, volume, and weight of feces. Three or more loose or liquid stools per day or more frequently than is normal for the individual are considered abnormal.[8] Many factors determine stool volume and consistency, including the water content of the colon and the presence of unabsorbed food, unabsorbable material, and intestinal secretions. Stool volume in the normal adult averages less than 200 g/day. Stool volume in children depends on age and size. An infant may pass up to 100 g/day. The adult intestine processes approximately 9 L of luminal contents per day; 2 L is ingested, and the remaining 7 L consists of intestinal secretions. Of this volume, 99% of the fluid is absorbed—90% (7 to 8 L) in the small intestine and 9% (1 to 2 L) in the colon. Normally, approximately 150 ml of water is excreted daily in the stool.

PATHOPHYSIOLOGY. Diarrhea in which the volume of feces is increased is called *large-volume diarrhea.* Large-volume diarrhea generally is caused by excessive amounts of water or secretions, or both, in the intestines. *Small-volume diarrhea,* in which the volume of feces is not increased, usually results from excessive intestinal motility. The three major mechanisms of diarrhea are osmotic, secretory, and motility.[9] (Specific mechanisms of diarrhea in children are described in Chapter 42.)

In **osmotic diarrhea,** a nonabsorbable substance in the intestine draws water into the lumen by osmosis. The excess water and the nonabsorbable substance cause large-volume diarrhea. Large oral doses of poorly absorbed ions, such as magnesium, sulfate, and phosphate, can increase intraluminal osmotic pressure. Excessive ingestion of synthetic, nonabsorbable sugars (e.g., sorbitol); introduction of full-strength tube feeding formulas; and dumping syndrome associated with gastric resection draw water into the intestinal lumen (see p. 1440). Osmotic diarrhea disappears when ingestion of the osmotic substance stops. Malabsorption related to lactase deficiency, pancreatic enzyme or bile salt deficiency, small intestine bacterial overgrowth, and celiac disease also cause diarrhea.

Secretory diarrhea is a form of large-volume diarrhea caused by excessive mucosal secretion of chloride- or bicarbonate-rich fluid or inhibition of net sodium absorption. Infectious causes include viruses (e.g., rotavirus), bacterial enterotoxins (e.g., *Escherichia coli* and *Vibrio cholerae*), or exotoxins from overgrowth of *Clostridium difficile* following antibiotic therapy. These infections cause secretion of transmitters from enteroendocrine cells (e.g., 5-HT) and activation of afferent neurons that stimulate submucosal secretomotor neurons and altered sodium and chloride transport resulting in decreased water absorption.[10,11] Neoplasms (such as gastrinoma or thyroid carcinoma) produce hormones that stimulate intestinal secretion causing diarrhea.

Small-volume diarrhea usually is caused by an inflammatory disorder of the intestine, such as ulcerative colitis, Crohn disease, or microscopic colitis. Inflammation of the colon causes smooth muscle contraction, cramping pain, urgency, and frequency. Small-volume diarrhea also can be caused by fecal impaction, a severe form of constipation. This diarrhea consists of secretions (mucus and fluid) produced by the colon to lubricate the impacted feces and move it toward the anal canal. These secretions flow around the impaction and cause low-volume, secretory diarrhea.

Motility diarrhea is caused by resection of the small intestine (short bowel syndrome), surgical bypass of an area of the intestine, fistula formation between loops of intestine, irritable bowel syndrome–diarrhea predominant, diabetic neuropathy, hyperthyroidism, and laxative abuse. Excessive motility decreases transit time, mucosal surface contact, and opportunities for fluid absorption, resulting in diarrhea.

CLINICAL MANIFESTATIONS. Diarrhea can be acute or chronic, depending on its cause. Systemic effects of prolonged diarrhea are dehydration, electrolyte imbalance (hyponatremia, hypokalemia), metabolic acidosis, and weight loss. Manifestations of acute bacterial or viral infection include fever, with or without cramping pain. Fever, cramping pain, and bloody stools accompany diarrhea caused by inflammatory bowel disease. Steatorrhea (fat in the stools) and diarrhea are common signs of malabsorption syndromes. Anal and perineal skin irritation can occur.

EVALUATION AND TREATMENT. A thorough history is taken to document the onset, frequency, and volume of stools. Exposure to contaminated food or water is indicated if the individual has traveled in foreign countries or areas where drinking water might be contaminated. Iatrogenic diarrhea is suggested if the individual has undergone abdominal radiation therapy, intestinal resection, or treatment with selected drugs (e.g., antibiotics, diuretics, antihypertensives, laxatives). Physical examination helps the clinician to identify underlying systemic disease. Stool culture, examination of stool specimens for blood, abdominal roentgenograms, endoscopy, and intestinal biopsies provide more specific data.[12]

Treatment for diarrhea includes restoration of fluid and electrolyte balance, antimotility (e.g., loperamide [an opiate] or Lomotil [atropine]) and/or water-absorbent (e.g., attapulgite and polycarbophil) medications, and treatment of causal factors. Nutritional deficiencies need to be corrected in cases of chronic diarrhea or malabsorption. Natural bran and commercial preparations of psyllium are inexpensive and effective treatments for mild diarrhea. Probiotics can be useful for treating *Clostridium difficile*–associated diarrhea as an approach to restoring normal microflora in addition to antibiotic therapy.[13] Fecal transplantation can be used for cases that are resistant to conventional therapies.[14]

Abdominal Pain

Abdominal pain is the presenting symptom of a number of gastrointestinal (GI) diseases and can be acute or chronic. The causal mechanisms are *mechanical, inflammatory,* or *ischemic.* (The physiology of pain is described in Chapter 16.) Abdominal pain may be generalized to the abdomen or localized to a particular abdominal quadrant. The pain is often described as sharp, dull, or colicky. Generally the abdominal organs are not sensitive to mechanical stimuli, such as cutting, tearing, or crushing. These organs are, however, sensitive to stretching and distention, which activate nerve endings in both hollow and solid structures. The onset of pain is associated with rapid distention; gradual distention causes little pain. Traction on the peritoneum caused by adhesions, distention of the common bile duct, or forceful peristalsis resulting from intestinal obstruction causes pain because of increased tension. Capsules that surround solid organs, such as the liver and gallbladder, contain pain fibers that are stimulated by stretching if these organs swell.

Biochemical mediators of the inflammatory response, such as histamine, bradykinin, and serotonin, stimulate pain nerve endings and produce abdominal pain. The edema and vascular congestion that accompany chemical, bacterial, or viral inflammation also cause painful stretching. Obstruction of blood flow from the distention of bowel obstruction or mesenteric vessel thrombosis produces the pain of ischemia, and increased concentrations of tissue metabolites stimulate pain receptors.

Abdominal pain can be parietal (somatic), visceral, or referred. **Parietal pain** arises from the parietal peritoneum. This pain is more localized and intense than visceral pain, which arises from the organs themselves. Nerve fibers from the parietal peritoneum travel with peripheral nerves to the spinal cord, and the sensation of pain corresponds to skin dermatomes T6 and L1. Parietal pain lateralizes because, at any particular point, the parietal peritoneum is innervated from only one side of the nervous system.

Visceral pain arises from a stimulus (distention, inflammation, ischemia) acting on an abdominal organ. Chronic low-grade inflammation can cause pain hypersensitivity with involvement of neurokinins, serotonin, and voltage-gated ion channels.[15,16] Pain is usually felt near the midline in the epigastrium, midabdomen, or lower abdomen. The pain is poorly localized, is dull rather than sharp, and is difficult to describe. Visceral pain is diffuse and vague because nerve endings in abdominal organs are sparse and multisegmented. Pain arising from the stomach, for example, is experienced as a sensation of fullness, cramping, or gnawing in the midepigastric area. **Referred pain** is visceral pain felt at some distance from a diseased or an affected organ. Referred pain is usually well localized and is felt in the skin dermatomes or deeper tissues that share a central afferent pathway with the affected organ. Gallbladder pain is, for example, referred to the right shoulder or scapulae.

Gastrointestinal Bleeding

Upper gastrointestinal (GI) bleeding is bleeding in the esophagus, stomach, or duodenum and is characterized by frank, bright red bleeding in emesis or dark, grainy digested blood ("coffee grounds") in stool. Upper GI bleeding is caused by esophageal or gastric varices, a Mallory-Weiss tear at the esophageal-gastric junction from severe retching, cancer, angiodysplasias, or peptic ulcers.[17] **Lower gastrointestinal (GI) bleeding,** bleeding from the small intestine (jejunum or ileum), colon, or rectum, can be

caused by polyps, inflammatory bowel disease, diverticulosis, cancer, vascular ectasias, or hemorrhoids.[18] **Occult bleeding** is usually caused by slow, chronic blood loss that is not obvious and results in iron deficiency anemia as iron stores in the bone marrow are slowly depleted. Acute, severe GI bleeding is life threatening depending on the volume and rate of blood loss, associated disease, age, and effectiveness of treatment.

Physiologic response to gastrointestinal bleeding depends on the amount and rate of the loss (Figure 41-1). Changes in blood pressure and heart rate are the best indicators of massive blood loss in the gastrointestinal tract. Blood losses of 1000 ml or more over a short time cause a decrease in blood pressure and a corresponding increase in heart rate. With losses of 1000 ml or more, the heart rate is greater than 100 beats/minute and

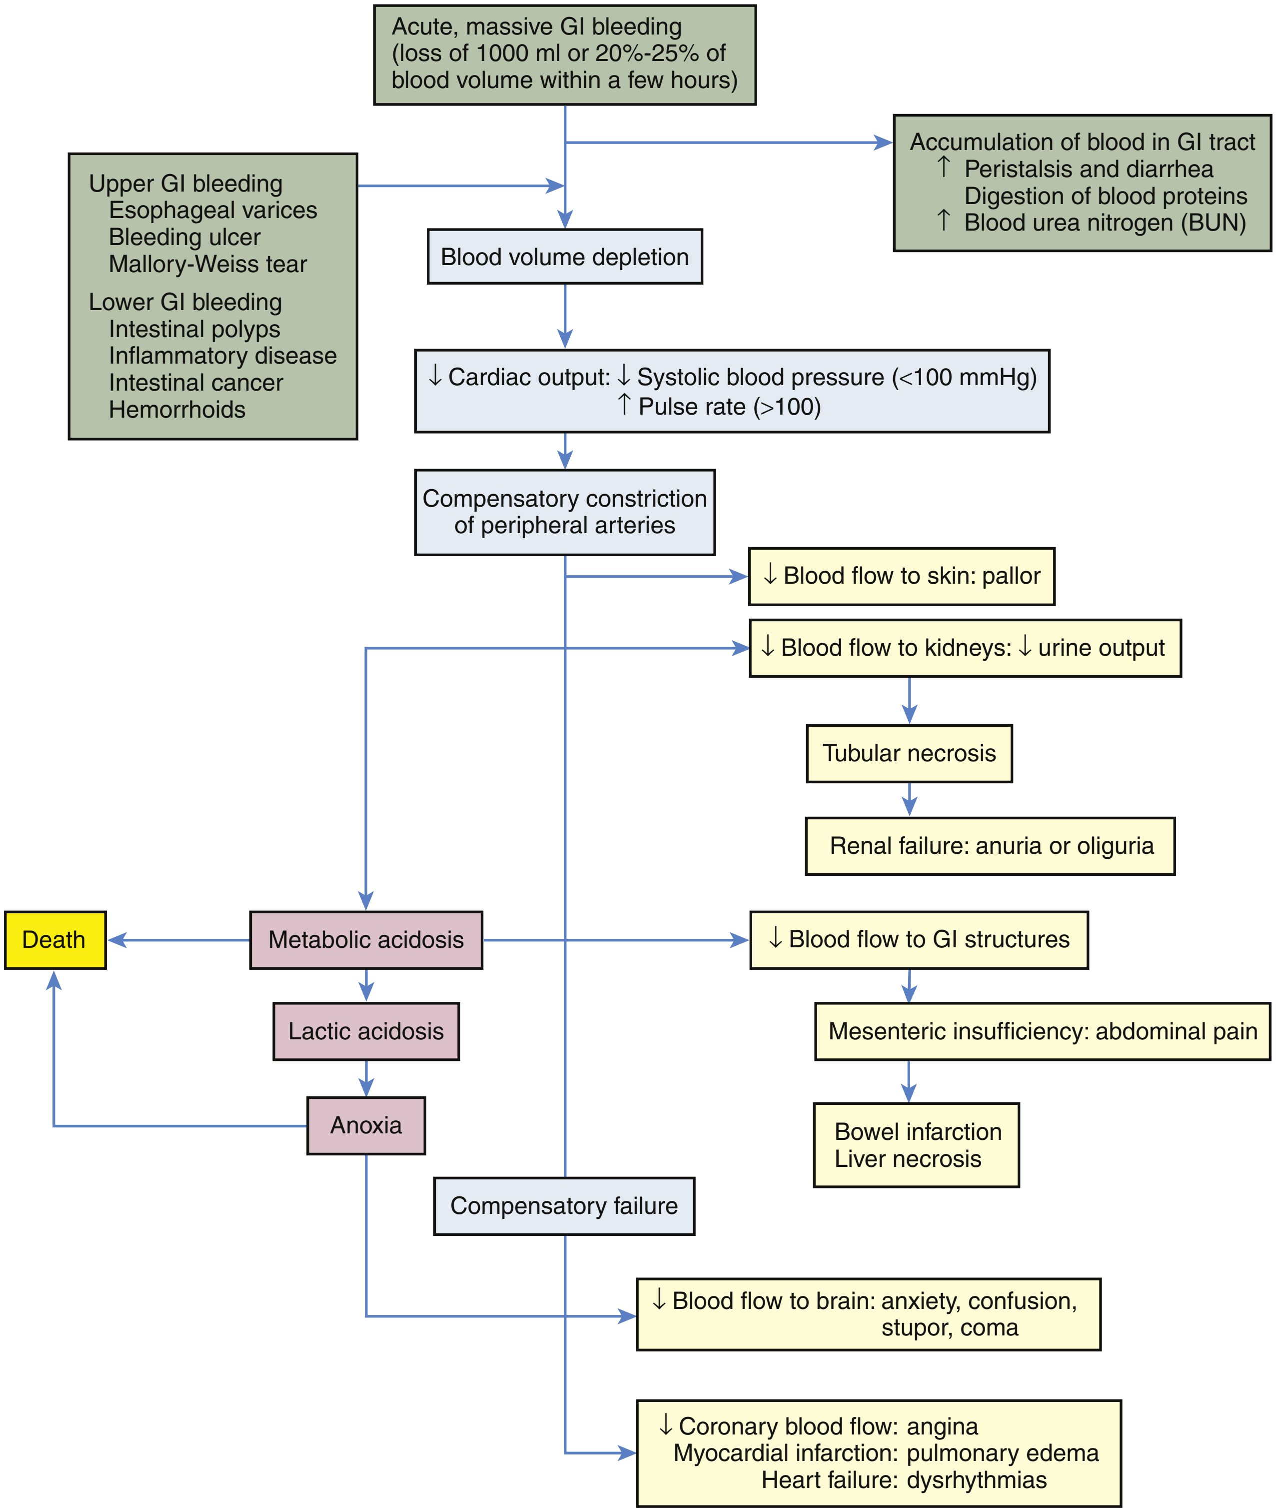

FIGURE 41-1 Pathophysiology of Gastrointestinal (GI) Bleeding.

systolic blood pressure is less than 100 mmHg. During the early stages of blood volume depletion, the peripheral arteries and arterioles constrict to shunt blood to vital organs, including the brain (see Chapters 32 and 48). Signs of large-volume blood loss are postural hypotension (a drop in blood pressure that occurs with a change from the recumbent position to a sitting or upright position), lightheadedness, and loss of vision. If blood loss continues, hypovolemic shock develops. Diminished blood flow to the kidneys causes decreased urine output and may lead to oliguria (low urine output), tubular necrosis, and renal failure. Ultimately, insufficient cerebral and coronary blood flow causes irreversible anoxia and death.

The presentation of GI bleeding is summarized in Table 41-1. The accumulation of blood in the gastrointestinal tract is irritating and increases peristalsis, causing vomiting **(hematemesis)** or diarrhea, or both. If bleeding is from the lower GI tract, the diarrhea is frankly bloody. Bleeding from the upper GI tract also can be rapid enough to produce bright red stools **(hematochezia),** but generally some digestion of the blood components will have occurred, producing **melena,** black or tarry stools that are sticky and have a characteristic foul odor. The digestion of blood proteins originating from massive upper GI bleeding is reflected by an increase in blood urea nitrogen (BUN) levels (see Figure 41-1).

The hematocrit and hemoglobin values are not the best indicators of acute gastrointestinal bleeding because plasma and red cell volume are lost proportionately. As the plasma volume is replaced, the hematocrit and hemoglobin values begin to reflect the extent of blood loss. The interpretation of these values is modified to account for exogenous replacement of fluids and the hydration status of the tissues. Anemia associated with chronic GI bleeding is caused by iron depletion. Evaluation and treatment involves identifying and treating the source of the bleeding and replacing iron losses. Administration of blood products may be used for massive hemorrhage. Guidelines are available for the diagnosis and management of gastrointestinal bleeding.[19-21]

Disorders of Motility

Dysphagia

PATHOPHYSIOLOGY. **Dysphagia** is difficulty swallowing. It can result from mechanical obstruction of the esophagus or a functional disorder that impairs esophageal motility. *Mechanical obstructions* can be intrinsic or extrinsic. Intrinsic obstructions originate in the wall of the esophageal lumen. Tumors, strictures, and diverticular herniations (outpouchings) are all causes of intrinsic mechanical obstruction. Extrinsic mechanical obstructions originate outside the esophageal lumen and narrow the esophagus by pressing inward on the esophageal wall. The most common cause of extrinsic mechanical obstruction is tumor.

Functional dysphagia is caused by neural or muscular disorders that interfere with voluntary swallowing or peristalsis. Disorders that affect the striated muscles of the upper esophagus interfere with the oropharyngeal (voluntary) phase of swallowing. Typical causes of functional dysphagia in the upper esophagus are dermatomyositis (a muscle disease) and neurologic impairments caused by stroke, multiple sclerosis, Parkinson disease, amyotrophic lateral sclerosis, or myasthenia gravis.[22]

Achalasia is a rare disorder related to loss of inhibitory neurons in the myenteric plexus with smooth muscle atrophy in the middle and lower portions of the esophagus. The etiology is unknown but may be related to viral or autoimmune mechanisms.[23] This leads to altered esophageal peristalsis and failure of the lower esophageal sphincter (LES) to relax, causing functional obstruction of the lower esophagus. Food accumulates above the obstruction, distends the esophagus, and causes dysphagia. Cough and aspiration can occur. As hydrostatic pressure increases, food is slowly forced past the obstruction into the stomach. Chronic inflammation from esophageal food retention can increase risk for esophageal cancer. Chronic esophageal distention requires dilation or surgical myomotomy of the lower esophageal sphincter (LES).[24]

CLINICAL MANIFESTATIONS. Clinical manifestations of dysphagia vary according to the location of the obstruction. Distention and spasm of the esophageal muscles during eating or drinking may cause a mild or severe stabbing pain at the level of obstruction. Discomfort occurring 2 to 4 seconds after swallowing is associated with upper esophageal obstruction. Discomfort occurring 10 to 15 seconds after swallowing is more common in obstructions of the lower esophagus. If the cause of obstruction is a growing tumor, dysphagia begins with difficulty swallowing solids and advances to difficulty swallowing semisolids and liquids. Retrosternal pain, regurgitation of undigested food, unpleasant taste, vomiting, and weight loss are common manifestations of all types of dysphagia. Aspiration of esophageal contents can lead to chronic cough and pneumonia.

EVALUATION AND TREATMENT. Knowledge of the individual's history and clinical manifestations contributes significantly to a diagnosis of dysphagia. Videofluoroscopy and high-frequency ultrasound are used to visualize the contours of the esophagus and identify structural defects. High-resolution manometry with topography and intraluminal impedance monitoring documents the duration and amplitude of abnormal pressure changes associated with obstruction or loss of neural regulation.[25] Esophageal endoscopy is performed to examine the esophageal mucosa, obtain biopsy specimens, or perform corrective surgery.

The individual is taught to manage symptoms by eating slowly, eating small meals, taking fluid with meals, and sleeping

TABLE 41-1 PRESENTATIONS OF GASTROINTESTINAL BLEEDING

PRESENTATION	DEFINITION
Acute bleeding	
Hematemesis	Bloody vomitus; either fresh, bright red blood or dark, grainy, digested blood with "coffee grounds" appearance
Melena	Black, sticky, tarry, foul-smelling stools caused by digestion of blood in the gastrointestinal tract
Hematochezia	Fresh, bright red blood passed from the rectum
Occult bleeding	Trace amounts of blood in normal-appearing stools or gastric secretions; detectable only with a guaiac test

with the head elevated to prevent regurgitation and aspiration. Oral medications may need to be formulated so they can be swallowed.[26] Tube feedings may be required for some individuals, particularly following stroke.[27] Anticholinergic drugs may alleviate symptoms. Definitive treatments include mechanical dilation of the esophageal sphincter and surgical separation of the lower esophageal muscles with a longitudinal incision (myotomy) widening the passage into the stomach.[28]

Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is the reflux of acid and pepsin from the stomach to the esophagus that causes **esophagitis.** Risk factors for GERD include obesity, hiatal hernia, and drugs or chemicals that relax the LES (anticholinergics, nitrates, calcium channel blockers, nicotine).[29] GERD may be a trigger for asthma or chronic cough.[30] Gastroesophageal reflux that does not cause symptoms is known as *physiologic reflux*. In *nonerosive reflux disease (NERD),* individuals have symptoms of reflux disease but no visible esophageal mucosal injury (functional heartburn).[31]

PATHOPHYSIOLOGY. The resting tone of the LES tends to be lower than normal from either transient relaxation or weakness of the sphincter in those who develop GERD. Vomiting, coughing, lifting, bending, or obesity increases abdominal pressure, contributing to the development of reflux esophagitis. Delayed gastric emptying contributes to reflux esophagitis by: (1) lengthening the period during which reflux is possible and (2) increasing the acid content of chyme. Disorders that delay emptying include gastric or duodenal ulcers, which can cause pyloric edema; strictures that narrow the pylorus; and hiatal hernia, which can weaken the LES.[32]

GERD causes inflammatory responses in the esophageal wall resulting in hyperemia, edema, tissue fragility, erosion, and ulcerations (Figure 41-2). Severity of inflammation is related to composition of gastric contents and length of exposure time.[33] Fibrosis, basal cell hyperplasia, and elongation of papillae are common.

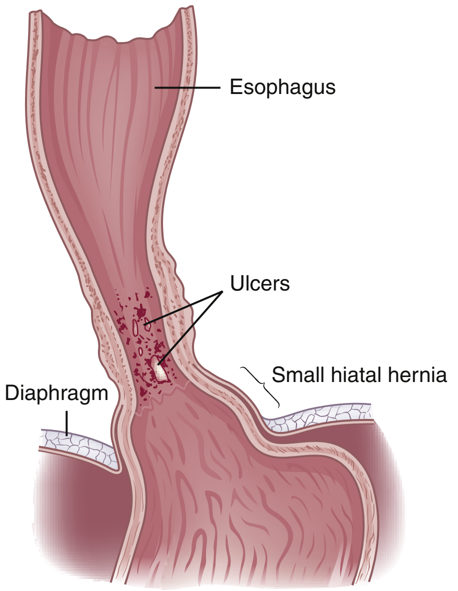

FIGURE 41-2 Esophagitis with Esophageal Ulcerations.

Precancerous lesions (Barrett esophagus, see p. 1466) with progression to adenocarcinoma can be a long-term consequence.[33,34]

CLINICAL MANIFESTATIONS. The clinical manifestations of reflux esophagitis are heartburn from acid regurgitation, chronic cough, asthma attacks (see Chapter 35), and laryngitis.[30] Upper abdominal pain usually occurs within 1 hour of eating and can be relapsing and remitting. Symptoms can worsen if the individual lies down or if intra-abdominal pressure increases (e.g., as a result of coughing, vomiting, or straining at stool). Symptoms may be present when no acid is in the esophagus.[35] Heartburn also may be experienced as chest pain, which requires ruling out cardiac ischemia. Edema, fibrosis (strictures), esophageal spasm, or decreased esophageal motility may result in dysphagia. Alcohol or acid-containing foods, such as citrus fruits, can cause discomfort during swallowing.

EVALUATION AND TREATMENT. Diagnosis of reflux esophagitis is based on the history and clinical manifestations. Esophageal endoscopy shows hyperemia, edema, erosion, and strictures. Dysplastic changes (Barrett esophagus) can be identified by tissue biopsy. Impedance/pH monitoring measures the movement of stomach contents upward into the esophagus and the acidity of the refluxate.

Proton pump inhibitors are the most effective monotherapy. Other therapies include histamine-2 (H2) receptor antagonists, prokinetics, and antacids. Pain medication may be used in resistant cases. Elevation of the head of the bed 6 inches prevents reflux. Weight reduction and cessation of smoking also help to alleviate symptoms. Laparoscopic fundoplication is the most common surgical intervention when medical treatment fails.[36,37]

Eosinophilic esophagitis is a rare, idiopathic inflammatory disease of the esophagus characterized by esophageal infiltration of eosinophils associated with atopic disease, including asthma and food allergies. It occurs in adults and children. Dysphagia, food impaction, vomiting, and weight loss are common symptoms. Endoscopy with biopsy identifies the eosinophilc infiltration and differentiation from GERD. Treatment is symptomatic including elimination diets, proton pump inhibitors, and immunosuppression.[38]

Hiatal Hernia

PATHOPHYSIOLOGY. **Hiatal hernia** is the protrusion (herniation) of the upper part of the stomach through the diaphragm and into the thorax.[39] There are four types: sliding (type I); paraesophageal (type II); mixed (type III), which include elements of types I and II (Figure 41-3).[40] In type IV the entire stomach and other abdominal organs slide into the thorax.

In type I, **sliding hiatal hernia** (the most common type, 90%), the proximal portion of the stomach moves into the thoracic cavity through the esophageal hiatus, an opening in the diaphragm for the esophagus and vagus nerves. A congenitally short esophagus, fibrosis or excessive vagal nerve stimulation, or weakening of the diaphragmatic muscles at the gastroesophageal junction contributes to the hernia. While the individual is in the supine position, the lower esophagus and stomach are pulled into the thorax. Standing causes the organs to “slide” back into the abdomen. Sliding hiatal hernia is exacerbated by factors that increase intra-abdominal pressure, such as coughing, bending,

wearing tight clothing, ascites, obesity, or pregnancy. This type of hernia is associated with gastroesophageal reflux because the hernia diminishes the resting pressure of the LES. In pregnant women with sliding hiatal hernia, progesterone and estrogen may lower the resting pressure of the LES further.

In type II, **paraesophageal hiatal hernia** (rolling hiatal hernia), herniation of the greater curvature of the stomach is through a secondary opening in the diaphragm (see Figure 41-3). A giant paraesophageal hiatal hernia develops when 30% to 60% of the stomach moves into the thorax. As the stomach protrudes through the opening into the thorax, it lies alongside the esophagus. The gastroesophageal junction remains below the diaphragm. With paraesophageal hernia, reflux is uncommon. The position of a portion of the stomach above the diaphragm, however, causes congestion of mucosal blood flow and can lead to gastritis and ulcer formation. A mechanical strangulation of the hernia is a major complication, and surgical correction is required. Strangulation occludes blood vessels and causes vascular engorgement, edema, ischemia, and hemorrhage. Type III, mixed hiatal hernia, is a combination of both types I and II and tends to occur in conjunction with several other diseases, including gastroesophageal reflux, peptic ulcer, cholecystitis (gallbladder inflammation), cholelithiasis (gallstones), chronic pancreatitis, and diverticulosis. Type IV is an aggravated form of type III.

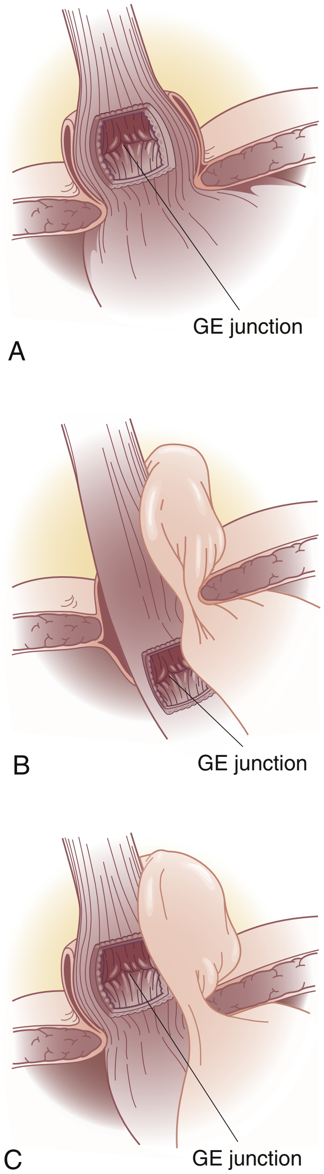

FIGURE 41-3 The Three Types of Hiatal Hernia. **A,** Type I—*sliding hernia.* The visceral peritoneum remains intact and restrains the size of the hernia in sliding hiatal hernia. **B,** Type II—*paraesophageal* or *rolling hernia.* The membrane becomes thinner or defective in paraesophageal hernia, allowing a true peritoneal sac to protrude into the posterior mediastinum where negative intrathoracic pressure causes it to enlarge. **C,** Type III—*mixed hernia. GE,* Gastroesophageal. (From Townsend CM et al: *Sabiston textbook of surgery,* ed 19, Philadelphia, 2012, Saunders.) **NOTE:** Type IV-complex paraesophageal hernia is not shown.

CLINICAL MANIFESTATIONS. Hiatal hernias are often asymptomatic. Generally, a wide variety of symptoms develop later in life and are associated with other gastrointestinal disorders, including GERD. Manifestations of the various types of hiatal hernia are difficult to distinguish. Symptoms include heartburn, regurgitation, dysphagia, and epigastric pain.[41] Ischemia from hernia strangulation causes acute, severe chest or epigastric pain, nausea, vomiting, and GI bleeding.

EVALUATION AND TREATMENT. Diagnostic procedures include chest x-ray with oral barium and endoscopy. A chest x-ray often will show the protrusion of the stomach into the thorax, indicating paraesophageal hiatal hernia.

Treatment for sliding hiatal hernia is usually conservative. The individual can diminish reflux by eating small, frequent meals and avoiding the recumbent position after eating. Abdominal supports and tight clothing are avoided, and weight control is recommended for obese individuals. Antacids alleviate reflux esophagitis. Drugs that relax the LES (anticholinergic, nitrates, calcium channel blockers) are contraindicated because they delay gastric emptying. Laparoscopic surgery (i.e., fundoplication) may be performed for paraesophageal hiatal hernia or if medical management fails to control symptoms.[42]

Pyloric Obstruction

PATHOPHYSIOLOGY. **Pyloric obstruction (gastric outlet obstruction)** is the narrowing or blocking of the opening between the stomach and the duodenum. This condition can be congenital (i.e., infantile hypertrophic pyloric stenosis, see Chapter 42) or acquired. Acquired obstruction is caused by peptic ulcer disease or carcinoma near the pylorus. Duodenal ulcers are more likely than gastric ulcers to obstruct the pylorus. Ulceration causes obstruction resulting from inflammation, edema, spasm, fibrosis, or scarring. Tumors cause obstruction by growing into the pylorus.[43]

CLINICAL MANIFESTATIONS. Early in the course of pyloric obstruction, the individual experiences vague epigastric fullness, which becomes more distressing after eating and later in the day. Nausea and epigastric pain may occur as the muscles of the stomach contract in attempts to force chyme past the obstruction. These symptoms disappear when the chyme finally moves into the duodenum. As obstruction progresses anorexia develops sometimes accompanied by weight loss. Severe obstruction causes gastric distention and atony (lack of muscle tone and gastric motility). Gastric distention stimulates

gastric secretion, which increases the feeling of fullness. Rolling or jarring of the abdomen produces a sloshing sound called the *succussion splash.* At this stage, vomiting is a cardinal sign of obstruction. It is usually copious and occurs several hours after eating. The vomitus contains undigested food but no bile. Prolonged vomiting leads to dehydration, which is accompanied by a hypokalemic and hypochloremic metabolic alkalosis caused by the respective loss of gastric potassium and acid. Because food does not enter the intestine, stools are infrequent and small. Prolonged pyloric obstruction causes severe malnutrition and dehydration.

EVALUATION AND TREATMENT. Diagnosis is based on clinical manifestations, a history of peptic ulcer disease, and examination of residual gastric contents. Endoscopy for the purpose of biopsy is performed if gastric carcinoma is the suggested cause of pyloric obstruction. Barium studies are contraindicated because the barium may harden and be retained in the stomach.

Obstructions resulting from ulceration often resolve with conservative management. Gastric drainage is used to decompress the stomach and restore normal motility. Gastric secretions that contribute to inflammation and edema can be suppressed with proton pump inhibitors or histamine-2 (H2) receptor antagonists. Fluids and electrolytes (sodium chloride and potassium) are given intravenously to effect rehydration and correct hypochloremia, alkalosis, and hypokalemia (see Chapter 3). Severely malnourished individuals may require parenteral hyperalimentation (intravenous nutrition). Surgery or stenting may be required to treat gastric carcinoma or persistent obstruction caused by fibrosis and scarring.[44]

Intestinal Obstruction and Ileus

Intestinal obstruction can be caused by any condition that prevents the normal flow of chyme through the intestinal lumen or failure of normal intestinal motility in the absence of an obstructing lesion (ileus). The small intestine is more commonly obstructed because of its narrower lumen. Common causes of intestinal obstruction are summarized in Table 41-2. Criteria for classifying intestinal obstruction are summarized in Table 41-3. Intestinal obstruction is classified by cause as simple or functional. *Simple obstruction* is mechanical blockage of the lumen by a lesion and is the most common type of intestinal obstruction. **Paralytic ileus,** or *functional obstruction*, is a failure of motility after gastrointestinal or abdominal surgery. Anesthetic agents, local inflammatory reactions, use of opioid analgesia, and hyperactivity of the sympathetic nervous system contribute to postoperative ileus.

Simple obstruction of the small intestine from fibrous adhesions is the most common type of intestinal obstruction.[45] Acute obstructions usually have mechanical causes, such as adhesions or hernias (Figure 41-4). Chronic or partial obstructions are more often associated with tumors or inflammatory disorders, particularly of the large intestine. Intussusception is rare in adults compared with the more frequent occurrence in infants. The most common causes of large bowel obstruction are colorectal cancer, volvulus (twisting), and strictures related to diverticulitis. Common causes of intestinal obstruction in children are presented in Chapter 42.

PATHOPHYSIOLOGY. The consequences of intestinal obstruction are related to its onset and location, the length of intestinal tract proximal to the obstruction, and the presence and severity of ischemia. The major pathophysiologic alterations are presented in Figure 41-5. Postoperative paralytic ileus results from inhibitory neural reflexes associated with inflammatory mediators, and the influence of exogenous (meperidine) and endogenous opioids (endorphins) that affect the entire GI tract, including the stomach.[46,47] **Small intestine obstruction** leads to accumulation of fluid and gas inside the lumen proximal to the obstruction. Fluids accumulate from impaired water and electrolyte absorption and enhanced secretion with net movement of fluid from the vascular space to the intestinal lumen. Gas from swallowed air, and to a lesser extent from bacterial overgrowth, contributes to the distention. Distention begins almost immediately, as gases and fluids accumulate proximal to the obstruction. Distention decreases the intestine's ability to absorb water and electrolytes and increases the net secretion of these substances into the lumen. Within 24 hours, up to 8 L of fluid and electrolytes enters the lumen in the form of saliva, gastric juice, bile, pancreatic juice, and intestinal secretions. Copious vomiting or sequestration of fluids in the intestinal lumen prevents their reabsorption and produces severe fluid

TABLE 41-2 COMMON CAUSES OF INTESTINAL OBSTRUCTION

CAUSE	PATHOPHYSIOLOGY
Herniation	Protrusion of the intestine through a weakness in the abdominal muscles or through the inguinal ring
Intussusception	Telescoping of one part of the intestine into another; this usually causes strangulation of the blood supply; more common in the ileocecal area in infants 10 to 15 months of age than in adults
Torsion (volvulus)	Twisting of the intestine on its mesenteric pedicle, with occlusion of the blood supply; often associated with fibrous adhesions in the small intestine; occurs most often in the large intestine in older adults
Diverticulosis	Inflamed saccular herniations (diverticula) of the mucosa and submucosa through the tunica muscularis of the colon; diverticula are interspersed between thick, circular, fibrous bands; most common in obese individuals older than 60 years
Tumor	Tumor growth into the intestinal lumen; adenocarcinoma of the colon and rectum is the most common tumoral obstruction; most common in individuals older than 60 years
Paralytic (adynamic) ileus	Loss of peristaltic motor activity in the intestine; associated with abdominal surgery, peritonitis, hypokalemia, ischemic bowel, spinal trauma, pneumonia, neuropathies, or myopathies; affects small and large intestines
Fibrous adhesions	Peritoneal irritation from surgery or trauma leads to formation of fibrin and adhesions that attach to intestine, omentum, or peritoneum and can cause traction and obstruction; most common in small intestine

TABLE 41-3 **CLASSIFICATION OF INTESTINAL OBSTRUCTION**

CRITERIA FOR CLASSIFICATION	DEFINITION
Onset	
Acute	Sudden onset; often caused by torsion, intussusception, or herniation
Chronic	Protracted onset; more commonly from tumor growth or progressive formation of strictures
Extent of Obstruction	
Partial	Incomplete obstruction of intestinal lumen
Complete	Complete obstruction of intestinal lumen
Location of Obstructing Lesion	
Intrinsic	Obstruction develops within intestinal lumen; examples: luminal edema or hemorrhage, foreign bodies (gallstones), tumors, or intraluminal fibrosis
Extrinsic	Obstruction originates outside the intestine; examples: tumors, torsion, fibrosis, hernia, intussusception
Effects on Intestinal Wall	
Simple	Luminal obstruction without impairment of blood supply
Strangulated	Luminal obstruction with occlusion of blood supply
Closed loop	Obstruction at each end of a segment of the intestine
Causal Factors	
Mechanical	Blockage of the intestinal lumen by intrinsic or extrinsic lesions; usually treated surgically
Functional (paralytic ileus)	Paralysis of the intestinal musculature as a result of accidental or surgical trauma, peritonitis, electrolyte imbalances, or spasmolytic agents; usually treated medically

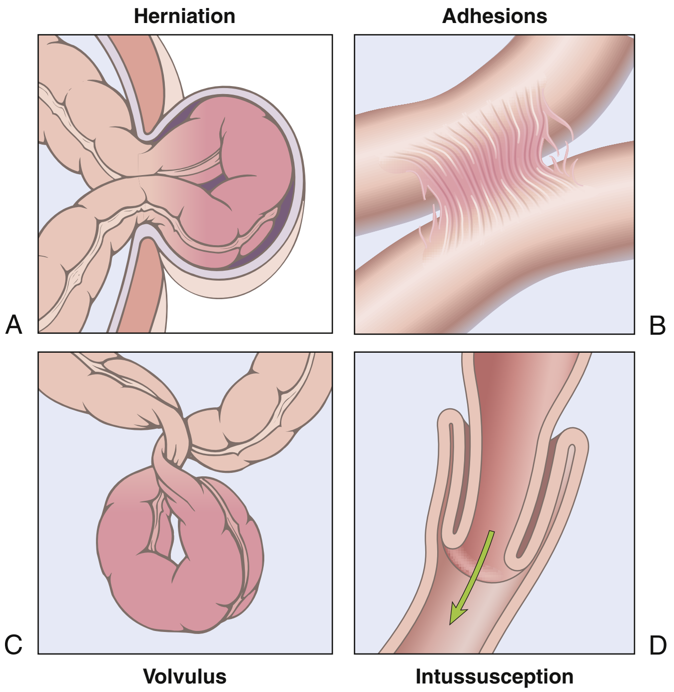

FIGURE 41-4 Intestinal Obstructions. **A,** Hernia. **B,** Constriction from adhesions. **C,** Volvulus. **D,** Intussusception. (From Kumar V, Abbas AK, Aster J: *Robbins basic pathology,* ed 9, Philadelphia, 2013, Saunders.)

and electrolyte disturbances. Extracellular fluid volume and plasma volume decrease, causing dehydration. Hemoconcentration (decreased plasma volume) elevates hematocrit level and causes hypotension and tachycardia. Severe dehydration leads to hypovolemic shock.

If the obstruction is at the pylorus or high in the small intestine, metabolic alkalosis develops initially as a result of excessive loss of hydrogen ions that normally would be reabsorbed from the gastric juice. With prolonged obstruction or obstruction lower in the intestine, metabolic acidosis is more likely to occur because bicarbonate from pancreatic secretions and bile cannot be reabsorbed. Hypokalemia from vomiting and decreased potassium absorption can be extreme, promoting acidosis and atony of the intestinal wall. Metabolic acidosis also may be accentuated by ketosis, the result of declining carbohydrate stores caused by starvation. Lack of circulation permits the buildup of significant amounts of lactic acid, which worsen the metabolic acidosis. If pressure from the distention is severe enough, it occludes the arterial circulation and causes ischemia, necrosis, perforation, and peritonitis. Fever and leukocytosis are often associated with overgrowth of bacteria, ischemia, and bowel necrosis. Bacterial proliferation and translocation across the mucosa to the mesenteric lymph nodes or systemic circulation cause sepsis. The release of inflammatory mediators into the circulation causes remote organ failure (see Chapter 48).

Consequences of **large bowel obstruction** are related to the competence of the ileocecal valve, which normally prevents reflux of colonic contents into the small intestine. When the ileocecal valve is competent, the cecum cannot decompress into the small intestine, resulting in distention. Ischemia occurs when the intraluminal pressure exceeds the capillary pressure in the lumen. **Acute colonic pseudo-obstruction** (Ogilvie syndrome) is a massive dilation of the large bowel that occurs in critically ill patients and immobilized older adults. It is characterized by significant dilation of the cecum and absence of mechanical obstruction, and is related to excessive sympathetic motor input or decreased parasympathetic motor input.

CLINICAL MANIFESTATIONS. Signs and symptoms of *small intestine obstruction* are consistent with the pathophysiology.

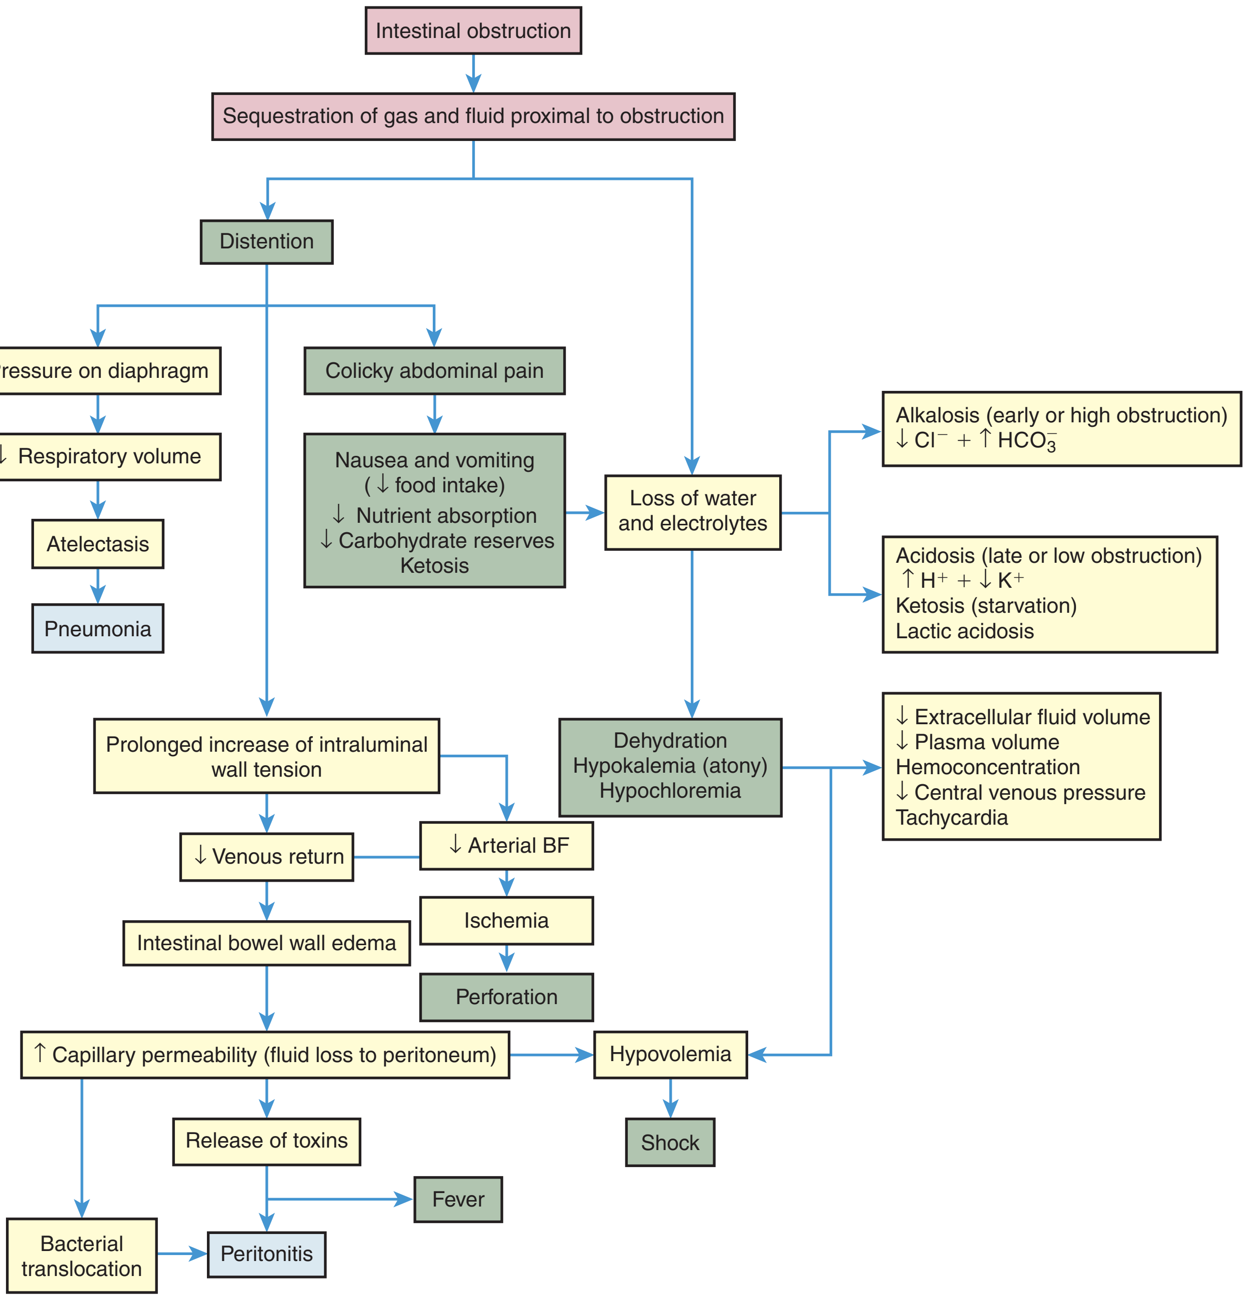

FIGURE 41-5 Pathophysiology of Intestinal Obstruction. *BF,* Blood flow.

Colicky pains caused by intestinal distention followed by nausea and vomiting are the cardinal symptoms. Typically the pain occurs intermittently. Pain intensifies for seconds or minutes as a peristaltic wave of muscle contraction meets the obstruction. The passing of the wave is followed by a pain-free interval. Pain may be continuous with severe distention and then diminish in intensity. If ischemia occurs, the pain loses its colicky character, becoming more constant and severe. Sweating and tachycardia occur as a sympathetic nervous system response to hypotension. Fever, severe leukocytosis, abdominal distention, and rebound tenderness develop as ischemia progresses to necrosis, perforation, and peritonitis.

Vomiting and abdominal distention vary, depending on the level and completion of the obstruction. Obstruction at the pylorus causes early, profuse vomiting of clear gastric fluid. Obstruction in the proximal small intestine causes mild distention and vomiting of bile-stained fluid. Obstruction in the distal small intestine causes more pronounced distention because a greater length of intestine is proximal to the obstruction. In this case, vomiting may not occur or may occur later and contain fecal material. Partial obstruction can cause diarrhea or constipation, but complete obstruction usually causes constipation only. Complete obstruction increases the number of bowel sounds, which may be tinkly and accompanied by peristaltic rushes and crampy, abdominal pain. Signs of hypovolemia and metabolic acidosis (see Chapter 3) may be observed as early as 24 hours after the occurrence of complete obstruction. Distention may be severe enough to push against the diaphragm and

decrease lung volume. This can lead to atelectasis and pneumonia, particularly in debilitated individuals.

Large intestine obstruction usually presents with hypogastric pain and abdominal distention. Pain can vary from vague to excruciating, depending on the degree of ischemia and the development of peritonitis.

EVALUATION AND TREATMENT. Evaluation is based on clinical manifestations and includes ultrasound and radiography.[48] Successful management requires early identification of the site and type of obstruction. Replacement of fluid and electrolytes and decompression of the lumen with gastric or intestinal suction are essential forms of therapy. Laparoscopic procedures can release adhesions. Immediate surgical intervention is required for strangulation and complete obstruction. Neostigmine, a parasympathomimetic, is used for colonic pseudo-obstruction and colonoscopic decompression may be required.[49]

Gastritis

Gastritis is an inflammatory disorder of the gastric mucosa. It can be acute or chronic and can affect the fundus or antrum, or both. Acute gastritis erodes the surface epithelium in a diffuse or localized pattern. The erosions are usually superficial.

Acute gastritis is usually caused by injury of the protective mucosal barrier by drugs, chemicals, or *Helicobacter pylori* infection (Figure 41-6). Nonsteroidal anti-inflammatory drugs (NSAIDs [ibuprofen, naproxen, indomethacin, and aspirin]) inhibit the action of cyclooxygenase-1 (COX-1), and are known to cause erosive gastritis because they inhibit prostaglandins, which normally stimulate the secretion of mucus and suppress inflammation. With the exception of aspirin, NSAIDs also cause gastric hypermotility, causing mucosal compression and injury.[50] Alcohol, histamine, digitalis, and metabolic disorders such as uremia are contributing factors. *H. pylori*–associated acute gastritis causes inflammation, increased gastric secretion in antral gastritis, decreased gastric section in fundal gastritis, pain, nausea, and vomiting[51] (Box 41-1).

The clinical manifestations of acute gastritis can include vague abdominal discomfort, epigastric tenderness, and bleeding. Healing usually occurs spontaneously within a few days. Discontinuing injurious drugs, using antacids, or decreasing acid secretion with a histamine H2-receptor antagonist and proton pump inhibitor also promote healing.

Chronic gastritis tends to occur in older adults and causes chronic inflammation, mucosal atrophy, and epithelial metaplasia. Chronic gastritis usually is classified as type A, or immune (fundal), or type B, nonimmune (antral), depending on the pathogenesis and location of the lesions. Both types of chronic gastritis can occur and is known as type AB, or pangastritis, with the antrum being more severely involved.

Chronic fundal gastritis is the most rare and severe type and is associated with loss of T-cell tolerance and development

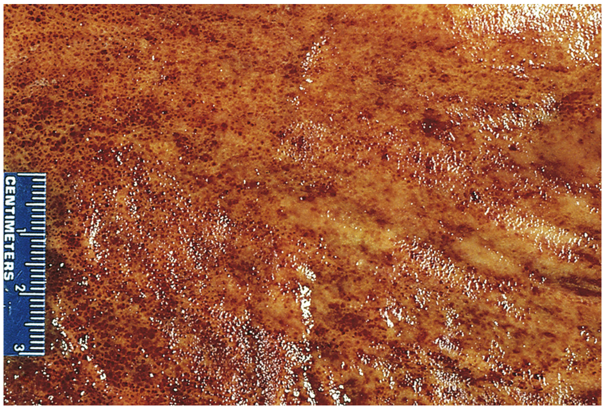

FIGURE 41-6 Acute Erosive Gastritis. Acute erosive gastritis is shown in the opened stomach. The mucosa appears hyperemic, and the foci of superficial ulceration are manifested as scattered, small, red areas termed erosions. (From Kumar V et al: *Pathologic basis of disease,* ed 7, Philadelphia, 2006, Saunders.)

BOX 41-1 PATHOGENESIS OF *Helicobacter pylori*–RELATED DISEASE

H. pylori is a gram-negative spiral bacterium with a flagella and is a major cause of acute and chronic gastritis, peptic ulcer disease in the duodenum and stomach, gastric adenocarcinoma, and gastric mucosa–associated lymphoid tissue (MALT) (see p. 1467) in about 20% of infected individuals. *H. pylori* is transmitted through the fecal-oral route and is usually acquired in childhood. Infection is asymptomatic in about 70% of cases. In other cases, inflammation and immune responses promote mucosal ulcerations or prevent healing of injured tissue. Gene-environment interaction and different pathogenic strains of *H. pylori* increase risk for disease. Patterns of gastritis and disease progression vary by site of infection and strain of *H. pylori*. Pathogenic and virulence factors include the following:

1. An ability to colonize and adhere to gastric epithelial cells
2. The possession of flagella that allows movement through the luminal mucous layer to a site of higher pH
3. An ability of adherent strains to suppress acid secretion to improve their survival, particularly *CagA* and *VacA*
4. Secretion of urease that produces ammonia and carbon dioxide, resulting in a more alkaline environment
5. Release of vacuolating cytotoxin *(VacA)* that promotes bacterial survival and causes epithelial injury
6. The presence of cytotoxin-associated gene *(CagA)* strains that can escape normal immune responses and cause inflammation with release of inflammatory cytokines and reactive oxygen metabolites that damage mucosal epithelial cells and cause loss of the protective mucosal barrier; they also promote tumor development by degrading *p53* tumor suppression
7. Recruitment and activation of neutrophils, macrophages, and mast cells with release of inflammatory cytokines (tumor necrosis factor-alpha [TNF-α], interleukin-1 [IL-1], IL-6, IL-8, histamine) that promote cellular injury
8. Down-regulation of antral somatostatin leading to increased gastrin, increased acid, impaired mucosal bicarbonate production, and increased mucosal exposure to acid and pepsin
9. Activation or inhibition of T- and B-cell immune responses that may contribute to mucosal injury
10. Release of cytokines and chemokines that promote gastric epithelial cell death (apoptosis) and cell proliferation that can result in atrophy, ulcers, or malignant growth

Data from Costa AM et al: *FEBS Lett* 587(3):259–265, 2013; Peek RM Jr, Fiske C, Wilson KT: *Physiol Rev* 90(3):831–858, 2010; Ruggiero P: *Curr Opin Infect Dis* 25(3):337–344, 2012; Suzuki R, Shiota S, Yamaoka Y: *Infect Genet Evol* 12(2):203–213, 2012; Varbanova M, Malfertheiner P: *Dig Dis* 29(6):592–599, 2011.

of autoantibodies to gastric H^+-K^+ ATPase. Infection with *H. pylori* can trigger the immune response through molecular mimicry.[52] The gastric mucosa degenerates extensively in the body and fundus of the stomach, leading to gastric atrophy. Loss of parietal cells diminishes secretion of hydrochloric acid and intrinsic factor. Because acid secretion is insufficient, the feedback mechanism that normally inhibits gastrin secretion is impaired, causing elevated plasma levels of gastrin. *Chronic antral gastritis* generally involves the antrum only and is more common than fundal gastritis. It is caused by *H. pylori* bacteria or chronic use of alcohol, tobacco, and nonsteroidal anti-inflammatory drugs. There are high levels of hydrochloric acid secretion with an increased risk of duodenal ulcers. *H. pylori* can also progress to autoimmune atrophic gastritis and involve the fundus, thus becoming pangastritis. In these cases there is greater risk for the development of gastric cancer.[53]

Signs and symptoms of chronic gastritis often do not correlate with the severity of the disease. Gastroscopic examination and biopsy may show a long-standing inflammatory process and gastric atrophy in an individual with no history of abdominal distress. The presence of antiparietal cell antibody and elevated plasma ghrelin level are specific for atrophic gastritis.[54]

H. pylori infection is evidence for *H. pylori* gastritis. In chronic fundal gastritis, failure to stimulate acid secretion confirms achlorhydria (diminished secretion of hydrochloric acid). The gastric secretions also can be evaluated for the presence of intrinsic factor. Pernicious anemia can develop because intrinsic factor is less available to facilitate vitamin B_{12} absorption. Individuals may report vague symptoms, including anorexia, fullness, nausea, vomiting, and epigastric pain. Gastric bleeding may be the only clinical manifestation of gastritis. Evaluation for gastric carcinoma is completed with chronic *H. pylori* infection.[55] Symptoms can usually be managed with consumption of smaller meals, including a soft, bland diet; and avoidance of alcohol and NSAIDs. Combination antibiotics are used to treat *H. pylori,* and the emergence of antimicrobial resistance is a concern.[56] Vitamin B_{12} is administered to correct pernicious anemia (see Chapter 28).[57]

Alkaline reflux gastritis is a stomach inflammation caused by reflux of bile and alkaline pancreatic secretions that contain proteolytic enzymes and disrupt the mucosal barrier in the remnant stomach. This form of gastritis occurs in 5% to 20% of individuals who have undergone gastrectomy or pyloroplasty. Clinical manifestations include nausea, bilious vomiting (vomiting in which the vomitus contains bile), and sustained epigastric pain that worsens after eating and is not relieved by antacids. Endoscopy shows a hemorrhagic and friable gastric mucosa. Antacids do not consistently improve symptoms. Avoidance of aspirin and alcohol may decrease gastric irritation, and a low-fat diet may limit bile secretion. Surgical correction may ultimately be required.[58]

Peptic Ulcer Disease

A **peptic ulcer** is a break, or ulceration, in the protective mucosal lining of the lower esophagus, stomach, or duodenum. It is estimated that 10% to 17% of the population have peptic ulcer disease; however, the true incidence is unkown.[59]

Risk factors for peptic ulcer disease include genetic predisposition, *H. pylori* infection of the gastric mucosa (see Box 41-1), and habitual use of NSAIDs. Additional factors include excessive use of alcohol, smoking, acute pancreatitis, chronic obstructive pulmonary disease, obesity, cirrhosis, and age greater than 65 years.[60,61] Psychologic stress may be a risk factor for peptic ulcer disease but the exact mechanism of causation is not known.[62,63]

Peptic ulcers can be acute or chronic, and superficial or deep. Superficial ulcerations are called *erosions* because they erode the mucosa but do not penetrate the muscularis mucosae (Figure 41-7). True ulcers extend through the muscularis mucosae and damage blood vessels, causing hemorrhage or perforating the gastrointestinal wall.

Chronic use of NSAIDs suppresses mucosal prostaglandin synthesis, resulting in decreased bicarbonate secretion and mucin (a component of the gut barrier) production and increased secretion of hydrochloric acid. The interaction of NSAIDs and *H. pylori* can contribute to the pathogenesis of peptic ulcer.[64] Disruption of the mucosa exposes submucosal areas to gastric secretions and autodigestion causing erosion and ulceration.

Duodenal Ulcers

Duodenal ulcers occur with greater frequency than other types of peptic ulcers. Idiopathic duodenal ulcers are rare and can be associated with altered mucosal defenses, rapid gastric emptying, elevated serum gastrin levels, or acid production stimulated by smoking.

PATHOPHYSIOLOGY. Causative factors, singly or in combination, cause acid and pepsin concentrations in the duodenum to penetrate the mucosal barrier and lead to ulceration[65] (Figure 41-8).

CLINICAL MANIFESTATIONS. The characteristic manifestation of a duodenal ulcer is chronic intermittent pain in the epigastric area. The pain begins 30 minutes to 2 hours after eating, when the stomach is empty. It is not unusual for pain to occur in the middle of the night and disappear by morning. The pain results from sensorineural stimulation by acid or muscle spasm, or both. Pain is relieved rapidly by ingestion of food or antacids, creating

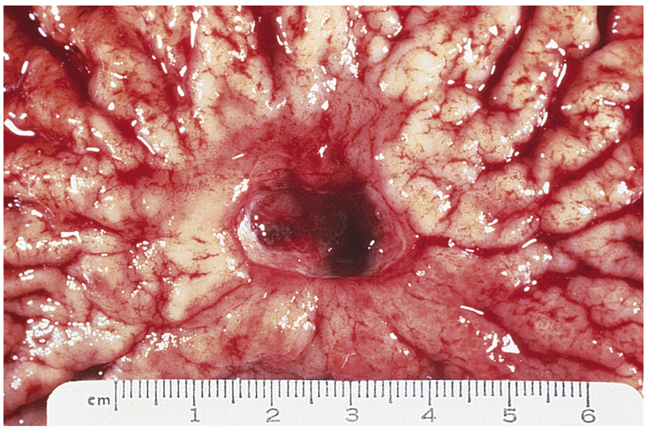

FIGURE 41-7 Chronic Peptic Ulcer. Gross photograph of a chronic peptic ulcer located in the lesser curvature, straddling the antrum and corpus of the stomach. (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

TABLE 41-4 **CHARACTERISTICS OF GASTRIC AND DUODENAL ULCERS**

CHARACTERISTICS	GASTRIC ULCER	DUODENAL ULCER
Incidence		
Age at onset	50-70 years	20-50 years
Family history	Usually negative	Positive
Gender (prevalence)	Equal in women and men	Equal in women and men
Stress factors	Increased	Average
Ulcerogenic drugs	Normal use	Increased use
Cancer risk	Increased	Not increased
Pathophysiology		
Helicobacter pylori infection	Often present (60-80%)	Often present (95-100%)
Abnormal mucus	May be present	May be present
Parietal cell mass	Normal or decreased	Increased
Acid production	Normal or decreased	Increased
Serum gastrin	Increased	Normal
Serum pepsinogen	Normal	Increased
Associated gastritis	More common	Usually not present
Clinical Manifestations		
Pain	Located in upper abdomen Intermittent Pain-antacid-relief pattern Food-pain pattern	Located in upper abdomen Intermittent Pain-antacid or food-relief pattern Nocturnal pain common
Clinical course	Chronic ulcer without pattern of remission and exacerbation	Pattern of remissions and exacerbations for years

a typical "pain-food-relief" pattern. Some individuals with duodenal ulcer have no symptoms, particularly older adults; the first manifestation may be hemorrhage or perforation, particularly with a history of NSAID or anticoagulant use. Healing is accompanied by relief of pain. Constant, unremitting pain may be caused by complications, such as intestinal obstruction or perforation. Bleeding from duodenal ulcers causes hematemesis or melena. It is not clear why individuals infected with *H. pylori* duodenal ulcers are negatively associated with gastric cancer.[66]

EVALUATION AND TREATMENT. Several diagnostic approaches are used to differentiate duodenal ulcers from gastric ulcers or gastric carcinoma. Endoscopic evaluation allows visualization of lesions and biopsy. Radioimmune assays of gastrin levels are evaluated to identify ulcers associated with gastric carcinomas. A urea breath test; measurement of levels of serum antibodies, stool, and serum antigen; and findings from gastric biopsy are used to detect *H. pylori* infection.[67]

Management of duodenal ulcers is aimed at relieving the causes and effects of hyperacidity and preventing complications. Antacids neutralize gastric contents, elevate pH, inactivate pepsin, relieve pain, and are cytoprotective.[67a] Acid secretion can be suppressed with drugs that block H2 receptors and inhibit the secretion of acid. Proton pump inhibitors inhibit acid production. Eradication of *H. pylori* with bismuth and combinations of antibiotics supplemented with vitamin C usually prevents relapse, although there is increasing drug resistance.[68,69] Ulcer-coating agents, such as sucralfate and colloidal bismuth, promote healing. Anticholinergic drugs may be used to inhibit gastric secretion, suppress gastric motility, and delay gastric emptying. Surgical resection may be required for complications including bleeding, perforation, obstruction, or peritonitis.[70] Risk of duodenal ulcer may be reduced with a diet high in vitamin A and fiber.[71] Development of a vaccine against *H. pylori* is progressing slowly.[72]

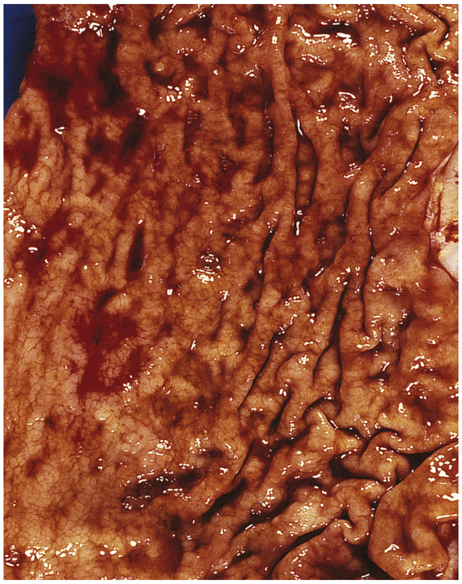

FIGURE 41-9 Macroscopic Appearance of Benign Gastric Ulcers. (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

Gastric Ulcers

Gastric ulcers are ulcers of the stomach. They usually occur between the ages of 55 and 65 years, and are about one fourth as common as duodenal ulcers (Table 41-4 and Figure 41-9).

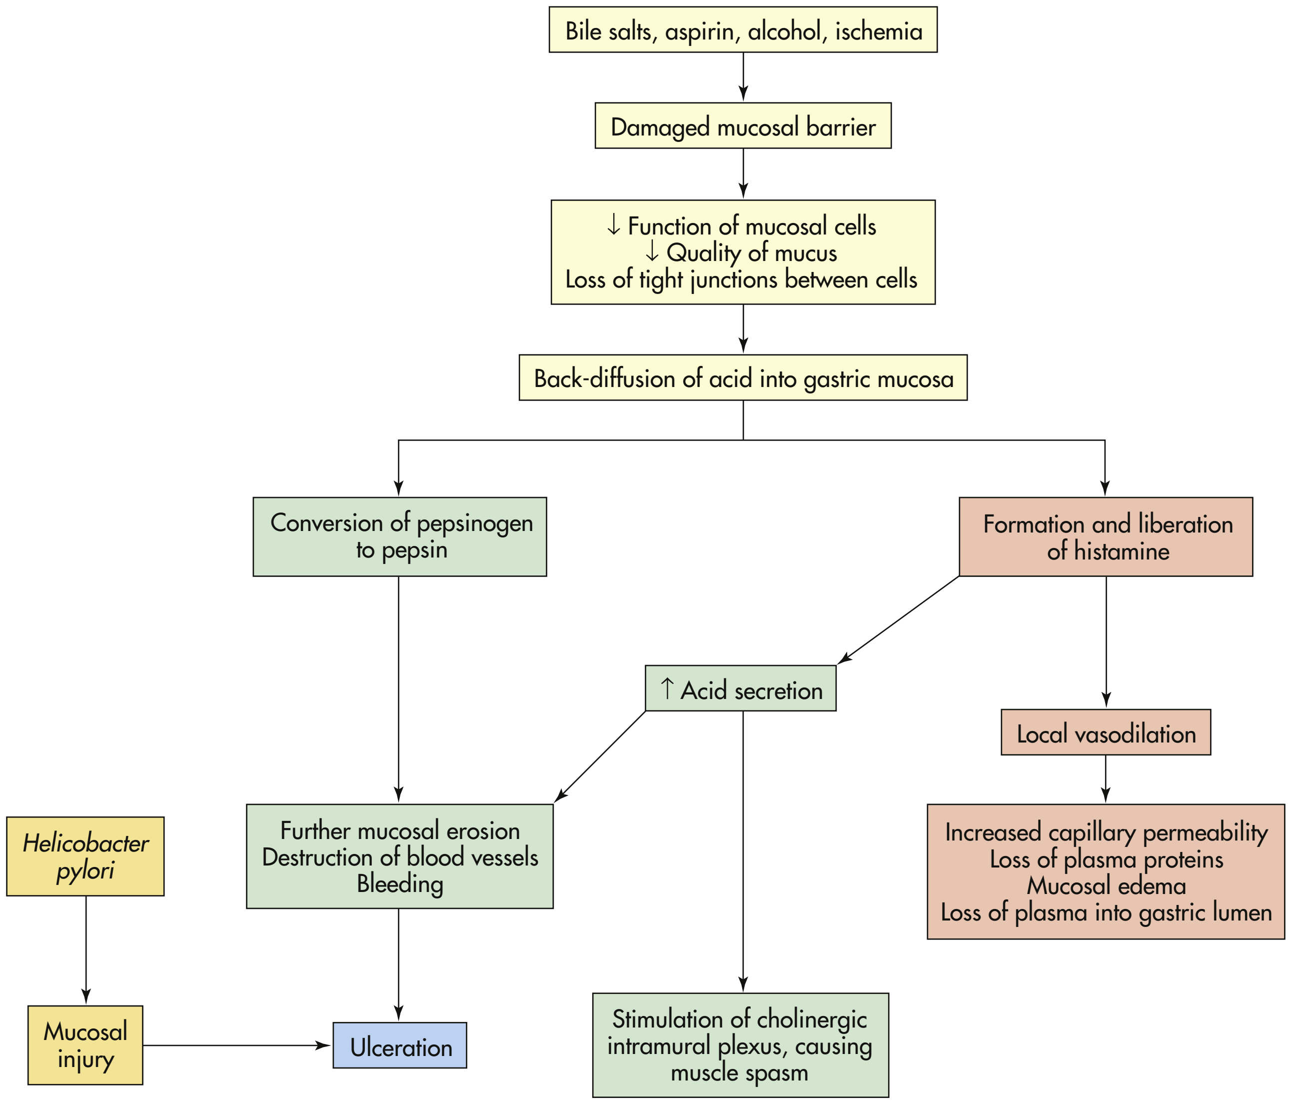

FIGURE 41-10 Pathophysiology of Gastric Ulcer Formation.

PATHOPHYSIOLOGY. Generally gastric ulcers develop in the antral region, adjacent to the acid-secreting mucosa of the body, and are frequently caused by *H. pylori* (see Box 41-1). The primary defect is an abnormality that increases the mucosal barrier's permeability to hydrogen ions. Gastric secretion may be normal or less than normal and there may be a decreased mass of parietal cells. Chronic pangastritis is often associated with development of gastric ulcers and may precipitate ulcer formation by limiting the mucosa's ability to secrete a protective layer of mucus (Figure 41-10).[73]

Duodenal reflux of bile is associated with gastric ulcer (alkaline reflux gastritis, p. 1435) and may occur after cholecystectomy, pyloroplasty, or gastrojejunostomy. The pyloric sphincter also may fail to respond to stimuli that normally increase resting tone, such as entry of acid, protein, and fat into the duodenum, allowing reflux of bile and pancreatic enzymes to damage the gastric mucosa. The damaged mucosal barrier permits hydrogen ions to diffuse into the mucosa, where they disrupt permeability and cellular structure. A vicious cycle can be established as the damaged mucosa liberates histamine, which stimulates the increase of acid and pepsinogen production, blood flow, and capillary permeability. The disrupted mucosa becomes edematous and loses plasma proteins. Destruction of small vessels causes bleeding.

Zollinger-Ellison syndrome is associated with peptic ulcers related to increased secretion of gastrin, which causes excess secretion of gastric acid. A gastrinoma (a gastrin-secreting neuroendocrine tumor or multiple tumors) of the pancreas or duodenum stimulates a proliferation of gastric parietal cells and chronic secretion of gastric acid. The resulting excess acid causes gastric and duodenal ulcers, gastroesophageal reflux with abdominal pain, and diarrhea. Diagnosis includes secretin- or calcium-stimulated measures of gastrin levels, gastric pH levels less than 2, and symptomatic evidence of peptic ulcer disease. Proton pump inhibitors reduce gastric acid secretion, and surgical removal of tumors limits metastasis.[74,75]

CLINICAL MANIFESTATIONS. The clinical manifestations of gastric ulcers are similar to those of duodenal ulcers (see Table 41-4). The pattern of pain, food, and relief is common, but the pain of gastric ulcers also occurs immediately after eating. Gastric ulcers

also tend to be chronic rather than alternate between periods of remission and exacerbation and cause more anorexia, vomiting, and weight loss than duodenal ulcers.

EVALUATION AND TREATMENT. The evaluation and treatment of gastric ulcers are similar to the evaluation and treatment of duodenal ulcers (see p. 1437).

Stress-Related Mucosal Disease

A **stress ulcer (stress-related mucosal disease)** is an acute form of peptic ulcer that tends to accompany the physiologic stress of severe illness; multisystem organ failure; or major trauma, including severe burns or head injury. Usually, multiple sites of ulceration are distributed within the stomach or duodenum. Stress ulcers may be classified as ischemic ulcers or Cushing ulcers.

Ischemic ulcers develop within hours of an event—such as hemorrhage, multisystem trauma, severe burns, heart failure, or sepsis—that causes ischemia of the stomach and duodenal mucosa. Stress ulcers that develop as a result of burn injury are often called **Curling ulcers.**

Cushing ulcer is a stress ulcer associated with severe head trauma or brain surgery. This ulcer results from decreased mucosal blood flow and hypersecretion of acid caused by overstimulation of the vagal nuclei. Excessive acid damages the mucosal barrier, initiating the processes summarized in Figure 41-10.

The primary clinical manifestation of stress-related mucosal disease is bleeding that occurs more readily with the presence of coagulopathy.[76] Other symptoms may not be present. The bleeding may be slight or, if a small vessel is perforated, amount to hundreds of milliliters. Prophylactic treatment regimens are used to prevent this disease.[77,78] Stress ulcers seldom become chronic.

Surgical Treatment of Ulcer

Advances in the medical treatment of peptic ulcer disease with proton pump inhibitors and eradication of *H. pylori,* and laparoscopic and endoscopic repair techniques have significantly reduced the number of cases requiring open surgery.[79] The indications for ulcer surgery are recurrent or uncontrolled bleeding and complicated perforation of the stomach or duodenum.[80]

Weight loss often follows gastric resection but stabilizes within 3 months. Inadequate food intake is a common cause because many individuals cannot tolerate the osmotic effect of carbohydrates or a normal-size meal. Foods may be poorly absorbed because the stomach is less able to mix, churn, and break down food particles. Abdominal pain, vomiting, diarrhea, and malabsorption of fats also contribute to weight loss. In the case of bariatric surgery for extreme obesity, weight loss is the intended outcome.

Acute complications of gastrectomy or anastomosis, such as poor wound healing, abscess formation, or suture failure, are relatively uncommon except in the debilitated person. Chronic complications, however, occur more often and are likely to develop if a large portion of the stomach has been removed. These complications and their pathophysiologic mechanisms are described in the next section.

Postgastrectomy Syndromes

Postgastrectomy syndromes are a group of signs and symptoms that occur after gastric resection. They are caused by changes in motor and control functions of the stomach and upper small intestine.[81]

Malabsorption Syndromes

Malabsorption syndromes interfere with nutrient absorption. Historically malabsorption disorders have been classified as maldigestion or malabsorption. **Maldigestion** is failure of the chemical processes of digestion that take place in the intestinal lumen or at the brush border of the intestinal mucosa of the small intestine. **Malabsorption** is the failure of the intestinal mucosa to absorb (transport) the digested nutrients. Often maldigestion and malabsorption are interrelated or occur together, making classification difficult. Generally, however, maldigestion is caused by deficiencies of enzymes, such as pancreatic lipase or intestinal lactase, which are necessary for digestion. Inadequate secretion of bile salts and inadequate reabsorption of bile in the ileum also contribute to maldigestion. Malabsorption is the result of mucosal disruption caused by gastric or intestinal resection, vascular disorders, or intestinal disease.

Pancreatic Insufficiency

The pancreatic enzymes (lipase, amylase, trypsin, chymotrypsin) are required for the digestion of proteins, carbohydrates, and fats. **Pancreatic insufficiency** is the deficient production of these enzymes by the pancreas. Causes of pancreatic insufficiency include chronic pancreatitis, pancreatic carcinoma, pancreatic resection, and cystic fibrosis. Significant damage to or loss of pancreatic tissue must occur before enzyme levels decrease sufficiently to cause maldigestion. Although pancreatic insufficiency causes poor digestion of all nutrients, fat maldigestion is the chief problem. Salivary amylase and enzymes secreted by the intestinal brush border assist in carbohydrate and protein digestion, but these enzymes do not digest fats. Absence of pancreatic bicarbonate in the duodenum and jejunum causes an acidic pH that worsens maldigestion by preventing activation of pancreatic enzymes that are present. A large amount of fat in the stool (steatorrhea) and weight loss are the most common signs of pancreatic insufficiency. Lipase supplementation is usually successful.[82]

Lactase Deficiency

Deficiency of disaccharidase at the villus brush border of the small intestine is caused by a congenital defect in the lactase gene. **Lactase deficiency** inhibits the breakdown of lactose (milk sugar) into monosaccharides and therefore prevents lactose digestion and absorption across the intestinal wall. Lactase deficiency is most common in blacks. Congenital lactase deficiency causes watery diarrhea in breast milk or lactose-containing formulas in infants. Lactase expression is lost before adulthood in adult-type lactose intolerance.[83] Secondary (acquired) lactase deficiency can be caused by several diseases of the intestine, including gluten-sensitive enteropathy (see Chapter 42), enteritis, and bacterial overgrowth.

The undigested lactose remains in the intestine, where bacterial fermentation causes gases to form. Undigested lactose also increases the osmotic gradient in the intestine, causing irritation and osmotic diarrhea. Clinical manifestations of lactose consumption with lactase deficiency are bloating, crampy pain, diarrhea, and flatulence. The disorder is diagnosed by genetic testing, a lactose-hydrogen breath test, dietary lactose withdrawal, or rarely small intestinal biopsy.[84] Avoiding milk products and adhering to a lactose-free diet relieve symptoms. Maintaining an adequate calcium intake with restricted intake of milk products decreases risk of osteoporosis.

Bile Salt Deficiency

Conjugated bile acids (bile salts) are necessary for the digestion and absorption of fats. Bile salts are conjugated in the bile that is synthesized from cholesterol and secreted from the liver.[85] When bile enters the duodenum, the bile salts aggregate with fatty acids and monoglycerides to form micelles. Micelle formation makes fat molecules more soluble and allows them to pass through the unstirred layer at the brush border of the small intestinal villi (see Chapter 40). A minimum concentration of bile salts, termed the *critical micelle concentration,* is required to allow micelles to form. Therefore, conditions that decrease the production or secretion of bile result in decreased micelle formation and fat malabsorption. These conditions include advanced liver disease, which decreases production of bile salts; obstruction of the common bile duct, which decreases flow of bile into the duodenum; intestinal stasis (lack of motility), which permits overgrowth of intestinal bacteria that deconjugate bile salts; and diseases of the ileum, which prevent the reabsorption and recycling of bile salts (enterohepatic circulation).[86]

Clinical manifestations of bile salt deficiency are related to poor intestinal absorption of fat and fat-soluble vitamins (A, D, E, and K). Increased fat in the stools (steatorrhea) leads to diarrhea and decreased plasma proteins. The losses of fat-soluble vitamins and their effects include the following:

1. Vitamin A deficiency results in night blindness.
2. Vitamin D deficiency results in decreased calcium absorption with bone demineralization (osteoporosis), bone pain, and fractures.
3. Vitamin K deficiency prolongs prothrombin time, leading to spontaneous development of purpura (bruising) and petechiae.
4. Vitamin E deficiency has uncertain effects but may cause testicular atrophy and neurologic defects in children.

The most effective treatment for fat-soluble vitamin deficiency is to increase the amount of medium-chain triglycerides in the diet, for example, by using coconut oil for cooking. Vitamins A, D, and K are given parenterally.

Dumping Syndrome

Dumping syndrome is the rapid emptying of hypertonic chyme from the surgically created, residual stomach into the small intestine 10 to 20 minutes after eating (early dumping syndrome). It occurs with varying severity in 5% to 10% of individuals who have undergone partial gastrectomy, bariatric surgical procedures, or pyloroplasty.[81,87] It is not as common in individuals who have undergone a Billroth II anastomosis (gastrojejunostomy) accompanied by vagotomy. Factors that promote *early dumping syndrome* include: (1) loss of gastric capacity, (2) loss of emptying control when the pylorus is removed, and (3) loss of feedback control by the duodenum when it is removed. Rapid gastric emptying and creation of a nonphysiologic, high osmotic gradient within the small intestine cause a sudden shift of fluid from the vascular compartment to the intestinal lumen. Plasma volume decreases, causing vasomotor responses, such as increased pulse rate, hypotension, weakness, pallor, sweating, and dizziness. Rapid distention of the intestine produces a feeling of epigastric fullness, cramping, nausea, and vomiting. Diarrhea can accompany dumping syndrome or occur as a solitary symptom. Diarrhea can occur as frequent, persistent elimination of liquid stool or as intermittent, precipitous, and unpredictable elimination of a large volume of stool. Both types can be either mild or severe.

A less common form of dumping syndrome, *late dumping syndrome* occurs 1 to 3 hours after eating. The symptoms include weakness, diaphoresis, and confusion but they cannot be explained by rapid gastric emptying. After a high-carbohydrate meal, individuals who have undergone gastrectomy may develop hypoglycemia, which causes the symptoms. The hypoglycemia is caused by an increase in insulin secretion stimulated by the hyperglycemia that follows eating. Other hormonal responses also may participate in the development of hypoglycemia.

Most cases of dumping syndrome respond well to dietary management.[88] Frequent small meals that are high in protein and low in carbohydrates relieve symptoms. Other measures include drinking fluids between meals instead of at mealtime and reclining on the left side after eating. Some cases require surgical intervention, including reconstruction of the pylorus or a gastrojejunostomy. Octreotide reduces abdominal and vasomotor symptoms of dumping syndrome by inhibiting insulin and gut hormone release, slowing intestinal transit time, and inhibiting food-induced circulatory changes.[89]

Inflammatory Bowel Disease

Ulcerative colitis and Crohn disease are chronic, relapsing inflammatory bowel diseases (IBDs) of unknown origin. The incidence of IBD is increasing around the world and varies from 3 to 300 per 100,000 persons.[90] Both diseases are associated with genetic factors, alterations in epithelial cell barrier functions, immunopathology related to abnormal T-cell reactions to commensal microflora and other luminal antigens, and varying phenotypes.[91] **Microscopic colitis** is increasing in prevalence and is reviewed in What's New? Microscopic Colitis.

Ulcerative Colitis

Ulcerative colitis (UC) is a chronic inflammatory disease that causes ulceration of the colonic mucosa and extends proximally from the rectum into the colon (Figure 41-11). The lesions appear in susceptible individuals between 20 and 40 years of age. Risk factors include family history of disease or Jewish descent, and the disease is more prevalent among white populations and Northern Europeans. UC is less common in smokers.[92]

Although the cause of UC is unknown, dietary, infectious, genetic, and immunologic factors are all suggested causes.[93] Inflammation may be caused by commensal or pathogenic enteric microorganisms with increased mucosal adherence and invasion and persistent activation of T cells. The familial tendency to develop ulcerative colitis and the occurrence of disease in identical twins support a genetic theory of causation. Perhaps most significant are the humoral and cellular immunologic factors associated with the disease. Colonic epithelial antibodies of the immunoglobulin G (IgG) class have been identified in the sera of individuals with ulcerative colitis and a large number of plasma cells are found in the inflamed colon. Lymphocytes (T cells) in individuals with ulcerative colitis may have cytotoxic effects on the epithelial cells of the colon, as well as damage caused by inflammatory cytokines (interleukin-1 [IL-1], IL-2, IL-6, IL-8, IL-10, tumor necrosis factor-alpha [TNF-α]), toxic oxygen free radicals, and interferon-gamma (IFN-γ).[94] Furthermore, autoimmune disorders, such as systemic lupus erythematosus and erythema nodosum, may accompany ulcerative colitis.

WHAT'S NEW?

Microscopic Colitis

Microscopic colitis is a relatively common cause of diarrhea and occurs primarily in females and older adults. There are two histologic forms: lymphocytic and collagenous. The symptoms of frequent chronic daily watery diarrhea are the same for both types and can be accompanied by abdominal pain and weight loss. The cause is unknown and the prevalence is increasing. There are associations with numerous drugs and celiac disease. Autoantibodies have been found in some individuals including intestinal goblet cells, antinuclear antibodies (ANAs), antineutrophil cytoplasmic antibodies, and anti–*Saccharomyces cerevisiae* antibody (ASCA). The colon mucosa appears normal on endoscopy. Biopsy reveals histopathologic descriptions. Lymphocytic colitis shows an increase in intraepithelial lymphocytes of more than 20 lymphocytes per 100 surface colonocytes. Collagenous colitis is characterized by a thickened subepithelial collagen layer of more than 10 μm, alteration of the vascular mucosal pattern, and mucosal nodularity. Antidiarrheal agents and budesonide (an anti-inflammatory steroid) are the best documented short-term treatments and new immunosuppressive agents are being evaluated. An optimal long-term strategy is yet to be identified. The disease is negatively associated with colorectal cancer.

Data from Gentile NM et al: *Am J Gastroenterol* 108(2):256–259, 2013; Ianiro G et al: *World J Gastroenterol* 18(43):6206–6215, 2012; Koulaouzidis A, Saeed AA: *World J Gastroenterol* 17(37):4157–4165, 2011; Mahajan D et al: *Adv Anat Pathol* 19(1):28–38, 2012; Yen EF et al: *Dig Dis Sci* 57(1):161–169, 2012.

PATHOPHYSIOLOGY. The primary lesions of UC are continuous with no skip lesions, are limited to the mucosa, and are not transmural. The mucous layer is thinner than normal and there is impairment of the epithelial barrier. The rectum is almost always involved. Inflammation begins at the base of the crypt of Lieberkühn in the large intestine, primarily the left colon, with infiltration and release of inflammatory cytokines from neutrophils, lymphocytes, plasma cells, macrophages, eosinophils, and mast cells. Activated macrophages also contribute cytokines that cause fever and the acute phase response. The inflammation damages the epithelial mucosal barrier with leak of fluids into the gut.[95] The disease is most severe in the rectum and sigmoid colon. With milder inflammation, the mucosa is hyperemic and edematous, and may appear dark red and velvety (Figure 41-12). In more severe inflammation, the mucosa becomes hemorrhagic, and small erosions form and coalesce into ulcers. Abscess formation occurs in the crypts. Necrosis and ragged ulceration of the mucosa ensue. Edema and thickening of the muscularis mucosae may narrow the lumen of the involved colon. In chronic disease, inflammatory polyps (pseudopolyps) develop in the colon from rapidly regenerating epithelium.

CLINICAL MANIFESTATIONS. The course of UC consists of intermittent periods of remission and exacerbation. Clinical

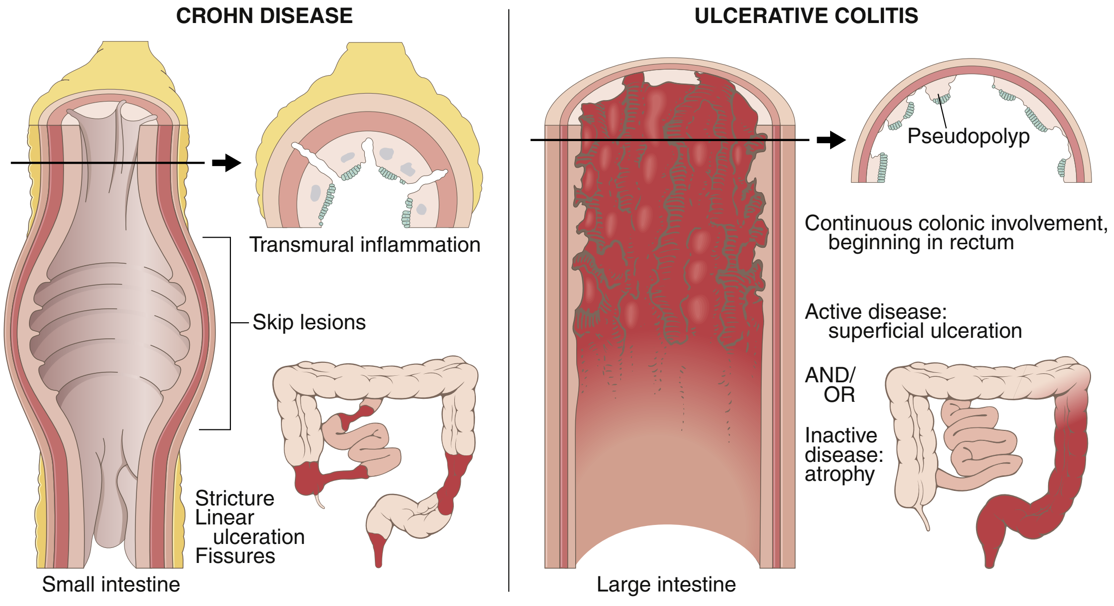

FIGURE 41-11 **Distribution Patterns of Crohn Disease and Ulcerative Colitis.** Comparison of distribution patterns of Crohn disease and ulcerative colitis as well as different conformations of ulcers and wall thickenings. (From Kumar V et al: *Robbins basic pathology,* ed 8, St Louis, 2008, Mosby.)

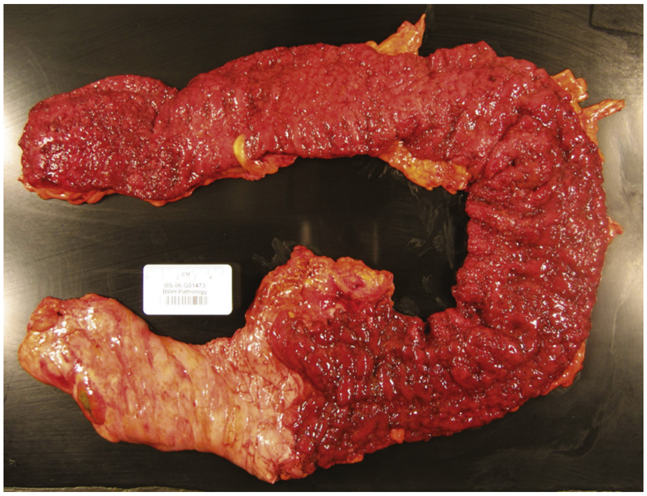

FIGURE 41-12 Acute Ulcerative Colitis. A gross specimen of subtotal ulcerative colitis showing diffuse continuous disease starting from the distal rectum and continuing up to the midportion of the ascending colon. (From Odze RD, Goldblum JR, editors: *Surgical pathology of the GI tract, liver, biliary tract, and pancreas,* ed 2, Philadelphia, 2009, Saunders.)

manifestations vary with the severity and extent of disease. Loss of the absorptive mucosal surface and decreased colonic transit time can cause large volumes of watery diarrhea. Mucosal destruction causes bleeding, cramping pain, and an urge to defecate. There is frequent bloody diarrhea with passage of purulent mucus.[96] Mild UC involves less mucosa and may be limited to proctitis, so that frequency of bowel movements, bleeding, and pain is minimal. Severe forms may involve the entire colon (pancolitis) and are characterized by fever, elevated pulse rate, frequent diarrhea (10 to 20 movements per day), urgency, obviously bloody stools, and continuous crampy pain. Dehydration, weight loss, anemia, and fever result from fluid loss, bleeding, and inflammation. Complications include toxic megacolon, anal fissures, hemorrhoids, and perirectal abscess. Severe hemorrhage is rare, but chronic blood loss may precipitate hypotension and shock. Edema, strictures, or fibrosis can obstruct the colon. Perforation is an unusual but possible complication. The risk of left-sided colon cancer increases significantly after many years of ulcerative colitis and the presence of primary sclerosing cholangitis.[97]

Extraintestinal manifestations of UC and Crohn disease occur in about 30% of cases and include cutaneous lesions (erythema nodosum and pyoderma gangrenosum), migratory polyarthritis and sacroiliitis, osteopenia and osteoporosis, mouth ulcers, episcleritis or anterior uveitis of the eye, and primary sclerosing cholangitis in the liver.[98] Gallstones are common. Chronic inflammation causes alterations in coagulation and can cause life-threatening microthrombi, deep vein thrombosis, and other thromboembolic events.[99]

EVALUATION AND TREATMENT. Diagnosis of ulcerative colitis is based on the medical history, clinical manifestations, imaging procedures, and histologic criteria.[100] Endoscopic evaluation shows an inflamed and hemorrhagic mucosa. Radiologic assessment may show loss of haustra, ulceration, and irregular mucosa. The laboratory data include low hemoglobin values, hypoalbuminemia, and low serum potassium levels. Infectious causes are ruled out by stool culture. The symptoms of ulcerative colitis can be very similar to those of Crohn disease, and serological markers may be used for differential diagnosis.[101]

Treatment depends on the severity of symptoms and the extent of mucosal involvement. First-line therapy is 5-aminosalicylic acid (mesalazine). Corticosteroids and salicylates suppress the inflammatory response and help alleviate the cramping pain. Immunosuppressive agents (e.g., 6-mercaptopurine or azathioprine), cyclosporine, tacrolimus, and infliximab (a monoclonal anti–TNF-α antibody) are used for chronic active disease.[102] Broad-spectrum antibiotics may induce remission.[103] For unknown reasons, nicotine may have a protective effect in ulcerative colitis but not in Crohn disease.[104] Severe, unremitting disease can require hospital admission and administration of intravenous fluids. Extreme malnutrition may require intravenous hyperalimentation. Surgical resection of the colon or a colostomy may be performed if other forms of therapy are unsuccessful.[105] *Pouchitis* is a complication of restorative proctocolectomy with ileal pouch–anal anastomosis performed as surgical treatment for both UC and Crohn disease. Antibiotic treatment is usually successful.[106]

Crohn Disease

Crohn disease (CD) (granulomatous colitis, ileocolitis, or regional enteritis) is an idiopathic inflammatory disorder that affects any part of the gastrointestinal tract from the mouth to the anus. The distal small intestine and proximal large colon are most commonly affected by the disease. In a small percentage of cases, CD is difficult to differentiate from ulcerative colitis (Table 41-5). Risk factors include family history, smoking, Jewish ethnicity, urban residency, age less than 40 years, and a slight predominance in women.[107] The *CARD15/NOD2* (nucleotide-binding-oligomerization-domains) gene mutations have the strongest association with CD (35% to 45% of cases) although many other genes have been identified.[108] The *CARD15 /NOD2* genes code for a protein (a Toll-like receptor; see Chapter 10) involved in the recognition of gram-negative and gram-positive bacteria. The pathogenesis of CD may be associated with an overly aggressive response to normal flora bacteria in genetically predisposed individuals.[109] Th1-mediated inflammation with activation of leukocytes and cytokines (TNF-α, IFN-γ, and interleukins) causes injury. Recruited leukocytes release proinflammatory substances, including prostaglandins, leukotrienes, proteases, reactive oxygen species, and nitric oxide, which cause further injury and inflammation. Elevations in IgG levels are associated with severity of disease.[110]

PATHOPHYSIOLOGY. The inflammatory process of CD begins in the intestinal submucosa and spreads across the intestinal wall to involve the mucosa and serosa in areas overlying lymphoid tissue. Progression of the disease involves neutrophil infiltration of the crypts, resulting in abscess formation and crypt destruction. The most common site of the disease is the ileocolon, but both the large and small intestines may be involved. The inflammation can affect some haustral segments but not others, creating a pattern called *skip lesions.* One side of the intestinal wall may be affected but not the other.

TABLE 41-5 FEATURES OF ULCERATIVE COLITIS AND CROHN DISEASE

FEATURE	ULCERATIVE COLITIS	CROHN DISEASE
Incidence		
Age at onset	Any age; 10-40 years most common	Any age; 10-30 years most common
Family history	Less common	More common
Gender (prevalence)	Equal in women and men	About equal in women and men
Cancer risk	Increased	Increased
Pathophysiology		
Location of lesions	Colon and rectum, no "skip" lesions	All of GI tract: mouth to anus, "skip" lesions common
Inflammation and ulceration	Mucosal layer involved	Entire intestinal wall involved
Granulomas	Rare	Common
Friable mucosa	Common	Less common
Fistulae and abscesses	Rare	Common
Strictures and possible obstruction	Rare	Common
Clinical Manifestations		
Abdominal pain	Occasional	Common
Diarrhea	Common	Common
Bloody stools	Common	Less common
Abdominal mass	Rare	Common
Small intestinal malabsorption	Rare	Common
Steatorrhea	Rare	Common
Potential for malignancy	Common	Common
Antineutrophil cytoplasmic antibodies	Common	Rare
Anti–*Saccharomyces cerevisiae* antibodies	Rare	Common
Clinical course	Remissions and exacerbations	Remissions and exacerbations

GI, Gastrointestinal.

The ulcerations of CD produce longitudinal and transverse fissures that extend inflammation into lymphoid tissue. The typical chronic lesion is a granuloma having cobblestone projections of inflamed tissue surrounded by areas of ulceration (Figure 41-13). (Granulomas are described in Chapter 7.) The lumen can narrow with inflammation, edema, and fibrotic strictures. Fistulae may form in the perianal area between loops of intestine or extend into the bladder.

CLINICAL MANIFESTATIONS. Individuals with CD may have no specific symptoms other than an "irritable bowel" for several years. Symptoms vary and are associated with disease location. Abdominal pain and diarrhea are the most common signs (more than five stools per day), with passage of blood and mucus. Diarrhea can result from decreased colonic absorption, bypass fistulae, medications, bacterial overgrowth, and the presence of bile in the colon that inhibits water absorption. Other manifestations are related to the location and extent of intestinal involvement. Inflammation of the ileum, for example, causes tenderness in the lower right side of the abdomen. If the ileum is involved, the individual may be anemic as a result of malabsorption of vitamin B_{12}. There also may be deficiencies in folic acid, vitamin D absorption, and calcium leading to bone disease. Proteins may be lost, leading to hypoalbuminemia. Weight loss is common. Anal manifestations occur in about 30% of cases, including anal fissure, perianal abscess, and fistula.[111] Individuals with CD of long duration are also at risk for intestinal adenocarcinoma.[112] Complications include obstruction, fistulae, abscess formation, and chronic blood loss. Extraintestinal manifestations are similar to those described for UC.

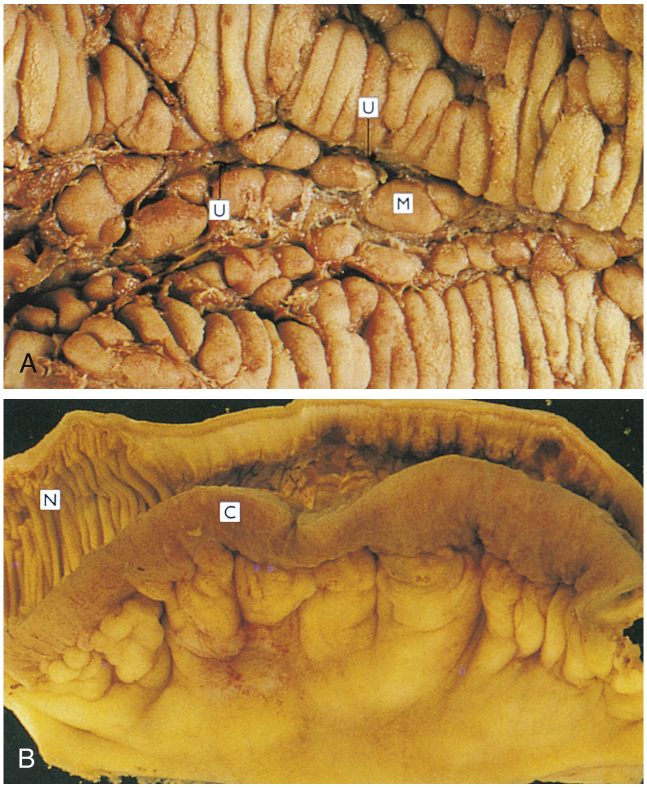

FIGURE 41-13 Crohn Disease. **A,** The mucosa in Crohn disease demonstrates a cobblestone pattern as a result of fissured ulcers *(U)* with intervening areas of edematous mucosa *(M).* **B,** Compared with normal small bowel wall *(N),* the Crohn segment *(C)* shows wall thickening that has caused a stenosis. (From Kumar V et al: *Pathologic basis of disease,* ed 7, Philadelphia, 2006, Saunders.)

EVALUATION AND TREATMENT. The diagnosis and treatment of CD are similar to the diagnosis and treatment of ulcerative colitis. Treatment with immunomodulatory agents can be effective. TNF-α–blocking agents are used for treatment of fistulae and to maintain remission.[113] Surgery is generally performed to manage complications such as strictures, fistulae, abscesses, and perforation, or to relieve obstruction.[114] When treatment involves surgical resection of small intestinal segments, complications related to **short bowel syndrome** can occur, including malabsorption, diarrhea, and nutritional deficiencies. Symptoms are related to the extent and location of resection.[115]

Diverticular Disease of the Colon

Diverticula are herniations or saclike outpouchings of mucosa through the muscle layers of the colon wall. **Diverticulosis** is asymptomatic diverticular disease. **Diverticulitis** represents inflammation. The cause of diverticular disease is unknown but is associated with age greater than 60 years, decreased dietary fiber, increased intracolonic pressure, abnormal neuromuscular function, and alterations in intestinal motility.[116]

PATHOPHYSIOLOGY. Diverticula can occur anywhere in the gastrointestinal tract but the most common site is the left colon. They rarely occur in the small intestine.[117] The diverticula form at weak points in the colon wall, usually where arteries penetrate the tunica muscularis to nourish the mucosal layer. The colonic mucosa herniates through the smooth muscle layers (Figure 41-14). A common associated finding is thickening of the circular and longitudinal (teniae coli) muscles surrounding the diverticula. Hypertrophy and contraction of these muscles increase intraluminal pressure and degree of herniation. Habitual consumption of a low-residue diet reduces fecal bulk, thus reducing the diameter of the colon. According to Laplace's law (see Chapter 31), wall pressure increases as the diameter of a cylindrical structure decreases. Therefore, pressure within the narrow lumen can increase enough to rupture the diverticula. Insoluble dietary fiber deficiency also may change the intestinal microflora, decreasing the immune response and levels of inflammatory cytokines in the colon.[118,119] Diverticulitis can cause abscess formation, fistula formation, peritonitis, or obstruction.[120]

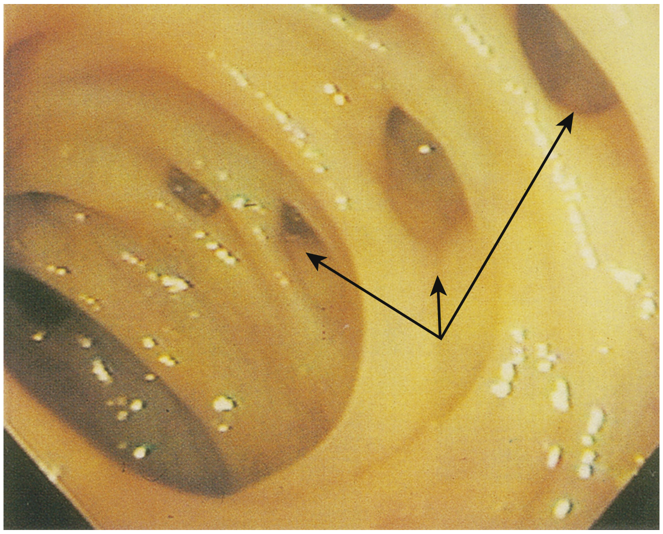

FIGURE 41-14 Diverticular Disease. In diverticular disease, the outpouches *(arrows)* of mucosa seen in the sigmoid colon appear as slitlike openings from the mucosal surface of the opened bowel. (From Townsend CM et al: *Sabiston textbook of surgery*, ed 19, Philadelphia 2012, Saunders.)

CLINICAL MANIFESTATIONS. Symptoms of diverticular disease are usually vague or absent and about 30% of individuals develop specific symptoms. Cramping pain of the lower abdomen can accompany constriction of the hypertrophied colonic muscles. Diarrhea, constipation, distention, or flatulence may occur. Diverticula with an obstructed opening become inflamed or abscesses form, and the individual develops fever, leukocytosis (increased white blood cell count), and tenderness of the lower left quadrant. Right lower quadrant pain and severe complications, such as hemorrhage, perforation with peritonitis, bowel obstruction, and fistula formation, are rare.[120]

EVALUATION AND TREATMENT. Diverticula are often discovered during diagnostic procedures performed for other problems. Ultrasound, sigmoidoscopy, or barium enema is used for diagnosis of uncomplicated diverticula. Abdominal computed tomography (CT) is used for complicated cases.

An increase of dietary fiber intake increases stool weight, lowers colonic pressures, improves transit times, and often relieves symptoms (see Nutrition & Disease: Diverticular Disease and Diet). Uncomplicated diverticular disease is treated with bowel rest and antibiotics.[121] Surgical resection may be required if there are severe complications, including hemorrhage, bowel stenosis, obstruction, abscesses, fistulae, bowel perforation, and peritonitis.[122]

NUTRITION & DISEASE

Diverticular Disease and Diet

Daily consumption of fiber-enriched foods is recommended for the prevention of diverticula. A high-fiber diet increases fecal bulk, decreases transit time, lowers intracolonic pressures, and eases stool elimination. The recommendation for fiber is 20 to 35 g/day. Some examples of high-fiber choices are whole wheat bread and other grain products, baked potato with skin, fresh fruit with skins, raw vegetables, beans, peas, legumes, wheat bran, and brown rice. Side effects may include flatulence, intestinal rumbling, cramps, and diarrhea. A gradual increase in dietary fiber over 1 or 2 months helps to avoid these problems. Other potential problems with an excessively high-fiber diet (greater than 40 to 45 g) might include a decrease in nutrient absorption because of the increased volume of intestinal contents, which in turn decreases the ability of the digestive enzymes to come into contact with the food. An increase of water intake (eight 8-ounce glasses) is important so intestinal blockage will not occur. For small children and older adults, a high-fiber diet increases the volume of food needed to meet energy requirements, and that increase may be difficult to obtain. Although some physicians recommend restricting nuts, seeds, and foods containing seeds such as berries, kiwi, and tomatoes that might lodge in the pouches, there is no evidence that this happens. If the diverticula become inflamed, a low-fiber, low-residue (no milk products), or elemental diet, or in complicated cases total parenteral nutrition (TPN), is required to prevent continued irritation of the inflamed tissue. Controlled clinical trials are needed to evaluate the effectiveness of high-fiber diets in preventing diverticular disease.

Data from Crowe FL et al: *BMJ* 343:d4131, 2011; Strate LL: *Dig Dis* 30(1):35–45, 2012; Ünlü C et al: *Int J Colorectal Dis* 27(4):419–427, 2012; Wick JY: *Consult Pharm* 27(9):613–618, 2012.

Appendicitis

Appendicitis is an inflammation of the vermiform appendix, which is a projection from the apex of the cecum. It is the most common surgical emergency of the abdomen and usually occurs between 20 and 30 years of age, although it may develop at any age.[123]

PATHOPHYSIOLOGY. The exact cause of appendicitis is controversial. Obstruction of the lumen with stool, tumors, or foreign bodies with consequent increased intraluminal pressure, ischemia, bacterial infection, and inflammation is a common theory. The obstructed lumen does not allow drainage of the appendix, and as mucosal secretion continues, intraluminal pressure increases. The resultant increased pressure decreases mucosal blood flow, and the appendix becomes hypoxic. The mucosa ulcerates, promoting bacterial or other microbial invasion with further inflammation and edema. Inflammation may involve the distal or entire appendix. Gangrene develops from thrombosis of the luminal blood vessels, followed by perforation.

CLINICAL MANIFESTATIONS. Epigastric or periumbilical pain is the typical symptom of an inflamed appendix. The pain may be vague at first, increasing in intensity over 3 to 4 hours. It may subside and then recur with a shift of location to the right lower quadrant with rebound tenderness. Right lower quadrant pain is associated with extension of the inflammation to the surrounding tissues. Nausea, vomiting, and anorexia follow the onset of pain, and fever is common. Diarrhea occurs in some individuals, particularly children; others have a sensation of constipation. Perforation, peritonitis, and abscess formation are the most serious complications of appendicitis.[124]

EVALUATION AND TREATMENT. In addition to clinical manifestations, the clinician can usually locate the painful site with one finger. Rebound tenderness is usually referred to the right lower quadrant. The white blood cell count ranges from 10,000 to 16,000 cells/mm^3 with elevations in the levels of neutrophils, C-reactive protein.[125] Abdominal CT scans and ultrasound assist diagnostic accuracy. The combined information provides the best discriminating diagnosis.[126]

Antibiotics and appendectomy is the treatment for simple or perforated appendicitis. Laparoscopic surgery provides quick recovery for simple appendicitis. Recovery is more complicated in cases of perforation or abscess formation and in individuals of older age.[127,128]

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is a functional gastrointestinal disorder characterized by abdominal pain and altered bowel habits that affects about 10% of individuals throughout the world and is more common in women, with a higher prevalence in youth and middle age. Individuals with IBS are more likely to have anxiety and depression.[129]

PATHOPHYSIOLOGY. There are no specific structural or biochemical alterations as a cause of IBS but there is increasing evidence to explain the varying symptom presentations and they are summarized as follows:

1. *Visceral hypersensitivity or hyperalgesia,* particularly with distention of the rectum but also other areas of the gut: This occurs in about 30% to 40% of those with IBS. The cause is unknown; it may originate in either the peripheral or the central nervous system. The mechanism may be related to pain and a dysregulation of the "brain-gut axis" (alterations in gut or central nervous system processing of gut nociceptive information), increased permeability that stimulates nociceptors, the role of serotonin in the enteric nervous system of the gut, infiltration and activation of mast cells and T lymphocytes, or alterations in the autonomic nervous system.[130]
2. *Abnormal gastrointestinal permeability, motility, and secretion:* Individuals with diarrhea-type IBS have more rapid colonic transit times and increased intestinal permeability, whereas those with bloating and constipation have delayed transit times and decreased intestinal permeability. The mechanisms may be related to visceral hypersensitivity and dysregulation of the brain-gut axis or to the role of serotonin in the function of the enteric nervous system and to activity of mast cells.[131]
3. *Postinfectious IBS:* Two or more of the following symptoms are present: fever, vomiting, diarrhea, and a positive stool culture Intestinal infection (bacterial enteritis) has been associated with symptoms of IBS and may be related to altered gut microbiota, ongoing low-grade inflammation, and an abnormal immune response in gut tissues.[132]
4. *Overgrowth of intestinal flora:* Small intestinal overgrowth of normal gut bacteria may precipitate IBS symptoms and it is proposed that methane gas may slow intestinal transit time, resulting in constipation and bloating.[133,134]
5. *Food allergy or food intolerance:* Food antigens may activate the mucosal immune system, mediating hypersensitivity reactions and IBS symptoms. Individualized food elimination approaches are helpful in some cases because different foods alter neural and hormonal small intestinal responses. Allergic conditions, including rhinitis and asthma, have been associated with IBS.[135]
6. *Psychosocial factors:* Psychosocial factors including emotional stress influence brain-gut interaction including neuroendocrine, neuroimmune, autonomic nervous system, and pain modulatory responses contributing to the symptoms of IBS.[136]

CLINICAL MANIFESTATIONS. IBS is characterized by lower abdominal pain, diarrhea-predominant, constipation-predominant, or alternating diarrhea/constipation (mixed), gas, bloating, and nausea. Individuals may also describe fecal urgency and incomplete evacuation. Symptoms are usually relieved with defecation and usually do not interfere with sleep.

EVALUATION AND TREATMENT. The diagnosis of IBS is based on signs and symptoms and includes the exclusion of structural or biochemical causes of disease. In the absence of "alarm symptoms" such as fever, weight loss, gastrointestinal bleeding, anemia, or abdominal mass, only limited diagnostic tests are needed. The individual may be evaluated for food allergies, lactose intolerance, parasites, or bacterial growth. The Rome III criteria for diagnosing IBS have been released to guide evaluation (Box 41-2).

There is no cure for IBS, and treatment is individualized. Treatment of symptoms may include laxatives and dietary

BOX 41-2 DIAGNOSTIC CRITERIA FOR IRRITABLE BOWEL SYNDROME

Rome III Criteria

For a disorder to be diagnosed as irritable bowel syndrome, at least two or more of the following conditions will have existed for at least 3 months, with onset occurring at least 6 months before the beginning of the recurrent abdominal pain or discomfort:

1. Improvement with defecation
2. Onset associated with a change in stool frequency
3. Onset associated with a change in form (appearance) of stool

Manning Criteria

1. Onset of pain linked to more frequent bowel movements
2. Looser stools associated with onset of pain
3. Pain relieved by passage of stool
4. Noticeable abdominal bloating
5. Sensation of incomplete evacuation more than 25% of the time
6. Diarrhea with mucus more than 25% of the time

Modified from Longstreth GF et al: *Gastroenterology* 130(5):1480–1491, 2006; Suares NC, Ford AC: *Discov Med* 11(60):425–433, 2011; Whitehead WE, Drossman DA: *Am J Gastroenterol* 105(4):814–820, 2010.

fiber, antidiarrheals, antispasmodics, low-dose antidepressants, and serotonin agonists or antagonists. For severe constipation, 5-hydroxytryptamine-4 agonists (e.g., tegaserod) may be used (not approved for use in North America since 2007 because of cardiac ischemic events) or CIC-2 chloride channel activators (e.g., lubiprostone). For severe diarrhea, 5-hydroxytryptamine-3 receptor antagonists (e.g., alosetron) or rifaximin (an antibiotic) may be used to normalize bowel habits. Low-dose tricyclic antidepressants and selective serotonin reuptake inhibitors (SSRIs) have been used for severe pain. Alternative therapies including prebiotics (stimulate growth of healthy gut bacteria), probiotics, selected herbal treatments (e.g., peppermint oil), hypnosis, and psychotherapy are treatment options. Research continues to advance the management of this complex syndrome.[137,138]

Intestinal Vascular Insufficiency

The stomach and intestines are supplied by three branches of the abdominal aorta: the celiac artery and the superior and inferior mesenteric arteries. Atherosclerotic lesions, thrombi, and emboli can develop in these vessels, occluding blood flow and causing ischemia or necrosis in the gastrointestinal tract.

Mesenteric venous thrombosis is the least common of the causes of mesenteric vascular insufficiency. Malignancies, right-sided heart failure, and deep vein thrombosis are risk factors.

Acute mesenteric ischemia caused by acute occlusion of the mesenteric artery results in a significant reduction in mucosal blood flow to the large and small intestines. Dissecting aortic aneurysms, arterial thrombi, or emboli can be causes. Embolic obstruction is associated with atrial fibrillation, mitral valve disease, heart valve prostheses, or myocardial infarction. The superior mesenteric artery has a more direct line of flow from the aorta; therefore, emboli enter it more readily than they enter the inferior branch, causing ischemia and necrosis of the small intestine. Ischemia and necrosis alter membrane permeability. There is initially increased motility, nausea and vomiting, urgent bowel evacuation, and severe abdominal pain. Ischemia leads to decreased motility and distention. The damaged intestinal mucosa cannot produce enough mucus to protect itself from digestive enzymes. Mucosal alteration causes fluid to move from the blood vessels into the bowel wall and peritoneum. Fluid loss causes hypovolemia and further decreases in intestinal blood flow. As intestinal infarction progresses, shock, fever, bloody diarrhea, and leukocytosis develop. Bacteria invade the necrotic intestinal wall, causing gangrene and peritonitis.[139,140]

Chronic mesenteric ischemia is rare. It can develop secondary to atherosclerosis (most common), congestive heart failure, dysrhythmias, hemorrhage, thrombus formation, aortic aneurysm, or any condition that decreases arterial blood flow. Chronic occlusion is often accompanied by formation of collateral circulation that may be able to nourish the resting intestine. After eating, however, when the intestine requires more blood, the arterial supply may be insufficient. Ischemia develops, causing a cramping abdominal pain, called *abdominal angina,* after meals. Progressive vascular obstruction eventually causes continuous abdominal pain and necrosis of the intestinal tissue. Reperfusion injury related to reactive oxygen metabolites and inflammatory mediators contributes to further tissue damage.

Colicky abdominal pain after eating is a cardinal symptom of chronic mesenteric insufficiency. Some individuals suffer significant weight loss because they stop eating to control the pain.

Diagnosis of acute and chronic mesenteric ischemia is based on clinical manifestations, laboratory findings, and imaging studies. Bruit often can be heard over a partially occluded artery. Medical management includes antibiotics, anticoagulation, vasodilators, and inhibitors of reperfusion injury. Surgery is required to remove necrotic tissue, repair sclerosed vessels, and revascularize tissue. Acute occlusion is a surgical emergency and mortality is high (50% to 90%). Early diagnosis and aggressive treatment result in the best survival rates.[141,142]

Disorders of Nutrition

Obesity

Obesity is an increase in body fat mass and a metabolic disorder that has become an epidemic worldwide. The incidence is rapidly increasing among children and adolescents and they tend to become obese adults.[143,144]

Obesity is defined as a body mass index (BMI) that exceeds 30 kg/m^2 and generally develops when caloric intake exceeds caloric expenditure in genetically susceptible individuals.[145] Obesity is a major risk factor for morbidity, death, and high healthcare cost in the United States and worldwide.[146] Three leading causes of death in the United States are associated with obesity: cardiovascular disease, type 2 diabetes mellitus, and cancer (colorectal, breast in postmenopausal women, endometrial, prostate, renal, and esophageal).[147] Obesity is also a risk factor for hypertension, stroke, hyperlipidemia, gallstones, nonalcoholic steatohepatitis, gastroesophageal reflux, osteoarthritis, infectious disease, asthma, and obstructive sleep apnea. However, some studies have shown that a BMI between 25 and 34 in older individuals is associated with lower mortality.[148,149]

The causes and consequences of obesity are multiple and complex and there is rapidly advancing research regarding

BOX 41-3 HORMONES AND ADIPOKINES SECRETED BY ADIPOSE TISSUE

Leptin

Satiety (hunger/appetite suppression) and regulation of eating behavior by hypothalamus
Sympathoactivation
Insulin sensitizing
Modulating role in reproduction, angiogenesis, immune response, blood pressure control, and osteogenesis

Adiponectin

Insulin sensitizing
Anti-inflammatory
Anti-atherogenic

Resistin

Promotes insulin resistance and increased blood glucose levels
Inhibits adipocyte differentiation and may function as a feedback regulator of adipogenesis

Apelin

Regulates glucose homeostasis and lowers serum glucose level; vasodilation

Visfatin (from Visceral Fat)

Mimics insulin and binds to insulin receptors in rats

Vaspin—May Be Insulin Sensitizing, Reduces Food Intake

Insulin sensitizing
Anti-inflammatory action

Retinol-Binding Protein 4 (RBP4)

Promotes insulin resistance, promotes fat deposition

Regulators of Lipoprotein Metabolism

Lipoprotein lipase
Lipotransin
Apolipoprotein E
Cholesterol ester transfer protein

Inflammatory Cytokines

Prostaglandins
Tumor necrosis factor-alpha
Interleukins (IL-1β, IL-6, IL-8, IL-10)
Plasminogen activator inhibitor 1
Monocyte chemoattractant protein 1

Other Hormones and Cytokines

Acylation stimulating protein
Adipocyte relaxing factor—decreased in obesity
Adipophilin
AdipoQ
Agouti protein
Angiotensinogen
Chemerin—adipocyte differentiation and lipolysis
Dipeptidyl peptidase IV (DPP-IV)
Estrogen
FABP4 (fatty acid binding protein 4)—suppresses cardiomyocyte contraction
Insulin-like growth factor
Monobutyrin
Nitric oxide synthase
Tissue factor
Transforming growth factor-beta

Data from Blüher M: *Diabetes Metab J* 36(5):317–327, 2012; Maenhaut N, Van de Voorde J: *BMC Med* 16(9):25, 2011.

causal mechanisms, complications, and treatment. Genotype and gene-envirnonment interactions are important predisposing factors.[150] Single-gene defects are rare and obesity is usually polygenic and associated with other phenotypes such as endocrine disorders (i.e., diabetes and hypothyroidism) and mental retardation (i.e., Down and Prader-Willi syndromes). Single-gene defects include the melanocortin-4 receptor gene (decreases appetite), leptin gene (also known as the *obesity gene*), and leptin-receptor gene. All single-gene defects are directly or indirectly related to leptin and melanocortin pathways.[151] Metabolic abnormalities contributing to obesity include Cushing syndrome, Cushing disease, polycystic ovary syndrome, hypothyroidism, and hypothalamic injury. Environmental factors include culture, socioeconomic status, food intake, and exercise. Obesity is associated with adverse social and psychologic consequences.[152,153]

PATHOPHYSIOLOGY. The pathophysiology of obesity is complex and involves the interaction of numerous cytokines, hormones, and neurotransmitters. Mechanisms contributing to the imbalance of energy intake in relation to energy expenditure and the multiple pathogenic effects of excess adipose tissue are not completely understood. The adipocyte is the cellular basis of obesity. Adipocytes secrete a number of hormones and cytokines known as adipokines[154] (Box 41-3). Adipokines participate in regulation of food intake, lipid storage and metabolism, insulin sensitivity, the alternative complement system, vascular homeostasis, blood pressure regulation, angiogenesis, the inflammatory and immune responses, female reproduction, and regulation of energy metabolism. Visceral fat accumulation causes dysfunction of adipocytes and results in alterations in the regulation and interaction of these hormones. Macrophages infiltrate excess adipocytes with increased expression of inflammatory cytokines (e.g., TNF-α and IL-1β). The low-grade inflammation and alterations in adipokines, and other hormones and neurotransmitters contributes to the causes and complications of obesity, particularly cardiovascular disease and type 2 diabetes mellitus.[155]

Regulation of appetite and satiety occurs through neuroendocrine regulation of eating behavior, energy metabolism, and body fat mass. The system is complex and controlled by a dynamic circuit of signaling molecules from the periphery acting on central controls including the brainstem, hypothalamus, and autonomic nervous system. An imbalance in this system is usually associated with excessive caloric intake in relation to exercise with the consequence of weight gain and obesity.

The arcuate nucleus (ARC) in the hypothalamus has two sets of neurons with opposing effects that interact to regulate

BOX 41-4 EXAMPLES OF HORMONES AND NEUROPEPTIDES THAT INFLUENCE EATING BEHAVIOR

Orexins (Appetite Stimulants)
Neuropeptide Y (NPY)
Melanin-concentrating hormone (MCH)
Agouti-related protein (AGRP)
Ghrelin
Galanin
Orexins A and B
Peptide YY (PYY)
Endocannabinoids
Cortisol

Anorexins (Appetite Suppressants)
Leptin
Insulin
Cholecystokinin (CCK)
Glucagon-like peptide 1 (GLP1)
Corticotropin-releasing factor (CRF)
Urocortin (a CRF satiety signaling hormone)
Cocaine- and amphetamine-regulated transcript (CART)
Alpha-melanocyte–stimulating hormone (α-MSH)
Bombesin
Serotonin
Calcitonin

and balance food intake and energy metabolism. One set of neurons produces neuropeptide Y (NPY) and agouti-related protein (AGRP), which promotes appetite, stimulates eating, and decreases metabolism (anabolic). Another set of neurons synthesizes pro-opiomelanocortin (POMC)–producing peptide and cocaine-and-amphetamine–regulated transcript (CART), collectively known as POMC/CART neurons, which suppress appetite, inhibit eating, and increase metabolism (catabolic).

Molecules that stimulate eating are called *orexins* (i.e., hypocretins [from the hypothalamus], a peptide family that act as neurotransmitters for stimulating eating). Molecules that inhibit eating are called *anorexins* (Box 41-4). Peripheral effects of these signaling pathways are transmitted through the autonomic nervous and endocrine systems to regulate appetite, food intake, and energy metabolism.[156]

Many different hormones also control appetite, satiety, and body weight. Their sources include ghrelin from the stomach; peptide YY, cholecystokinin (CCK), and glucagon-like peptide 1 (GLP-1) from the intestines; insulin from pancreatic beta cells; leptin, adiponectin, and retinol-binding protein 4 (RBP4) from adipose tissue; and endocannabinoids (arachidonic acid based lipids) from brain and peripheral nerves. These hormones circulate in the blood at concentrations that increase or decrease in relation to body fat mass, and serve as *peripheral signals* to the ARC in the hypothalamus, where appetite (food intake) and metabolism (energy expenditure) are regulated. Leptin and insulin normally decrease appetite by inhibiting NPY/AGRP neurons (anabolic circuits) and stimulating POMC/CART neurons (catabolic circuits). Ghrelin and other hormones stimulate appetite by activating NPY/AGRP-expressing neurons. Intestinal peptide YY (PYY), CCK, endocannabinoids, and other hormones decrease appetite. Other peripheral hormones and neurotransmitters also can influence the hypothalamus and affect appetite and energy expenditure (see Box 41-4). Obesity is associated with increased circulating plasma levels of leptin (leptin resistance), retinol-binding protein 4, insulin (insulin resistance), and ghrelin. There are decreased levels of adiponectin and peptide YY. Interaction among these hormones and adipokines at the level of the hypothalamus and in the periphery may be important determinants of excessive fat mass. Leptin resistance, decreased adiponectin levels, increased ghrelin levels, insulin resistance, and inflammation are particularly important in the complications of obesity.

Leptin, a product of the obesity gene (*Ob* gene) and expressed primarily by adipocytes, acts on the hypothalamus to suppress appetite and regulates body weight within a fairly narrow range. Low leptin levels during fasting normally stimulate food intake and reduce energy expenditure and high leptin levels in the fed state inhibit food intake and increase energy expenditure. Leptin secretion increases as adipocytes increase in size or number (hyperleptinemia). The high levels of leptin in obesity are ineffective at decreasing appetite and increasing energy expenditure—this is known as decreased leptin sensitivity or **leptin resistance.** Leptin resistance disrupts hypothalamic satiety signaling, promotes overeating and excessive weight gain, and is a factor in the development of obesity.[157]

The cause of leptin resistance is unknown. It may be related to a defect in leptin transport, an inability of leptin to cross the blood-brain barrier; an alteration in the permissive effect of leptin on urocortin (a satiety-signaling molecule); or a defect in the leptin receptor. *Hyperleptinemia* also stimulates the sympathetic nervous system, chronic inflammation, oxidative stress, and ventricular hypertrophy and may contribute to the pathogenesis of hypertension, atherosclerosis, and cardiovascular disease associated with obesity.[158-160]

Adiponectin, produced primarily by visceral adipose tissue, has insulin-sensitizing properties and plasma levels decrease with visceral obesity, contributing to insulin resistance and type 2 diabetes mellitus. Decreased levels of adiponectin are associated with complications of obesity, including increased risk for coronary artery disease resulting from hyperlipidemia, hypertension, and factors that promote thrombosis and inflammation[161] (see Chapter 32). Decreased adiponectin levels are associated with increased hepatic gluconeogenesis, decreased skeletal muscle glucose uptake, and increased levels of inflammatory markers, such as IL-6 and TNF-α. Adiponectin may serve as an anti-inflammatory and anti-atherogenic plasma protein and has an important role in vascular remodeling that is limited with obesity.[162,163]

Insulin resistance is associated with obesity. The mechanisms are not clear but there is an association between hyperlipidemia and fat storage, macrophages and inflammation, and alterations in adipokines. Leptin resistance and decreased adiponectin contribute to insulin resistance.[164] Retinol-binding protein 4 is an adipokine that is increased in visceral adiposity and contributes to insulin resistance in liver and muscle.[165] Insulin resistance results in hyperglycemia and predisposition to type 2 diabetes mellitus.

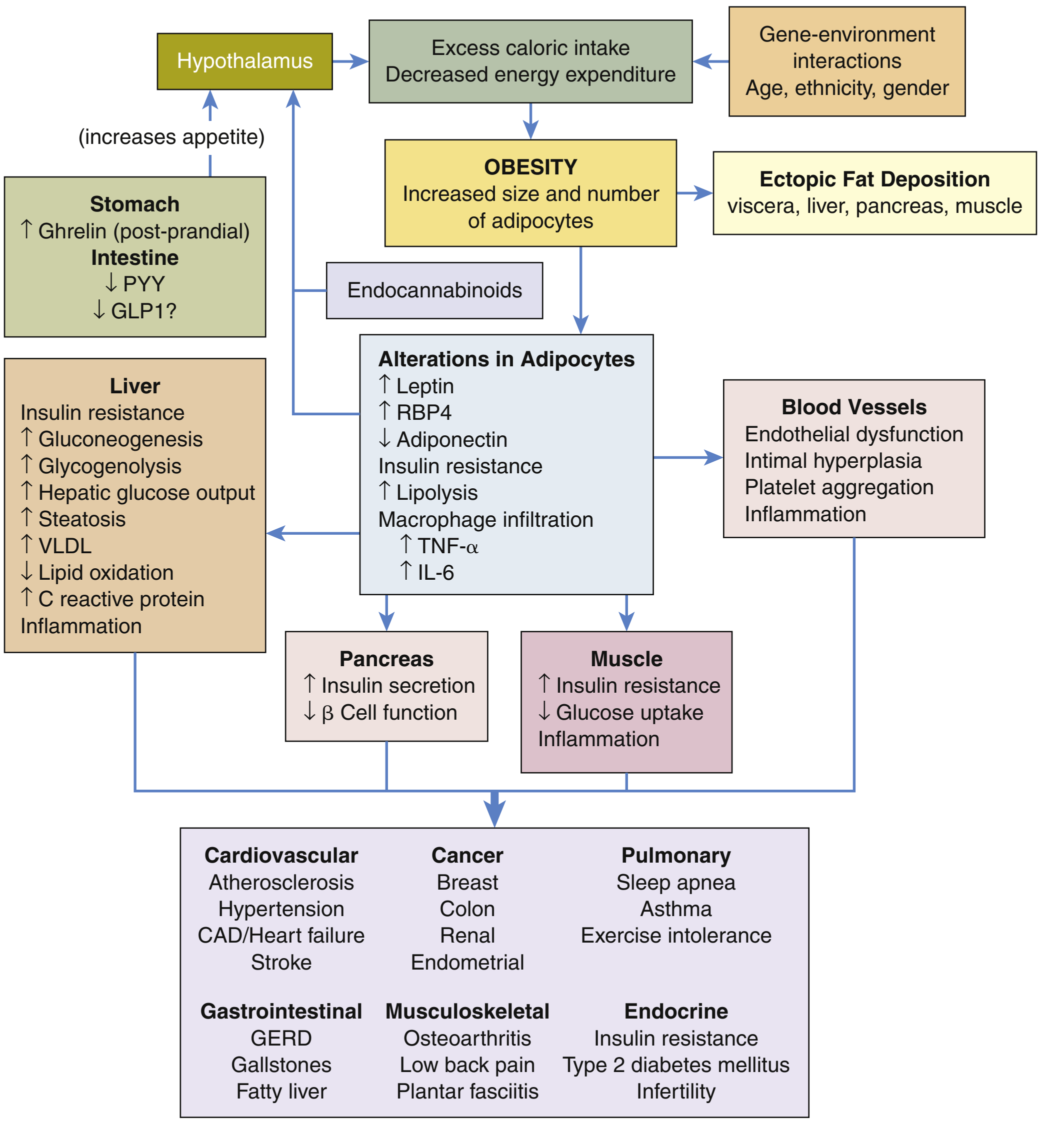

FIGURE 41-15 Pathophysiology and Common Complications of Obesity. See text for details. *CAD,* Coronary artery disease; *GERD,* gastroesophageal reflux disease; *GLP1,* glucagon-like peptide 1; *IL-6,* interleukin-6; *PYY,* intestinal peptide YY; *RBP4,* retinol-binding protein 4; *TNF-α,* tumor necrosis factor-alpha; *VLDL,* very-low-density lipoprotein.

Ghrelin is produced by the stomach in response to hunger and stimulates food intake through activation of the ghrelin receptor (GHS-R) located on neuropeptide Y (NPY)/agouti-related peptide (AGRP) neurons in the hypothalamus. Ghrelin induces metabolic changes leading to an increase in body weight and body fat mass. Ghrelin also stimulates release of growth hormone (GH) from anterior pituitary cells, release of gastric acid, gastrointestinal motility, and pancreatic functions. It has satiety, vasodilatory, cardioprotective, and antiproliferative effects.[166]

Leptin and ghrelin are complementary, yet antagonistic signals reflecting acute and chronic changes in energy balance, the effects of which are mediated by hypothalamic neuropeptides, such as NPY and AGRP. In obesity, plasma ghrelin level does not decrease after eating and its role in contributing to obesity is yet to be defined. Endocrine and vagal afferent pathways are also involved in the actions of ghrelin and leptin, adding to the complexity of mechanisms that can affect obesity.[167]

Glucose-like peptide 1 is an incretin secreted from intestinal endocrine cells when nutrients enter the small intestine. GLP-1 stimulates pancreatic glucose-dependent insulin secretion, delays gastric emptying, and suppresses appetite. GLP-1 levels may be decreased in obese individuals.[168]

Peptide YY (PYY) is released from intestinal endocrine cells in response to nutrients entering the intestine and inhibits gastric motility and decreases appetite. The level of PYY decreases with increases in adiposity and decreased PYY level is associated with obesity.[169]

Endocannabinoids (i.e., anandamide) are expressed in both the brain and peripheral nerve tissues and have effects on endocannabinoid receptors in orexigenic pathways. They increase appetite, enhance nutrient absorption, stimulate lipogenesis, and increase adipose tissue accumulation by acting at both central (CB1 receptor) and peripheral sites (CB2 receptor). An increase in endocannabinoids is proposed to be associated with obesity.[170] Figure 41-15 summarizes the pathophysiology and complications of obesity.

CLINICAL MANIFESTATIONS. Obesity usually presents with two different forms or phenotypes of adipose tissue distribution.[171] **Visceral obesity** (also known as intra-abdominal, central, or masculine obesity) occurs when the distribution of body fat is localized around the abdomen and upper body, resulting in an apple shape. Visceral obesity is associated with accelerated lipolysis and has an increased risk for inflammation, metabolic syndrome (hypertriglyceridemia, reduced high-density lipoprotein, increased low-density lipoproteins, hypertension, and insulin resistance), type 2 diabetes mellitus, cardiovascular complications, and cancer. Visceral venous blood drains into the portal vein, contributing to higher liver synthesis of plasma lipids.[172,173] **Peripheral obesity** (also known as gluteal-femoral, feminine, or subcutaneous obesity) occurs when the distribution of body fat is extraperitoneal and distributed around the thighs and buttocks and through the muscle, resulting in a pear shape; it is more common in women. Peripheral and subcutaneous fat is less metabolically active and less lipolytic and releases fewer adipocytokines (particularly adiponectin) than visceral fat. Risk factors are still present for the complications of obesity but they are less severe than for visceral obesity.[174]

EVALUATION AND TREATMENT. There are several methods for measuring or estimating body fat mass, including anthropometric measurements, such as skinfold thickness, circumferences, various body diameters (i.e., waist-to-hip ratios and waist circumference, BMI tables), underwater weighing, and bioimpedance analysis.[175,176] The BMI and waist-to-hip ratios are most commonly used because they are the easiest to measure and most cost-effective. Overweight is defined as a BMI greater than 25 kg/m^2 and obesity is a BMI greater than 30 kg/m^2. BMI charts are available for children ages 2 to 20 years; these can be used for comparison during adulthood because obese children generally become obese adults. No specific diagnostic criteria for obesity have been established.[177]

Obesity is a chronic disease for which various treatment approaches have been used, including correction of metabolic abnormalities, individually tailored weight-reduction diets, and exercise programs.[178] A combination of weight reduction and exercise is the most effective. Self-motivation and support systems are critical aspects of treatment.[179] Additional treatments include psychotherapy, behavioral modification, and anti-obesity drugs.[180] Bariatric surgical procedures (i.e., the Roux-en-Y gastric bypass, gastric banding, or sleeve gastrectomy) also are prescribed and when successful result in a significant reduction in weight, reduction in comorbidities, and a decrease in insulin resistance. Unraveling the causes of obesity will lead to more specific prevention and pharmacotherapies.[181-183]

Anorexia Nervosa, Bulimia Nervosa, and Binge Eating Disorder

Many young adults and adolescents—as many as 1% of women and adolescent girls in the United States—are affected by complex and related eating disorders: anorexia nervosa, bulimia nervosa, and binge eating. These disorders are included in the proposed *DMS-5* classification of eating disorders by the American Psychiatric Association (Box 41-5). They rarely occur in black women, and only 5% to 10% of cases are men.[184] Onset may occur in children and women over age 50 years.[185] Risk factors include genetic, epigenetic, familial, biologic, psychologic, and social factors.[186,187] There is an association between posttraumatic stress and sexual assault history and eating disorders.[188] An increasing number of children, young men, and older adult women are experiencing eating disorders, often with an associated depression, anxiety, or personality disorder.[189,190] The death rate is highest among women with anorexia nervosa.[191]

BOX 41-5 CLASSIFICATION OF EATING DISORDERS

Anorexia Nervosa
1. Fear of becoming obese despite progressive weight loss
2. Distorted body image: the perception that the body is fat when it is actually underweight
3. Restriction of energy intake leading to significantly low body weight
4. Behavioral resistance to gaining weight

Bulimia Nervosa
1. Recurrent episodes of binge eating during which the individual fears not being able to stop
2. Self-induced vomiting, use of laxatives, or fasting to oppose the effect of binge eating
3. One binge eating episode per week for at least 3 months
4. Undue influence of body shape or weight on self-evaluation
5. Does not meet anorexia nervosa criteria

Binge Eating Disorder
1. Recurrent episodes of binge eating
2. Binge eating associated with three or more of the following:
   a. Eating much more rapidly than normal
   b. Eating until uncomfortably full
   c. Eating large amounts of food when not physically hungry
   d. Eating alone because of being embarrassed
   e. Feeling disgusted, depressed, or very guilty after overeating
3. Marked distress regarding binge eating
4. One binge eating episode per week for at least 3 months
5. Does not meet criteria for anorexia nervosa or bulimia nervosa

Data from: Sysko R et al: *Psychiatry Res* 196(2):302–308, 2012.

Starvation

Malnutrition is lack of nourishment from inadequate amounts of calories, protein, vitamins, or minerals and is caused by improper diet, alterations in digestion or absorption, chronic disease, or a combination of these factors. **Starvation** is a reduction in energy intake leading to weight loss. Short-term starvation and long-term starvation have different effects. Therapeutic short-term starvation is part of many weight-reduction programs because it causes an initial rapid weight loss that reinforces the individual's motivation to diet. Therapeutic long-term starvation is used in medically controlled environments to facilitate rapid weight loss in morbidly obese individuals. Pathologic long-term starvation can be caused by poverty; chronic diseases of the cardiovascular, pulmonary, hepatic, and digestive systems; malabsorption syndromes; human immunodeficiency virus (HIV) infection; and cancer.[192]

Short-term starvation, or extended fasting, consists of several days of total dietary abstinence or deprivation. The body responds with protective mechanisms. For 4 to 6 hours after the last meal, the body is in a well-fed state and its energy requirements are supplied by glucose from recently ingested carbohydrates. Once all available energy has been absorbed from the intestine, glycogen in the liver is converted to glucose through **glycogenolysis,** the splitting of glycogen into glucose. This process peaks within 4 to 8 hours, and gluconeogenesis begins. **Gluconeogenesis** is the formation of glucose from noncarbohydrate molecules: lactate, pyruvate, amino acids, and the glycerol portion of fats. Like glycogenolysis, gluconeogenesis takes place within the liver. Both of these processes deplete stored nutrients and thus cannot meet the body's energy needs indefinitely. Proteins continue to be catabolized to a minimal degree, providing carbon for the synthesis of glucose.[193]

Long-term starvation begins after several days of dietary abstinence and eventually causes death. Absolute deprivation of food causes **marasmus** or protein-energy malnutrition (loss of muscle mass and body fat depletion). Protein deprivation in the presence of carbohydrate intake is called **kwashiorkor** (loss of muscle mass with sustained body fat). Marasmic kwashiorkor (edematous, severe childhood malnutrition) is a combination of chronic energy deficiency and chronic or acute protein deficiency and inadequate micronutrients.[194] Anorexia nervosa is a psychologic cause of long-term starvation (see Box 41-5). **Cachexia** (also known as cytokine-induced malnutrition) is physical wasting with loss of weight and muscle atrophy, fatigue, and weakness. Inflammatory mediators (i.e., TNF-α, interferon-γ, IL-1, IL-6) and a blunted response to ghrelin and adiponectin are associated with the cachexia of advanced cancer.[195] Cancer, AIDS, tuberculosis, and other major chronic progressive diseases contribute to cachexia. Anorexia and cachexia often occur together. Cachexia is not the same as food deprivation starvation. A healthy person's body can adjust to starvation by slowing metabolism; however, in cachexia, the body does not make this adjustment.

The major characteristic of long-term starvation is a decreased dependence on gluconeogenesis and an increased use of ketone bodies (products of lipid and pyruvate metabolism) as a cellular energy source. During long-term starvation, depressed insulin levels and increased levels of glucagon, cortisone, epinephrine, and growth hormones promote lipolysis in adipose tissue. Lipolysis liberates fatty acids, which supply energy to cardiac and skeletal muscle cells, and ketone bodies, which sustain brain tissue. Fatty acid, or ketone body, oxidation meets most of the energy needs of the cells. (Some glucose is still needed as fuel for brain tissue.) Once the supply of adipose tissue is depleted, proteolysis begins. The breakdown of muscle and visceral protein is the last process the body engages to supply energy for life. Death results from severe alterations in electrolyte balance and loss of renal, pulmonary, and cardiac function.[196]

Adequate ingestion of appropriate nutrients is the obvious treatment for starvation. In medically induced starvation the body is maintained in a ketotic state until the desired amount of adipose tissue has been lysed. Starvation imposed by chronic disease, long-term illness, or malabsorption is treated with enteral or parenteral nutrition and there is the potential to develop refeeding syndrome. Perioperative or critical care management of nutrition is necessary to prevent unnecessary starvation.[197] Care must be taken to prevent **refeeding syndrome** during the treatment of long-term starvation (see What's New? Refeeding Syndrome).

WHAT'S NEW?

Refeeding Syndrome

Refeeding syndrome occurs in severely malnourished individuals when parenteral or enteral nutritional therapy is initiated. During starvation, loss of body minerals causes the movement of phosphate, magnesium, and potassium ions out of the cells and into the plasma. When refeeding starts, an increase in insulin levels stimulates the movement of glucose and these ions back into the cells, and the plasma concentrations can decrease to dangerously low levels, causing hypophosphatemia, hypomagnesemia, hypokalemia, hyponatremia, hypocalcemia, and vitamin deficiency. Rapid expansion of the extracellular fluid volume also can occur with carbohydrate refeeding and may cause fluid overload. Hypophosphatemia contributes to alterations in red blood cell shape and function contributing to tissue hypoxia and increased respiratory drive. The consequence of these alterations includes life-threatening dysrhythmias, congestive heart failure, muscle weakness (including respiratory muscles), and death. Individuals at greatest risk are those with starvation from any cause including anorexia nervosa, chronic alcoholism, morbid obesity with massive weight loss, and prolonged fasting. Refeeding syndrome is prevented by slowly reinstituting feeding (about 20 kcal/kg/day for the first few days) and monitoring plasma levels of phosphate, potassium, magnesium, and calcium.

Data from Byrnes MC, Stangenes J: *Curr Opin Clin Nutr Metab Care* 14(2):186–192, 2011; Kohn MR, Madden S, Clarke SD: *Curr Opin Pediatr* 23(4):390–394, 2011; Skipper A: *Nutr Clin Pract* 27(1):34–40, 2012.

DISORDERS OF THE ACCESSORY ORGANS OF DIGESTION

The accessory organs of digestion (liver, gallbladder, pancreas) secrete substances necessary for digestion and, in the case of the liver, carry out metabolic functions needed to maintain life.

Common Complications of Liver Disorders

Of all the accessory organ disorders, acute or chronic liver disease leads to the most systemic, life-threatening complications. Complications of chronic liver disorders include portal hypertension, ascites, hepatic encephalopathy, jaundice, and hepatorenal syndrome.

Acute Liver Failure

Acute liver failure (fulminant liver failure) is a rare clinical syndrome (2000 cases in the United States annually)[198] resulting from severe impairment or necrosis of liver cells without preexisting liver disease or cirrhosis. Acetaminophen overdose is the leading cause of acute liver failure in the United States[199] (see What's New? Acetaminophen and Acute Liver Failure). It also may occur as a complication of viral hepatitis, particularly hepatitis B virus (HBV) infection compounded by infection with the delta virus, as well as metabolic liver disorders.

WHAT'S NEW?

Acetaminophen and Acute Liver Failure

Acetaminophen (paracetamol) toxicity from chronic use or intentional overdose is the leading cause of acute liver failure in the United States and Great Britain. Liver injury may occur with doses of 4 to 10 g and hepatotoxicity with mitochondrial injury and hepatocyte necrosis should be suspected when doses exceed 4 g/day. The onset is sudden and unpredictable accompanied by coagulopathy and encephalopathy. Elevated serum aminotransferase levels (may be up to 400 times normal) accompanied by hypoprothrombinemia, metabolic acidosis, and renal failure support a diagnosis of acute liver failure caused by acetaminophen. Complications of cerebral edema and infection are difficult to diagnose and treat and may lead to multiorgan failure and irreversible brain damage. Early treatment with correct dosing with *N*-acetylcysteine provides a 66% chance of recovery and there is 70% survival at 1 year after liver transplant.

Data from Hodgman MJ, Garrard AR: *Crit Care Clin* 28(4):499–516, 2012; Jaeschke H, McGill MR, Ramachandran A: *Drug Metab Rev* 44(1):88–106, 2012; Khandelwal N et al: *Hepatology* 53(2):567–576, 2011.

Pathogenic mechanisms of acute liver failure are poorly understood. Hepatocytes become edematous, and patchy areas of necrosis and inflammatory cell infiltrates disrupt the parenchyma. The hepatic necrosis is irreversible.

Acute liver failure usually develops 6 to 8 weeks after the initial symptoms of viral hepatitis or a metabolic liver disorder (e.g., Wilson disease). Anorexia, vomiting, abdominal pain, and progressive jaundice are initial signs, followed by ascites and gastrointestinal bleeding. Coagulopathy and encephalopathy occur in individuals without preexisting liver disease and can cause cerebral edema manifested as lethargy, altered motor functions, coma, and death. Liver function tests show elevations the levels of both conjugated and unconjugated serum bilirubin, serum transaminases, and blood ammonia. Prothrombin time is prolonged.[198] Treatment of acute liver failure requires rapid evaluation and critical care. *N*-Acetylcysteine is used for acetaminophen poisoning; antiviral therapy appears to improve survival in cases of viral hepatitis; and lowering blood ammonia levels may improve prognosis. Liver transplantation may be lifesaving but needs to be performed early and obtaining a liver for transplant can be difficult.[200] Artificial liver support systems and use of hepatic stem cells are still in experimental stages of development.[198,201] Survivors usually do not develop cirrhosis or chronic liver disease.

Portal Hypertension

Portal hypertension is abnormally high blood pressure in the portal venous system primarily caused by resistance to portal blood flow. Pressure in this system is normally 3 mmHg; portal hypertension is an increase to at least 10 mmHg.

PATHOPHYSIOLOGY. Portal hypertension is caused by disorders that obstruct or impede blood flow through any component of the hepatic portal system. *Intrahepatic* causes result from vascular remodeling with intrahepatic shunts, thrombosis, inflammation, or fibrosis, as occurs in cirrhosis of the liver, viral hepatitis, or schistosomiasis (a parasitic infection). *Posthepatic* causes

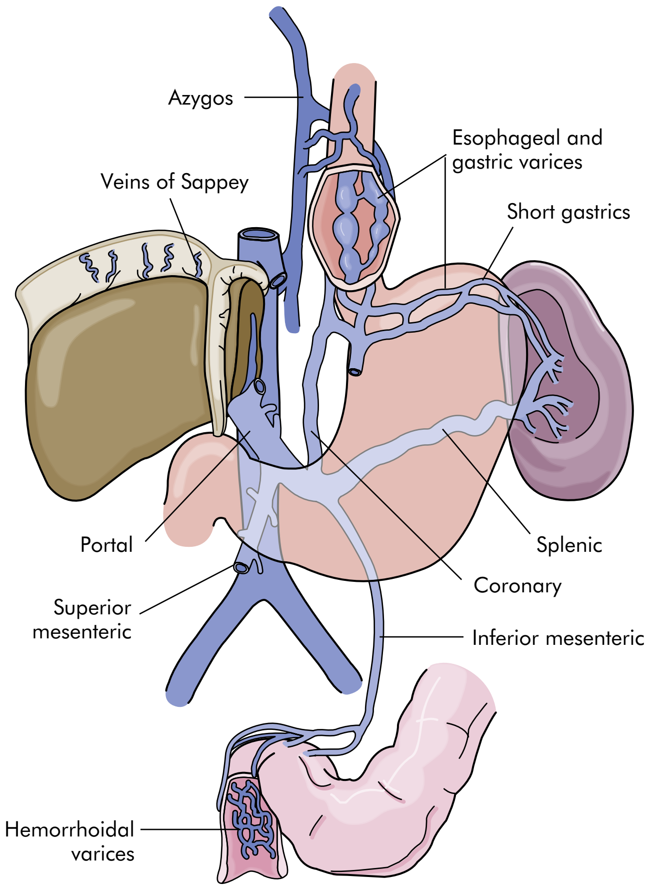

FIGURE 41-16 **Varices Related to Portal Hypertension.** Portal vein, its major tributaries, and the most important shunts (collateral veins) between the portal and caval systems. (From Monahan FD et al: *Phipps' medical-surgical nursing: concepts and clinical practice,* ed 8, St Louis, 2007, Mosby.)

occur from hepatic vein thrombosis or cardiac disorders that impair the pumping ability of the right side of the heart (i.e., right-sided heart failure).[202] This causes blood to back up and increase pressure in the portal system. Thrombosis or narrowing of the hepatic portal vein is the major *prehepatic* cause. Long-term portal hypertension causes several pathophysiologic problems that are difficult to treat and can be fatal. These problems include varices, splenomegaly, hepatopulmonary syndrome, ascites, and hepatic encephalopathy.

Varices are distended, tortuous, collateral veins. Prolonged elevation of pressure in the hepatic portal vein causes collateral veins to open between the portal vein and systemic veins and their transformation into varices, particularly in the lower esophagus and stomach but also over the abdominal wall (known as the caput medusae [Medusa head]) and rectum (hemorrhoidal varices) (Figure 41-16). Rupture of varices can cause life-threatening hemorrhage.[203,204]

Splenomegaly is an enlargement of the spleen. Portal hypertension contributes to congestive splenomegaly caused by increased pressure in the splenic vein, a tributary to the hepatic portal vein. Thrombocytopenia from platelet sequestration is the most common manifestation and can contribute to an increased bleeding tendency. Splenomegaly also can be predictive of esophageal varices severity.[205]

Hepatopulmonary syndrome (intrapulmonary vasodilation, intrapulmonary shunting, and hypoxia)[206] and **portopulmonary hypertension** (pulmonary vasoconstriction and vascular remodeling)[206] are common respiratory complications of advanced liver disease and portal hypertension. Hyperdynamic (high-flow) state, increased pulmonary venous congestion, and vascular constriction or obstruction of the pulmonary arterial bed are contributing factors.[207] There are no specific clinical manifestations, although dyspnea, cyanosis, and digital clubbing may occur. Diagnosis is made by contrast echocardiography and right heart catheterization. In portopulmonary hypertension, pulmonary artery pressure is greater than 25 mmHg. Treatment may include systemic vasodilators and endothelin receptor antagonists, which can reduce pulmonary and portal hypertension.[208]

CLINICAL MANIFESTATIONS. The most common clinical manifestation of portal hypertension is vomiting of blood from bleeding **esophageal varices.**[204,209] Bleeding is usually from varices that have developed slowly over a period of years. Slow, chronic bleeding from varices causes anemia or melena.

Acute rupture of esophageal varices causes hemorrhage and voluminous vomiting of dark blood. The ruptured varices are usually painless. Rupture is caused by a combination of erosion by gastric acid and elevated venous pressure. Mortality from ruptured esophageal varices ranges from 15% to 20%. Hemorrhoidal varices present as hematochezia and copious rectal bleeding. Recurrent bleeding of esophageal or gastric varices indicates a poor prognosis. Most individuals die within 1 year.

EVALUATION AND TREATMENT. Diagnosis of portal hypertension is often made at the time of variceal bleeding and confirmed by endoscopy and evaluation of portal venous pressure. Distended collateral veins may radiate over the abdomen, giving rise to caput medusae (Medusa's head) from opening of the paraumbilical veins. The individual usually has a history of hepatitis or alcoholism.

Beta-blockers can be effective in preventing variceal bleeding. Emergency management of bleeding varices includes fluid resuscitation, prophylactic antibiotics, vasoactive drugs (e.g., nonselective β-receptor antagonists and terlipressin, a vasopressin derivative), endoscopic variceal band ligation, compression of the varices with an inflatable tube or balloon, and injection of a sclerosing agent. Surgical construction of a transjugular intrahepatic portosystemic shunt (TIPS) (anastomosis of the portal vein to the inferior vena cava) may decompress the varices, but this treatment can precipitate encephalopathy or liver failure resulting from reduced hepatic blood flow. There is no definitive treatment for portal hypertension.[204] Liver transplant is the most successful option for liver failure.[210]

Ascites

Ascites is the accumulation of fluid in the peritoneal cavity and is a complication of portal hypertension. Ascites traps body fluid in the peritoneal cavity from which it cannot escape. The effect reduces the amount of fluid available for normal physiologic functions. Cirrhosis is the most common cause of ascites; ascites is the most common complication of cirrhosis. Other diseases associated with ascites include right heart failure, abdominal malignancies, nephrotic syndrome, and malnutrition. Twenty-five percent of individuals who develop ascites caused by cirrhosis die within 1 year. Continued heavy drinking of alcohol is associated with this mortality because of increased risk for cirrhosis.

PATHOPHYSIOLOGY. Several factors contribute to the development of ascites, including portal hypertension, splanchnic vasodilation, hypoalbuminemia, and sodium and water retention. The *overflow theory* proposes that renal sodium retention is stimulated by portal hypertension with intravascular hypervolemia and overflow into the peritoneal cavity (transudative effusion). Portal hypertension also increases capillary hydrostatic pressures in the intestinal wall, which causes fluid to "weep" into the peritoneal cavity. Reduced capillary oncotic pressure adds to the fluid shift. The *underfill theory* proposes an increase in hepatic sinusoidal hydrostatic pressure and decreased plasma oncotic pressure with weeping of lymph fluid from the surface of the liver. The resulting decrease in effective circulating plasma volume activates the renin-angiotensin-aldosterone system, stimulating the kidney to retain more sodium and water and leading to intravascular volume overload. The *peripheral arterial vasodilation theory,* or *forward theory,* is a synthesis of the overflow and underfill theories and the most accepted theory. This theory proposes that circulating nitric oxide and carbon monoxide causes splanchnic vasodilation. The decrease in systemic vascular resistance overcomes compensatory cardiac output. Stimulation of baroreceptors activates renal sodium retention through activation of the renin-angiotensin-aldosterone system, increased sympathetic tone, secretion of antidiuretic hormones, and fluid retention. Combined portal hypertension and splanchnic vasodilation causes fluid transudation and lymph formation producing ascites. The release of endotoxin from translocation of intestinal bacteria also can trigger arterial vasodilation of the splanchnic organs.[211] Ascites can be complicated by bacterial peritonitis. Figure 41-17 summarizes the mechanisms by which cirrhosis of the liver causes ascites.

CLINICAL MANIFESTATIONS. The accumulation of ascitic fluid causes abdominal distention, increased abdominal girth, and weight gain (Figure 41-18). Large volumes of fluid (10 to 20 L) displace the diaphragm and cause dyspnea by decreasing lung capacity. Respiratory rate increases, and the individual assumes a semi-Fowler position to relieve the dyspnea. Some peripheral edema is usually present. Dilutional hyponatremia is a consequence of excess fluid volume. Approximately 10% of individuals with ascites develop bacterial peritonitis, either spontaneously or as a result of paracentesis (needle aspiration of ascitic fluid). Peritonitis causes fever, chills, abdominal pain, decreased bowel sounds, and cloudy ascitic fluid.

EVALUATION AND TREATMENT. Diagnosis of ascites is usually based on clinical manifestations and identification of liver disease. The serum-ascites albumin gradient (SAAG) is the most specific diagnostic indicator for portal hypertension–related ascites. Chest and abdominal x-rays, ultrasonography, or CT scans are used to evaluate the cause and extent of the ascites, and complications such as peritonitis. The goal of treatment is to relieve discomfort. If the restoration of liver function is possible (e.g., in ascites caused by viral hepatitis), the ascites diminishes spontaneously. In the meantime, dietary salt restriction

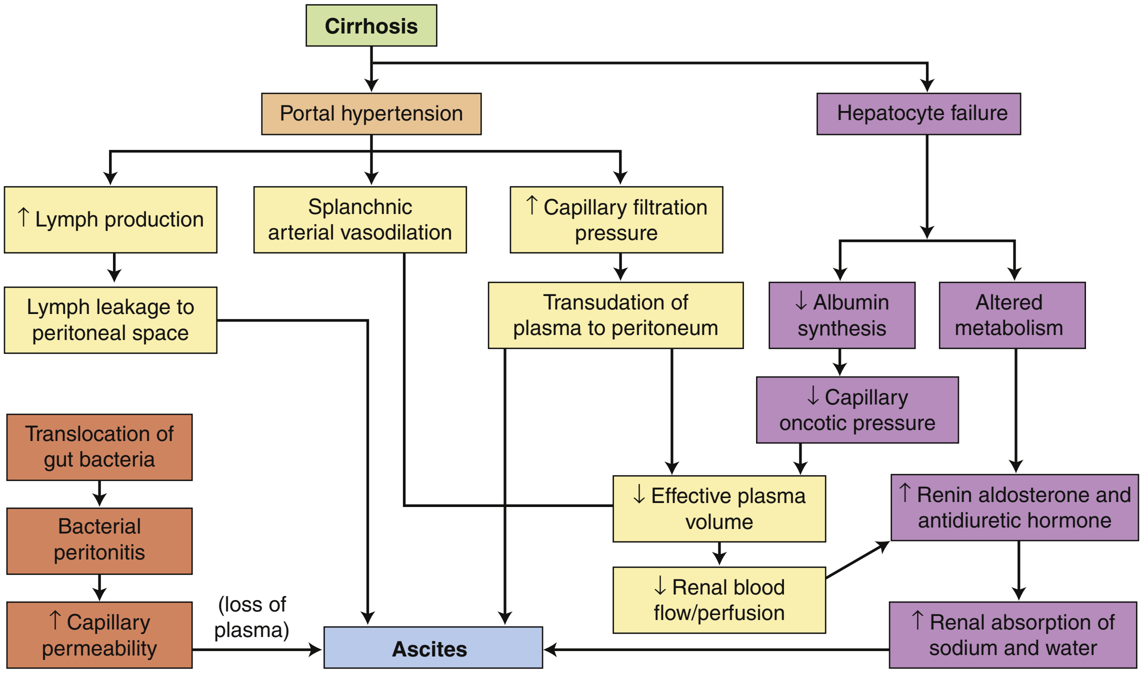

FIGURE 41-17 Mechanisms of Ascites Caused by Cirrhosis.

FIGURE 41-18 Massive Ascites in an Individual with Cirrhosis. Distended abdomen, dilated upper abdominal veins, and everted umbilicus are classic manifestations. (From Goldman L, Schafer AI: *Goldman's Cecil medicine,* ed 24, Philadelphia, 2012, Saunders.)

and potassium-sparing diuretics can reduce ascites. Strong diuretics, such as furosemide or ethacrynic acid, may be used and vasopressin receptor-2 antagonists are effective for dilutional hyponatremia. Albumin may be given.[212] Serum electrolyte levels are monitored carefully because the individual is at risk for hyponatremia and hypokalemia.[213]

Palliative measures include paracentesis to remove 1 or 2 L of ascitic fluid and relieve respiratory distress. This procedure can have serious complications, however. The removal of too much fluid too fast relieves pressure on blood vessels, causing arteriolar vasodilation, which carries the risk of hypotension, shock, or death. Despite repeated paracentesis, ascitic fluid reaccumulates in individuals with irreversible disease, drawing more albumin and electrolytes out of the vascular compartment. Paracentesis is also likely to cause peritonitis. Peritonitis is treated with long-term antibiotics. A transjugular intrahepatic portosystemic shunt or peritoneovenous shunt may be used to treat refractory ascites. Individuals with ascites and portal hypertension have a poor prognosis, and liver transplant is the best treatment option.[214]

Hepatic Encephalopathy

Hepatic encephalopathy (portosystemic encephalopathy) is a complex neurologic syndrome characterized by impaired cognitive function, flapping tremor (asterixis), and electroencephalogram (EEG) changes. The syndrome may develop rapidly during acute fulminant hepatitis (type A) in association with portosystemic bypass and in the absence of intrinsic liver disease (type B); or slowly during the course of chronic liver disease (type C: episodic, persistent, or covert).[215] Risk factors in the presence of advanced liver disease include gastrointestinal bleeding, increased dietary protein, electrolyte imbalance, and hypoxia.

PATHOPHYSIOLOGY. Hepatic encephalopathy results from a combination of biochemical alterations that affect neurotransmission. Liver dysfunction and collateral vessels that shunt blood around the liver to the systemic circulation permit neurotoxins and other harmful substances absorbed from the gastrointestinal tract to accumulate and circulate freely to the brain. Substances include inflammatory cytokines, short-chain fatty acids, serotonin, tryptophan, and false neurotransmitters. The most hazardous substances are end-products of intestinal protein digestion, particularly ammonia, which cannot be converted to urea by the diseased liver. The digestion of blood from leaking or ruptured varices adds to the amount of ammonia present in systemic blood, as does the action of ammonia-forming bacteria in the colon. Ammonia

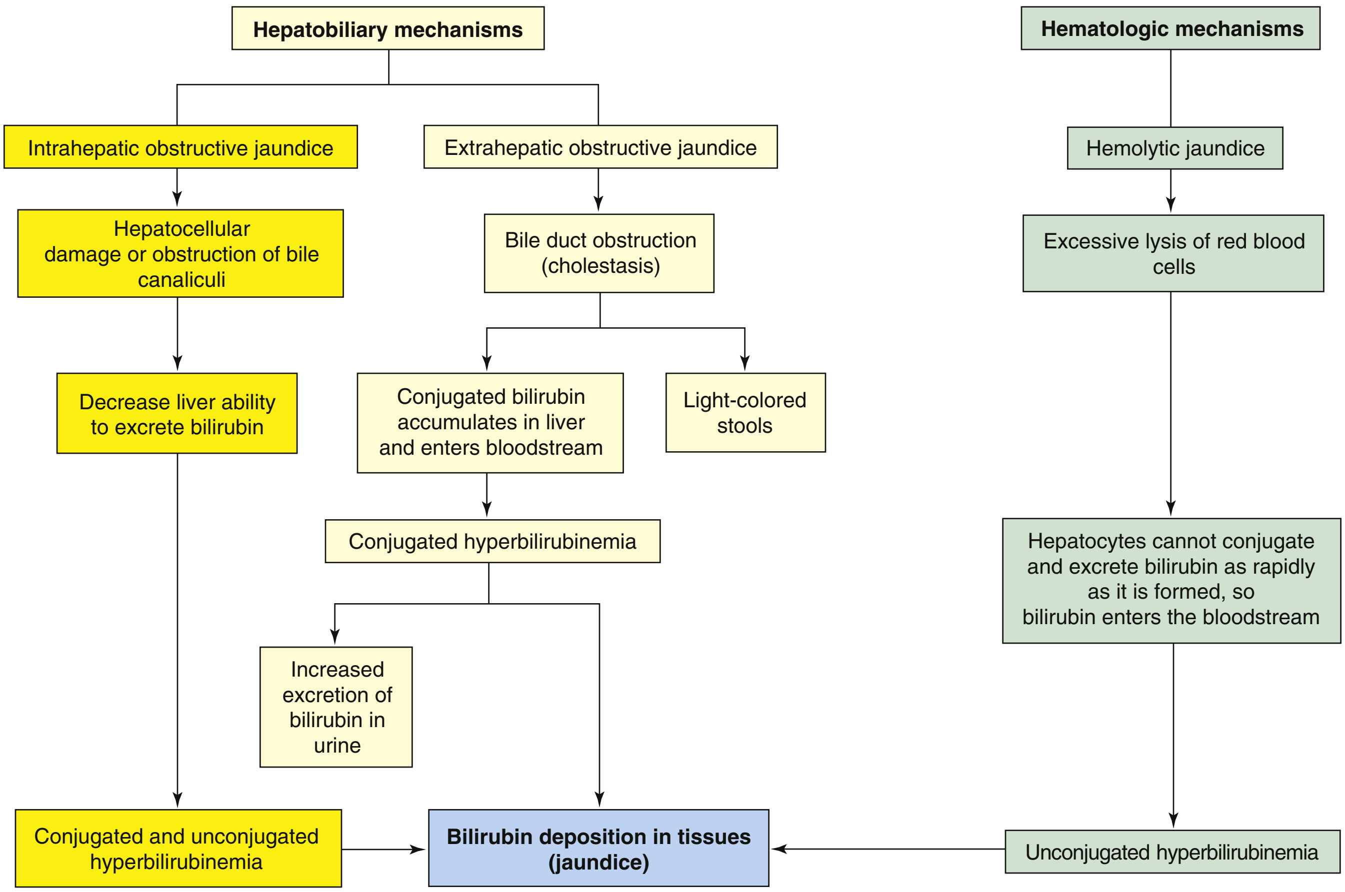

FIGURE 41-19 Mechanisms of Jaundice.

that reaches the brain is metabolized to glutamine with osmotic disturbances and alterations in cerebral blood flow that interfere with neurotransmitters and cause astrocyte edema (cytotoxic edema) and oxidation. Permeability of the blood-brain barrier also may be increased (vasogenic edema), contributing to brain edema and intracranial hypertension.[216,217] Excessive amounts of gamma-aminobutyric acid (GABA), an inhibitory neurotransmitter, may contribute to reduced levels of consciousness. Infection, hemorrhage, inflammation, electrolyte imbalance, sedatives, and analgesics also can precipitate stupor and coma in the presence of liver disease.[218,219]

CLINICAL MANIFESTATIONS. Subtle changes in personality, memory loss, irritability, lethargy, and sleep disturbances are common initial manifestations of hepatic encephalopathy and can be invisible (minimal hepatic encephalopathy). In acute liver failure, symptom onset can be rapid with confusion, flapping tremor of the hands, stupor, convulsions, and coma. Coma is usually a sign of severe liver dysfunction and ultimately results in death.[220]

EVALUATION AND TREATMENT. There is no specific diagnostic test of hepatic encephalopathy. Diagnosis is based on a history of liver disease, clinical manifestations, and psychometric testing. Electroencephalography and blood chemistry tests, including blood ammonia levels, provide supportive data. Tracking levels of serum ammonia assesses treatment effectiveness and liver function.

Correction of fluid and electrolyte imbalances and withdrawal of depressant drugs metabolized by the liver are the first steps in the treatment of hepatic encephalopathy. Reduction of blood ammonia levels is a major objective. This is accomplished by restricting dietary protein intake and eliminating intestinal bacteria. Neomycin is effective in sterilizing the bowel, but it can be nephrotoxic. Lactulose may be administered to prevent ammonia absorption in the colon.[221] Rifaximin decreases intestinal production and absorption of ammonia by altering gastrointestinal flora and is minimally absorbed. Sodium benzoate and L-ornithine-L-aspartate also detoxify ammonia and lactulose enemas promote ammonia excretion.[222]

Jaundice

Jaundice (icterus) is a yellow or greenish pigmentation of the skin caused by **hyperbilirubinemia** (total plasma bilirubin concentrations greater than 2.5 to 3 mg/dl). Hyperbilirubinemia and jaundice can result from (1) extrahepatic obstruction to bile flow (gallstones), (2) intrahepatic obstruction (hepatocellular disease such as cirrhosis or hepatitis), or (3) excessive production of bilirubin (excessive hemolysis of red blood cells)[223] (Figure 41-19). Jaundice in newborns is caused by impaired bilirubin uptake and conjugation (see Chapter 42).

PATHOPHYSIOLOGY. **Obstructive jaundice** can result from extrahepatic or intrahepatic obstruction.[224] *Extrahepatic obstructive jaundice* develops if the common bile duct is occluded by

a gallstone, tumor, or compression from edema of pancreatitis. Because the bile duct is obstructed, bilirubin is conjugated by the hepatocytes but cannot flow into the duodenum. (Conjugated bilirubin is soluble in water and is then soluble in aqueous bile.) Therefore, it accumulates in the liver and enters the bloodstream, causing hyperbilirubinemia. Because conjugated bilirubin is water soluble, it appears in the urine. The stools may be light colored or clay colored because they lack bile pigments. The stools also lack urobilinogen because bile is not available for conversion to urobilinogen.

Intrahepatic obstructive jaundice involves disturbances in hepatocyte function and obstruction of *bile canaliculi*. The uptake, conjugation, and excretion of bilirubin are affected with elevated levels of both conjugated and unconjugated bilirubin. Hepatocellular damage increases plasma concentrations of unconjugated bilirubin. The major disorder, however, is obstruction of bile canaliculi, which diminishes flow of conjugated bilirubin into the common bile duct with elevations in the plasma. In mild cases, some of the bile canaliculi open. Consequently, the amount of bilirubin in the intestinal tract may be only slightly decreased. The stools may appear normal or light colored.

Excessive hemolysis (breakdown) of red blood cells or absorption of hematoma can cause **hemolytic jaundice (prehepatic** or **nonobstructive jaundice).** An increased amount of unconjugated bilirubin is formed through metabolism of the heme component of destroyed red blood cells. The extra amount of unconjugated bilirubin exceeds the conjugation ability of the liver, causing blood levels of unconjugated bilirubin to rise. Because unconjugated bilirubin is not water soluble, it is not excreted in the urine. The reserve conjugation ability of the liver usually prevents long-term unconjugated hyperbilirubinemia greater than 4 to 5 mg/dl. If unconjugated hyperbilirubinemia exceeds 5 mg/dl, both hemolytic and liver disorders are indicated.

Hyperbilirubinemia and jaundice can be caused also by metabolic defects that impair the uptake or conjugation of unconjugated bilirubin in the liver. *Gilbert disease,* for example, causes an elevation of unconjugated bilirubin level in the plasma but no other symptoms of liver disease. Gilbert disease is probably caused by an inherited deficiency of glucuronyl transferase enzyme, which is required for the hepatic uptake of unconjugated bilirubin. The causes of jaundice are summarized in Table 41-6.

CLINICAL MANIFESTATIONS. The clinical manifestations of jaundice vary and are related to the underlying pathology. Conjugated hyperbilirubinemia may cause the urine to darken several days before the onset of jaundice. The complete obstruction of bile flow from the liver to the duodenum causes light-colored stools. With partial obstruction, stool color is normal and bilirubin is present in the urine. Extrahepatic biliary obstruction is associated with increased intestinal permeability and bacterial translocation, and may contribute to the pathogenesis of sepsis and renal failure.[225]

Fever, chills, and pain often accompany jaundice resulting from viral or bacterial inflammation of the liver (e.g., viral hepatitis). Manifestations of liver injury from any cause commonly include anorexia, malaise, and fatigue. Yellow discoloration may first occur in the sclera of the eye and then progress to the skin. Skin xanthomas (cholesterol deposits) and pruritus commonly accompany jaundice with an elevation of serum alkaline phosphatase level.[226]

EVALUATION AND TREATMENT. Laboratory evaluation establishes whether the elevated level is plasma bilirubin is conjugated or unconjugated or both. The history, physical examination, and laboratory tests identify underlying disorders, such as alcoholism, exposure to hepatitis virus, or gallbladder disease. The treatment for jaundice consists of correcting the cause.

Hepatorenal Syndrome

Hepatorenal syndrome (HRS) is functional renal failure; it develops as a complication of advanced liver disease that tends to occur with ascites. Renal disorders associated with liver disease can have numerous causes but HRS is usually associated with alcoholic cirrhosis. The renal failure is not caused by primary renal disease or other extrinsic factors, but rather by arterial vasodilation of the splanchnic vasculature, reduced effective blood volume, and renal vasoconstriction.[227] There are two types of HRS: type 1 involves rapid and progressive renal failure

TABLE 41-6 THREE COMMON TYPES OF JAUNDICE

TYPE	MECHANISM	CAUSES
Hemolytic jaundice (predominantly unconjugated bilirubin)	Excessive destruction of erythrocytes	Membrane defect of erythrocytes Hemolytic anemias Immune reaction Severe infection Toxic substances in the circulation (e.g., snake venom) Transfusion of incompatible blood
Obstructive (cholestatic) jaundice (predominantly conjugated bilirubin)	Obstruction to passage of conjugated bilirubin from liver to intestine	Obstruction of bile duct by gallstones or tumor (extrahepatic obstructive jaundice) Obstruction of bile flow through the liver (intrahepatic obstructive jaundice) Drugs
Hepatocellular jaundice (both conjugated and unconjugated bilirubin)	Failure of liver cells (hepatocytes) to conjugate bilirubin and of bilirubin to pass from liver to intestine	Genetic defect of hepatocyte (decreased enzymes), such as occurs in premature infants (see Chapter 42) Hepatitis or biliary cirrhosis

related to severe reduction in blood volume and decreased cardiac output; type 2 is slower, is more stable, and is accompanied by refractory ascites.[228]

PATHOPHYSIOLOGY. Hepatorenal syndrome generally accompanies a sudden decrease in blood volume secondary to massive gastrointestinal or variceal bleeding and hypotension caused by bleeding and splanchnic vasodilation associated with failing liver function. Hypotension also can be caused by the excessive use of diuretics to treat ascites. The decrease in blood volume and hypotension result in decreased renal perfusion, decreased glomerular filtration, and oliguria (see Chapter 39). The ability to concentrate and dilute urine is usually maintained. Intrarenal vasoconstriction may result from the selective effects of vasoactive substances that accumulate in the blood because of liver failure. The diseased liver fails to remove excessive angiotensin, vasopressin, prostaglandins, and catecholamines from the blood, which travel to the kidneys and cause vasoconstriction. Vasoconstriction also may be a compensatory response to portal hypotension and vasodilation in the splanchnic circulation. The exact reason for the renal vasoconstriction is unknown but is related to vasoconstrictive mediators and sympathetic nerve stimulation.[229]

CLINICAL MANIFESTATIONS. The onset of hepatorenal manifestations may be gradual or acute. Oliguria and complications of advanced liver disease, including jaundice, ascites, and gastrointestinal bleeding, are usually present. Systolic blood pressure is usually less than 100 mmHg. Nonspecific symptoms of hepatorenal syndrome include anorexia, weakness, and fatigue.

EVALUATION AND TREATMENT. Diagnosis of HRS is made by excluding all other causes of renal failure. Despite decreased glomerular filtration, serum potassium levels do not become dangerously elevated until the terminal stages of the hepatorenal syndrome. Serum creatinine values increase rapidly (within 2 weeks) in type 1 HRS and slowly or not at all in type 2 HRS. Urine osmolality is increased, but urine sodium concentrations are below normal (unlike acute tubular necrosis). Urine specific gravity is greater than 1.015. The prognosis for hepatorenal syndrome is usually poor and is related to liver function. Secondary problems, including fluid and electrolyte disorders, bleeding, infections, and encephalopathy, are vigorously treated. Treatments to increase renal perfusion include systemic vasoconstrictors (α-adrenergic agonists and telepressin) and albumin, which are effective in 50% of individuals with type 1 HRS. Vasoconstrictors also may be combined with TIPS as a bridge to liver transplant. Liver transplant reverses symptoms in most individuals and it may be combined with kidney transplantation.[230-232]

Disorders of the Liver

Autoimmune Hepatitis

Autoimmune hepatitis is a rare chronic, progressive T-cell–mediated inflammatory liver disease that affects females, both adults and children. Serologically, there is hypergammaglobulinemia and an association with human leukocyte antigens DR3 or DR4 and absence of viral hepatitis. Biopsy shows interface (parenchymal–connective tissue interface) hepatitis. Aspartate and alanine aminotransferase levels are elevated. There may be no symptoms or jaundice, fatigue, loss of appetite, and amenorrhea. Most individuals respond to immunosuppressive drug therapy (e.g., corticosteroids or in combination with azathioprine) with remission within 24 months. Relapses are common with treatment withdrawal. About 10% of cases require liver transplant.[233-235]

Viral Hepatitis

Viral hepatitis is a relatively common systemic disease that affects primarily the liver. Different strains of viruses cause different types of hepatitis: hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis D virus (HDV) associated with HBV, hepatitis C virus (HCV), and hepatitis E virus (HEV) (Table 41-7). Hepatitis A was previously known as infectious hepatitis, and hepatitis B as serum hepatitis. Coinfection of HBV, HCV, HDV,

TABLE 41-7 CHARACTERISTICS OF VIRAL HEPATITIS

CHARACTERISTIC	HEPATITIS A	HEPATITIS B	HEPATITIS D	HEPATITIS C	HEPATITIS E
Size of virus	27-nm RNA virus	47-nm DNA virus	36-nm RNA virus, defective virus with HBsAg coat	30- to 60-nm RNA virus	32-nm RNA virus
Incubation phase	30 days	60-180 days	30-180 days; dependent on HBV for multiplication	35-72 days	15-60 days
Route of transmission	Fecal-oral, parenteral, sexual	Parenteral, sexual	Parenteral, fecal-oral, sexual	Parenteral	Fecal-oral
Onset	Acute with fever	Insidious	Insidious	Insidious	Acute
Carrier state	Negative	Positive	Positive	Positive	Negative
Severity	Mild	Severe; may be prolonged or chronic	Severe	Mild to severe	Severe in pregnant women
Chronic hepatitis	No	Yes	Yes	Yes	No
Age-group affected	Children and young adults	Any	Any	Any	Children and young adults
Prophylaxis	Hygiene, immune serum globulin, HAV vaccine	Hygiene, HBV vaccine	Hygiene, HBV vaccine	Hygiene, screening blood, interferon-alpha or combined with ribavirin	Hygiene, safe water and meat

and HIV occurs because these viruses share the same routes of transmission (contact between infected body fluids, broken skin or mucous membranes, or intravenously). Progression of liver disease is more rapid in these cases.[236] Characteristics of the various types of hepatitis are presented in Table 41-7.

Hepatitis A Virus (HAV). HAV can be recovered from the feces, bile, and sera of infected individuals. The usual mode of transmission is the fecal-oral route (contaminated food or water), but the virus can be spread also by the transfusion of infected blood. Approximately 45% of adults in urban areas have HAV antibodies in their blood. The disease spreads readily in crowded, unsanitary conditions, usually through contaminated food or water. Person-to-person spread is more likely to occur in institutional care settings where there is contact between clients and caregivers who are not vaccinated.

The incubation period (the time between exposure and onset of symptoms) for HAV is 4 to 6 weeks (Figure 41-20). Fecal shedding of the virus is greatest for 10 to 14 days before the onset of symptoms and during the first week of symptoms and up to 3 months after onset of symptoms. The disease is most contagious during this time. Antibodies to HAV (anti-HAV) develop about 4 weeks after infection. The serum immunoglobulin M (IgM) concentration increases initially and is followed by an increase of serum IgG, whose levels remain elevated for several years after infection, creating immunity to the disease. (See Chapters 7 and 8 for a description of immune functions.) The administration of immunoglobulin before exposure or early in the incubation period can prevent hepatitis A. HAV vaccine and combined HAV and HBV vaccines are available and effective in preventing the disease and confer long-term immunity.[237] Transmission of HAV is prevented by handwashing and use of gloves when disposing fecal matter. Molecular procedures are available for direct surveillance of HAV in food and water.[238]

Hepatitis B Virus (HBV). HBV is transmitted through blood-blood contact and the sexual route. People who are immunosuppressed; receive hemodialysis, multiple blood transfusions, or immunosuppressive drugs; have multiple sex partners; or share needles, syringes, or other drug equipment or infants born to infected mothers have a greater risk of exposure or less resistance to HBV coinfection with HCV, HDV. HIV is common because these viruses share the same routes of transmission.[239,240]

Mother-infant transmission of HBV occurs if the mother becomes infected during the third trimester of pregnancy. In women who are seropositive for both hepatitis B surface antigen (HBsAg) and hepatitis B e antigen (HBeAg), vertical transmission is approximately 90%.[241,242] Transmission among homosexual men may be by oral or genital contact with bleeding lesions in the rectal mucosa. Up to 400 million people worldwide carry the hepatitis B surface antigen (HBsAg) marker for active HBV. HBV is a major cause of chronic hepatitis, cirrhosis, and hepatocellular carcinoma.[243]

Three types of viral particles are involved in HBV infection. The larger (47 nm) Dane particle probably represents the intact HBV. The Dane particle has a double-layered outer coat and carries HBsAg, which was originally called the *Australia antigen.* HBsAg can be identified in the serum by radioimmunoassay. Hepatitis B core antigen (HBcAg) usually is not detected in the serum. The HBeAg is a derivative of HBcAg and is a marker of HBV replication. The HBV has an incubation period of 6 to 8 weeks. The initial serologic change is a transient increase in IgM levels. Levels of IgG antibodies to HBsAg rise more slowly and remain elevated for years (Figure 41-21). Chronic infection develops in 15% to 30% of those with acute infection. HBV DNA measures viral load and the efficacy of drug treatment. Persistent liver cell injury and deregulation of cellular growth control genes lead to increased risk for cirrhosis and hepatocellular carcinoma.[244] Antiviral and immunomodulatory treatment for chronic hepatitis B includes monotherapy, combination therapy, and prevention of drug resistance. Vaccine prevents transmission of hepatitis B, the development of acute or chronic hepatitis B, and reduction of hepatocellular

carcinoma, particularly in high-risk populations. Mutant strains can develop with escape from vaccine protection or diagnosis with HBsAg.[245] Hepatitis B immunoglobulin provides postexposure prophylaxis against HBV after contact with blood or body fluids of individuals infected with hepatitis B.[246] HBV vaccine or a combined vaccine for HAV and HBV provides protective immunity.

Hepatitis C Virus (HCV). HCV (previously known as non-A, non-B hepatitis) is a parenterally transmitted flavivirus with six genotypes. About 40% of HCV cases involve intravenous drug users, who also have a high incidence of HIV infection.[247] Coinfection with HBV also is prevalent. Approximately 80% of cases develop chronic liver disease.[248] HCV is diagnosed through detection of anti-HCV IgG.[249] Persistent infection with recurring acute symptoms and elevated aminotransferase levels represent the clinical presentation. Antiviral drug therapy is available.[250] Progression of disease to cirrhosis or hepatocellular carcinoma is greatest among individuals with HIV or coexisting liver disease.[251] The variants of HCV make vaccine development difficult and resistance to drug therapy is common.[252] There is no vaccine for HCV. The Centers for Disease Control and Prevention have recommended that all persons born from 1945 through 1965 be screened for HCV infection.[253]

Hepatitis D Virus (HDV). HDV occurs in individuals with hepatitis B. The delta virus depends on the HBV for its replication because the viral coat consists of HBsAg molecules that are on the surface of HBV. Hepatitis D has been shown to suppress replication of HBV. Parenteral drug users have a high incidence of HDV infection. HDV symptoms can be mild or severe with progression to fulminant liver failure. HDV is diagnosed by the presence of antibodies directed against HDAg (anti-HD) and HDV RNA in serum. Treatment for chronic HDV includes pegylated interferon alpha and it is effective in about 25% of individuals. New treatments are in clinical development.[254,255]

Hepatitis E Virus (HEV). HEV is most common in Asian and African countries and is transmitted by the fecal-oral route, usually by way of contaminated water or uncooked meat. It is also found in developed countries and must be differentiated from drug-induced liver injury. Animal reservoirs of HEV include domestic pigs, wild boars, deer, and rodents. It is more prevalent among adults and has the highest mortality in pregnant women. Clinically, it resembles HAV and is diagnosed based on detection of anti-HEV IgM. A vaccine for HEV has been approved in China but not in other countries.[256,257]

PATHOPHYSIOLOGY. The pathologic lesions of hepatitis are similar to those caused by other viral infection. Hepatic cell necrosis, scarring, Kupffer cell hyperplasia, and infiltration by mononuclear phagocytes occur with varying severity. Cellular injury is promoted by cell-mediated immune mechanisms (i.e., cytotoxic T cells, T regulatory cells, and natural killer cells).[258] Regeneration of hepatic cells begins within 48 hours of injury. The inflammatory process can damage and obstruct bile canaliculi, leading to cholestasis and obstructive jaundice. In milder cases the liver parenchyma is not damaged. Damage tends to be most severe in cases of hepatitis B and hepatitis C. Hepatitis B is also associated with *acute fulminating hepatitis,* a rare form of the disease that is characterized by massive hepatic necrosis. Acute fulminating hepatitis causes severe encephalopathy, which is manifested as confusion, stupor, and coma. Liver failure can occur, leading to GI bleeding, cardiorespiratory insufficiency, and hepatorenal syndrome. Mortality is high, but recovery can be complete.

CLINICAL MANIFESTATIONS. The clinical manifestations of the various types of hepatitis are very similar. The spectrum of manifestations ranges from absence of symptoms to fulminating hepatitis, with rapid onset of liver failure and coma. Acute viral hepatitis causes abnormal liver function test results. The serum aminotransferase values, aspartate transaminase (AST) and alanine transaminase (ALT), are elevated, but their elevation may not be consistent with the extent of cellular damage. The clinical course of hepatitis usually consists of four phases: incubation, prodromal, icteric, and recovery phases. The **incubation phase** and manifestations vary depending on the virus (see Table 41-7).

Prodromal Phase. The **prodromal (preicteric) phase** of hepatitis begins about 2 weeks after exposure and ends with the appearance of jaundice. Fatigue, anorexia, malaise, nausea, vomiting, headache, hyperalgia, cough, and low-grade fever are prodromal symptoms that precede the onset of jaundice. About 10% of individuals may develop extrahepatic symptoms including rash, arthralgias, and purpura. HBV and HCV may cause nephritis related to glomerular immune complex deposition.[259,260] Infection with HCV may have no symptoms. Right upper abdominal pain is common, and a weight loss of 2 to 4 kg is not unusual. The infection is highly transmissible during this phase.

Icteric Phase (Jaundice). The **icteric phase** begins about 1 to 2 weeks after the prodromal phase and lasts 2 to 6 weeks. Individuals who develop chronic HBV infection do not become jaundiced and may not be diagnosed.[261] Hepatocellular destruction and intrahepatic bile stasis cause jaundice (icterus). The urine may be dark and the stools clay colored before the onset of jaundice from conjugated hyperbilirubinemia. The icteric phase is the actual phase of illness. The liver is enlarged, smooth, and tender, and percussion over the liver causes pain. During the icteric phase, gastrointestinal and respiratory symptoms subside, but fatigue and abdominal pain may persist or become more severe. The stools may be lighter in color as a result of cholestasis. Serum bilirubin levels range from 5 to 10 mg/dl, with conjugated bilirubin fraction increasing. The jaundice may last 2 to 6 weeks or longer. Mild and transient itching often accompanies jaundice. The prothrombin time may be prolonged in individuals with more serious forms of the disease.

Recovery Phase. The posticteric or **recovery phase** begins with resolution of jaundice, about 6 to 8 weeks after exposure. Although the liver may still be enlarged and tender, symptoms diminish. In most cases, liver function test results return to normal within 2 to 12 weeks after the onset of jaundice.

Chronic hepatitis may begin at this point and is associated with HBV, HCV, and HDV infection. **Chronic active hepatitis** is the persistence of clinical manifestations and liver inflammation after the acute stages. Liver function tests remain abnormal

BOX 41-6 CAUSES OF CIRRHOSIS

Hepatitis virus—B and C (common)
Excessive alcohol intake (common)
Idiopathic (common)
Nonalcoholic fatty liver disease (NAFLD), also known as nonalcoholic steatohepatitis (NASH)
Autoimmune disorders
- Autoimmune hepatitis
- Primary biliary cirrhosis
- Primary sclerosing cholangitis

Hereditary metabolic disorder
- α_1-Antitrypsin deficiency
- Hemochromatosis
- Wilson disease
- Glycogen or lipid storage diseases

Prolonged exposure to chemicals (e.g., carbon tetrachloride, cleaning and industrial solvents, copper salts)
Hepatic venous outflow obstruction
- Budd-Chiari syndrome
- Right sided heart failure

for longer than 6 months, and HBsAg persists. Chronic, active HBV and HBC is a predisposition to cirrhosis and primary hepatocellular carcinoma. Chronic active hepatitis constitutes a carrier state, and HBV and HCV can be transmitted from mothers to infants.[262]

EVALUATION AND TREATMENT. Diagnosis and treatment were previously described for the different types of hepatitis viruses. Physical activity may be restricted. A low-fat, high-carbohydrate diet is beneficial if bile flow is obstructed.

There should be no direct contact with blood or body fluids of individuals with hepatitis B or hepatitis C. A combined vaccine for HAV and HBV is available. Hepatitis B immunoglobulin provides passive prophylactic immunity against HBV. Prophylaxis is recommended for healthcare workers, liver transplant recipients, and others who are at risk for contact with infected body fluids.[263]

Cirrhosis

Cirrhosis is an irreversible inflammatory, fibrotic liver disease and the twelfth leading cause of death in the United States. Many disorders can cause cirrhosis and are summarized in Box 41-6. Alcohol abuse and viral hepatitis are the most common causes.[264] The process of cellular injury depends on the cause of cirrhosis; however, not all causes are clearly understood. Structural changes result from injury (alcoholism, viruses, steatosis, chemicals) and fibrosis. Fibrosis is a consequence of Kupffer cell (liver macrophages) activation with release of inflammatory mediators, reactive oxygen species, and growth factors and activation of fibrogenic fibroblasts.[265] Chaotic fibrosis alters or obstructs biliary channels and blood flow, producing jaundice and portal hypertension. New vascular channels form shunts, and blood from the portal vein bypasses the liver, contributing to portal hypertension, metabolic alterations, and toxin accumulation. The process of regeneration is disrupted by hypoxia, necrosis, atrophy, and (ultimately) liver failure. The formation of fibrous bands and regenerating nodules distorts the architecture of the liver parenchyma and gives the liver a cobbly appearance.[266] The liver may be larger or smaller than normal and is usually firm or hard when palpated. Cirrhosis develops slowly over a period of years. Its severity and rate of progression depend on the cause.

If alcohol is involved, the rate of cell death and the severity of inflammation depend on the amount of alcohol present.[267] Removal of alcohol slows the progression of liver damage and enhances the process of regeneration.

Alcoholic Liver Disease. Abuse of any type of alcoholic beverage can cause alcoholic liver disease and the severity of disease is related to the amount and duration of alcohol consumed and formation of acetaldehyde (see Chapter 2 and Figure 2-15).[267] The incidence of alcoholic cirrhosis is greatest in middle-aged men; however, women develop more severe liver injury than men.[268] In the United States, mortality resulting from cirrhosis is highest among Hispanic white males and females; however, the death rates for all groups are declining.[269] Malnutrition may add to the risk of cirrhosis in alcohol abusers. Many alcoholics are malnourished and the liver cannot regenerate without adequate nutrition. The spectrum of alcoholic liver disease includes steatosis, alcoholic hepatitis, and alcoholic cirrhosis (fibrosis).[270]

PATHOPHYSIOLOGY. **Alcoholic fatty liver (steatosis)** is the mildest form of alcoholic liver disease. It can be caused by chronic ingestion of relatively small amounts of alcohol (more than one alcoholic drink [14 grams of alcohol] per day for women and two alcoholic drinks [28 grams of alcohol] per day for men), may be asymptomatic, and is reversible with cessation of drinking.[271,272] Fat deposition (deposition of triglycerides) within the liver is caused primarily by increased lipogenesis and decreased fatty acid oxidation and fat metabolism by hepatocytes. Lipids mobilized from adipose tissue or dietary fat intake may contribute to fat accumulation.

Alcoholic hepatitis (steatohepatitis) is a precursor of cirrhosis characterized by inflammation; degeneration and necrosis of hepatocytes; infiltration of neutrophils, macrophages, and lymphocytes; immunologic alterations; and lipid peroxidation. The injured hepatocytes contain Mallory bodies (hyaline endoplasmic reticulum), indicating the onset of fibrosis. Neutrophils infiltrate and surround degenerating hepatocytes. The mechanism of hepatocyte injury is not clearly understood, but inflammatory mediators, acetaldehyde, reactive oxygen and nitrogen species, and genetic factors are involved.[273,274] Alcohol also increases gut permeability, and translocation of bacteria-derived lipopolysaccharide contributes to inflammation, oxidative stress, and the severity of alcoholic liver disease.[275] Serum IgA level is often elevated in individuals with alcoholic hepatitis, and liver antigens and antibodies have been identified in persons with progressive alcoholic liver disease.[276] The inflammation and necrosis caused by alcoholic hepatitis stimulate the fibrosis characteristic of the cirrhotic stage of disease. Corticosteroids and pentoxifylline are used for treatment.[277]

Alcoholic cirrhosis is caused by the toxic effects of alcohol metabolism on the liver, immunologic alterations, oxidative stress from lipid peroxidation, and malnutrition.[278] Alcoholic cirrhosis is more severe when associated with HCV.[279]

Although alcoholic cirrhosis is the most prevalent of the various types of cirrhosis, the occurrence of cirrhosis among persons with alcoholism is relatively low (approximately 35%). Alcohol is transformed to acetaldehyde. Excessive amounts of acetaldehyde are toxic and induce lipid peroxidation and oxidative stress and disrupt cytoskeletal and membrane function. Acetaldehyde inhibits export of proteins from the liver, alters metabolism of vitamins and minerals, promotes liver fibrosis, and contributes to malnutrition.[280] Mitochondrial function is impaired, decreasing oxidation of fatty acid. Enzyme and protein synthesis may be depressed or altered, and hormone and ammonia degradation is diminished. Alcohol also may stimulate the formation of autoantibodies specific to hepatic cells.[270] Alcohol also increases gut permeability, and translocation of bacteria-derived endotoxin from the intestine contributes to progressive injury and inflammation.[275] Cellular damage initiates an inflammatory response. Inflammatory cytokines, including TNF-α and IL-6, IL-8, and IL-18, and activation of complement are associated with alcoholic liver disease. Inflammation and necrosis result in excessive collagen formation. Transforming growth factor-beta (TGF-β) contributes to fibrosis and is produced in part by activated Kupffer cells. TGF-β activates hepatic stellate cells to produce excess collagen. Dense bands of fibrosis surround regenerative hepatocellular nodules. Fibrosis and scarring alter the structure of the liver and obstruct biliary and vascular channels and hepatocytes lose their ability to regenerate.[270] There is increased risk for hepatocellular carcinoma. Examples of liver damage are shown in Figure 41-22.

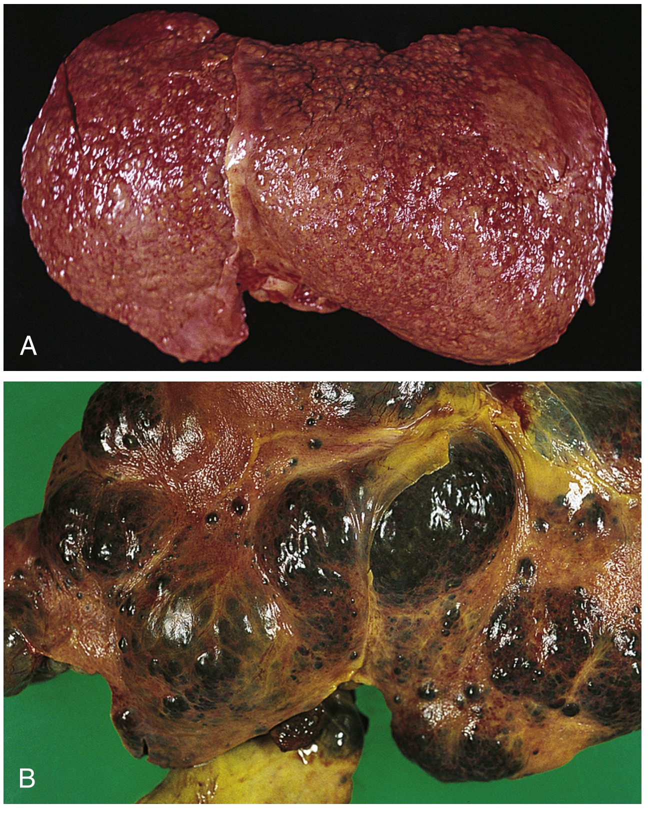

FIGURE 41-22 Cirrhosis. **A,** Micronodular cirrhosis. The nodular appearance develops from regeneration of hepatocytes projecting through fibrous bands of tissue. **B,** Macronodular cirrhosis. (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

CLINICAL MANIFESTATIONS. Fatty infiltration causes no specific symptoms or abnormal liver function test results. The liver is usually enlarged, however, and the individual has a history of continuous alcohol intake during the previous weeks or months. The clinical manifestations of alcoholic hepatitis can be mild or severe. Nonspecific symptoms include fatigue, weight loss, and anorexia. Manifestations of acute illness include nausea, anorexia, fever, abdominal pain, and jaundice.[281] Toxic effects of alcohol also can cause gynecomastia, testicular atrophy, reduced libido, azoospermia, and decreased testosterone level in men.[282] Cirrhosis is a multiple-system disease and causes hepatomegaly, splenomegaly, ascites, gastrointestinal hemorrhage, portal hypertension, hepatic encephalopathy, and esophageal varices. Anemia results from blood loss, malnutrition, and hypersplenism. Hepatorenal syndrome is usually a late complication. Risk for infection is greater, in part because of innate immune dysfunction.[283] The presence of numerous and severe manifestations increases the risk of death. The clinical features of alcoholic cirrhosis depend on the duration of the disease and the severity of liver damage (Figure 41-23).

EVALUATION AND TREATMENT. The diagnosis of alcoholic hepatitis is based on the individual's history and clinical manifestations. The results of liver function tests are abnormal, and serologic studies show elevated levels of serum enzymes and bilirubin and decreased serum albumin levels. Prolonged prothrombin time cannot easily be corrected with vitamin K therapy. Liver biopsy can confirm the diagnosis of cirrhosis, but biopsy is not necessary if clinical manifestations of cirrhosis are evident.

There is no specific treatment for alcoholic liver disease, but many of the complications are treatable. Rest, a nutritious diet, corticosteroids, antioxidants, drugs that slow fibrosis, and management of complications such as ascites, gastrointestinal bleeding, infection, and encephalopathy slow disease progression.[284] Cessation of alcohol consumption slows the progression of liver damage, improves clinical symptoms, and prolongs life. Although the liver damage is irreversible, measures that halt the inflammation and destruction of liver cells prolong life. Liver transplant is the treatment for liver failure and artificial liver support systems are being developed.[285,286]

Nonalcoholic Fatty Liver Disease and Nonalcoholic Steatohepatitis. **Nonalcoholic fatty liver disease (NAFLD)** is infiltration of hepatocytes with fat, primarily in the form of triglycerides, but it occurs in the absence of alcohol intake. It is associated with obesity (including obese children), high levels of cholesterol and triglycerides, metabolic syndrome, and type 2 diabetes mellitus, and is the most common chronic liver disease in the United States. Some individuals with NAFLD will develop **nonalcoholic steatohepatitis (NASH)** with hepatocellular injury, inflammation, and fibrosis; this condition is difficult to distinguish from alcohol-induced liver fibrosis.[272] NAFLD is usually asymptomatic and may remain undetected for years. The most severe forms of NASH progress to cirrhosis, end-stage liver disease, and an increased risk for hepatocellular carcinoma.[287]

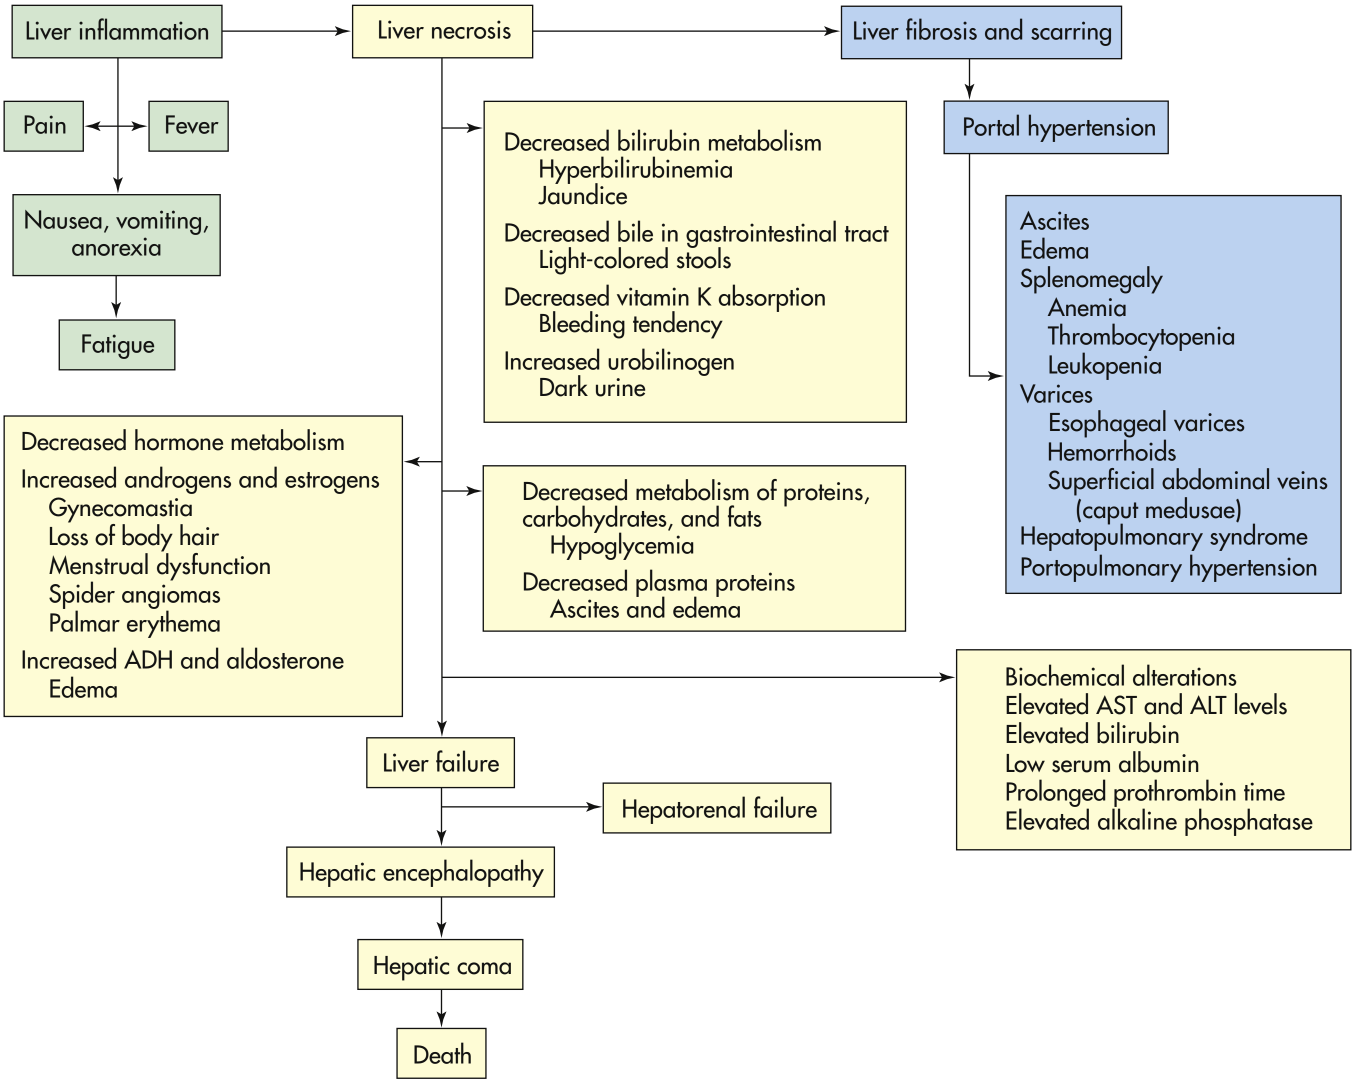

FIGURE 41-23 Clinical Manifestations of Cirrhosis. *ADH,* Antidiuretic hormone; *ALT,* alanine transaminase; *AST,* aspartate transaminase.

Biliary Cirrhosis. **Biliary cirrhosis** differs from alcoholic cirrhosis in that the damage and inflammation leading to cirrhosis begin in bile canaliculi and bile ducts, rather than in the hepatocytes. The two types of biliary cirrhosis are *primary* and *secondary*. Although both involve bile duct pathology, they differ with respect to cause, risk factors, and mechanisms of obstruction and inflammation.

Primary Biliary Cirrhosis. Primary biliary cirrhosis (PBC) is a T lymphocyte- and antibody-mediated destruction of the small intrahepatic bile ducts. The disease is thought to be caused by superimposed environmental antigens (e.g., infectious agents) in genetically susceptible individuals. Women are affected more commonly (90%) than men. Symptoms rarely develop before the age of 30 years. Primary biliary cirrhosis often accompanies other autoimmune diseases.[288]

PBC develops insidiously. Antimitochondrial antibody is the hallmark of the disease and 30% to 50% of individuals have antinuclear antibodies. Expression of glycoprotein 210 (gp210) antibodies and anticentromere antibodies confers different risks for disease progression with anti-gp210 causing the most severe disease.[289] Pathogenesis includes inflammation, destruction, fibrosis, and obstruction of the intrahepatic bile ducts. Nodular regeneration, cirrhosis, and portal hypertension can develop during later stages of the disease.

Diagnosis is based on two of the following three criteria: (1) biochemical evidence of cholestatic liver disease for at least 6-month's duration, (2) antimitochondrial antibody (AMA) positivity, and (3) histologic features of PBC on liver biopsy.[290] Serologic tests show elevated levels of alkaline phosphatase and γ-glutamyl transpeptidase, hyperbilirubinemia, and hyperlipidemia with or without other clinical manifestations. Most individuals have a circulating IgG antimitochondrial antibody that is not found in other types of liver disease. Biopsy shows cholangitis and excludes other inflammatory liver diseases. Evaluation involves ruling out biliary obstruction caused by gallstones, tumor, or inflammation of the common bile duct (i.e., secondary biliary cirrhosis).

Individuals with primary biliary cirrhosis may be asymptomatic or symptomatic at diagnosis and may have minimal disease or rapid progression to cirrhosis and liver failure. The

earliest manifestations are pruritus, fatigue, and abdominal pain. Jaundice and light-colored stools are symptoms of advanced disease. These symptoms are caused by intrahepatic obstruction of bile flow. Steatorrhea and fat-soluble vitamin deficiencies are present in some cases. The malabsorption can lead to osteomalacia and osteoporosis. Cirrhosis, symptoms of portal hypertension, encephalopathy, and ultimately liver failure develop in untreated individuals.

Long-term treatment with ursodeoxycholic acid is highly effective.[288] The distressing pruritus may be relieved by cholestyramine, which binds bile salts in the intestine. Intramuscular injections of vitamins D and K alleviate the vitamin deficiency. The other symptoms of cirrhosis are managed as they develop. Liver transplant is the only option for those with progressive disease not responding to medical treatment.[291]

Secondary Biliary Cirrhosis. **Secondary biliary cirrhosis** develops when there is prolonged partial or complete obstruction of the common bile duct or its branches. The obstruction may be caused by gallstones, tumors, fibrotic strictures, or chronic pancreatitis. Biliary atresia and cystic fibrosis cause secondary biliary cirrhosis in children.

Chronic obstruction to bile flow increases pressure in the hepatic bile duct and results in the accumulation of bile in the centrilobular spaces. Necrotic areas develop and are followed by proliferation and inflammation of the portal ducts that result in edema and fibrosis. Pools of bile form when the portal ducts rupture into surrounding necrotic areas. Injury is accompanied by regeneration of hepatic cells with the development of finely nodular cirrhosis.

Clinical manifestations are similar to those of primary biliary cirrhosis, with jaundice and pruritus the most distressing symptoms. Right upper quadrant pain is common, and a low-grade fever may be present from bile duct inflammation (cholangitis).

Cholangiography provides the most definitive diagnosis. Laboratory tests usually show elevated conjugated bilirubin and alkaline phosphatase levels. Aminotransferase level increases if there is an accompanying cholangitis. Surgery or endoscopy relieves obstruction, prolongs survival, and diminishes or resolves symptoms. Continued obstruction leads to advanced cirrhosis and liver failure.

Primary Sclerosing Cholangitis. Primary sclerosing cholangitis (PSC) is a chronic inflammatory fibrotic disease of the hepatic bile ducts that leads to secondary biliary cirrhosis. The disease is immune-mediated but the exact mechanism is unknown. PSC is associated with inflammatory bowel disease (75%) and primarily affects genetically susceptible males. There is no effective sustaining medical or surgical therapy and liver transplant is required for liver failure.[292,293]

Disorders of the Gallbladder

Obstruction and inflammation are the most common disorders of the gallbladder. Obstruction is caused by **gallstones** (cholelithiasis), which are aggregates of substances in the bile. The gallstones may remain in the gallbladder or be ejected, with bile, into the cystic duct. Gallstones that become lodged in the cystic duct obstruct the flow of bile into and out of the gallbladder and cause inflammation. Gallstone formation is termed *cholelithiasis*. Inflammation of the gallbladder or cystic duct is known as *cholecystitis*.

FIGURE 41-24 Resected Gallbladder Containing Mixed Gallstones. (From Kissane JM, editor: *Anderson's pathology,* ed 9, St Louis, 1990, Mosby.)

Cholelithiasis (Gallstones)

Cholelithiasis is a prevalent disorder in developed countries, where the incidence is 10% to 15%. The actual incidence is unknown because many individuals who have gallstones are asymptomatic. Risk factors include obesity; rapid weight loss in obese individuals; middle age; female gender; use of oral contraceptives; American Indian ancestry; gallbladder, pancreatic, or ileal disease; low HDL cholesterol level and hypertriglyceridemia; and gene-environmental interactions.[294]

PATHOPHYSIOLOGY. Gallstones are commonly of two types: cholesterol and pigmented. Cholesterol stones are the most common. *Cholesterol gallstones* form in bile that is supersaturated with cholesterol produced by the liver. Supersaturation sets the stage for cholesterol crystal formation, or the formation of "microstones." More crystals then aggregate on the microstones, which grow to form "macrostones" within a mucin matrix. This process usually occurs in the gallbladder. The stones may lie "silent" or become lodged in the cystic or common duct, causing pain and cholecystitis. Gallstone formation may be such that the stones accumulate and fill the entire gallbladder (Figure 41-24).

It is not known why the hepatocytes secrete bile that is supersaturated with cholesterol. Proposed mechanisms include: (1) an enzymatic defect that increases the hepatocytes' synthesis of cholesterol; (2) diminished secretion of bile acids, which normally promote cholesterol solubility; (3) decreased resorption of bile salts from the ileum, which decrease the bile acid pool; (4) gallbladder smooth muscle hypomotility and stasis; (5) genetic predisposition; and (6) some combination of these mechanisms.[295] In obese individuals the mechanism appears to involve cholesterol synthesis, whereas in nonobese individuals, it appears to involve decreased secretion of bile acids.

Pigmented stones are black (hard) or brown (soft). Black pigmented stones are formed in a sterile environment and consist primarily of calcium bilirubinate polymer. They are associated with hyperbilirubinbilia (biliary hypersecretion of bilirubin conjugates) and hemolytic diseases, such as sickle cell anemia and Gilbert syndrome (hereditary hyperbilirubinemia). The formation of brown stones is associated with bacterial infection of the bile ducts with formation of stone composed of calcium soaps, unconjugated bilirubin, cholesterol, fatty acids, and mucin. They are more common in East Asia.[296]

CLINICAL MANIFESTATIONS. Epigastric and right hypochondrium pain and intolerance to fatty foods are the cardinal manifestations of cholelithiasis. Vague symptoms include heartburn, flatulence, epigastric discomfort, pruritus, jaundice, and food intolerances, particularly to fats and cabbage. The pain, often called *biliary colic,* is most characteristic and is caused by the lodging of one or more gallstones in the cystic or common duct.[297] The pain can be intermittent or steady. It usually is located in the right upper quadrant and radiates to the mid-upper back. Jaundice indicates that the stone is located in the common bile duct. Abdominal tenderness and fever indicate cholecystitis. Complications can include pancreatitis from obstruction of the pancreatic duct.

EVALUATION AND TREATMENT. Diagnosis is based on the individual's medical history, physical examination, and imaging evaluation. An oral cholecystogram usually outlines the stones. Intravenous cholangiography is used to differentiate cholelithiasis from other causes of extrahepatic biliary obstruction if the cholecystogram is negative. Endoscopic or percutaneous cholangiography and endoscopic or transabdominal ultrasonography are diagnostic options.[298]

Laparoscopic cholecystectomy is the preferred treatment for gallstones that cause obstruction or inflammation. Use of transluminal endoscopic surgery is advancing rapidly. Endoscopic retrograde cholangiopancreatography and sphincterotomy with stone retrieval is used for the treatment of bile duct stones. Large stones may be managed with lithotripsy.[299,300] An alternative treatment is the administration of drugs that dissolve smaller stones. For example, the bile acid chenodeoxycholic acid (CDCA) can completely or partially dissolve cholesterol gallstones. Ursodeoxycholic acid (UDCA), which is structurally similar to CDCA, is also effective, is less toxic to hepatocytes, and does not cause fatty diarrhea, as does CDCA.

Cholecystitis

Cholecystitis can be acute or chronic. Both forms are almost always caused by the lodging of a gallstone in the cystic duct. Obstruction causes the gallbladder to become distended and inflamed. The pain is similar to that caused by gallstones. Pressure against the distended wall of the gallbladder decreases blood flow. Ischemia, necrosis, and perforation of the gallbladder are possible. Fever, leukocytosis, rebound tenderness, and abdominal muscle guarding are common findings. Serum bilirubin and alkaline phosphatase levels may be elevated. Nevertheless, the acute abdominal pain of cholecystitis must be differentiated from the pain caused by other disorders, such as pancreatitis, intestinal vascular insufficiency, and acute pyelonephritis of the right kidney. Cholescintigraphy tracks the production and flow of bile from the liver to the gallbladder and small intestine and shows if bile is blocked at any point along the way; it has the highest diagnostic accuracy but involves the use of ionizing radiation. Ultrasound and magnetic resonance imaging have a substantial margin of error but can demonstrate nonspecific morphologic changes.[301]

Treatment includes pain control, replacement of fluid and electrolytes, and fasting. Antibiotics are often prescribed to manage bacterial infection in severe cases. Immediate cholecystectomy is required for complications such as peritonitis from gallbladder perforation. Persistent symptoms or development of chronic cholecystitis punctuated by recurrent acute attacks usually requires cholecystectomy.[302]

Disorders of the Pancreas

Pancreatitis, or inflammation of the pancreas, is a relatively rare (about 17 cases per 100,000 people in the United States)[303] and a potentially serious disorder. Incidence is about equal in men and women and is more common between 50 and 60 years of age. Risk factors include alcoholism, obstructive biliary tract disease (particularly cholelithiasis), peptic ulcers, abdominal trauma, hyperlipidemia, certain drugs, and genetic factors (hereditary pancreatitis, cystic fibrosis). The cause is unknown in 15% to 25% of cases.[304] Pancreatitis can be acute or chronic.

Acute Pancreatitis

Acute pancreatitis is usually a mild disease and resolves spontaneously, but about 20% of those with the disease develop a severe acute pancreatitis requiring hospitalization. Pancreatitis develops because of obstruction to the outflow of pancreatic digestive enzymes caused by bile duct or pancreatic duct obstruction (e.g., gallstones). Chronic alcohol use may also cause spasm of the sphincter of Oddi and formation of protein plugs in pancreatic ducts, resulting in obstruction. Acute pancreatitis can also result from direct cellular injury from drugs or viral infection.[305]

PATHOPHYSIOLOGY. In obstructive disease, the backup of pancreatic secretions causes activation and release of enzymes (activated trypsin activates chymotrypsin, lipase, and elastase) within the pancreatic acinar cells. The activated enzymes cause autodigestion (e.g., proteolysis, lipolysis) of pancreatic cells and tissues, resulting in inflammation. The autodigestion causes vascular damage, coagulative necrosis, fat necrosis (see Chapter 2), and formation of pseudocysts (walled-off collections of pancreatic secretions).[306] Edema within the pancreatic capsule leads to ischemia and can contribute to necrosis.

Systemic effects are associated with severe acute pancreatitis. Proinflammatory cytokines (e.g., interleukin-6, tumor necrosis factor-alpha, transforming growth factor-beta, and platelet-activating factor) and vasoactive peptides are released into the bloodstream. Activation of leukocytes, injury to vessel walls, and coagulation abnormalities with development of vasodilation, hypotension, and shock occur.[307] These systemic effects can lead to acute respiratory distress syndrome (ARDS), heart failure, renal failure, coagulopathies, and the systemic inflammatory response syndrome (SIRS) (see Chapter 48) (Figures 41-25 and 41-26). Translocation of intestinal bacteria to the bloodstream may cause peritonitis or sepsis. Anti-inflammatory cytokines and specific cytokine inhibitors are produced in response to the systemic inflammatory response and may increase risk of infection.[308] As the pancreatitis progresses, pancreatic stellate cells become activated, causing pancreatic fibrosis, strictures, and duct obstruction and leading to chronic pancreatitis.

CLINICAL MANIFESTATIONS. Epigastric or midabdominal pain is the cardinal symptom of acute pancreatitis. The pain may radiate to the back because of the retroperitoneal location of

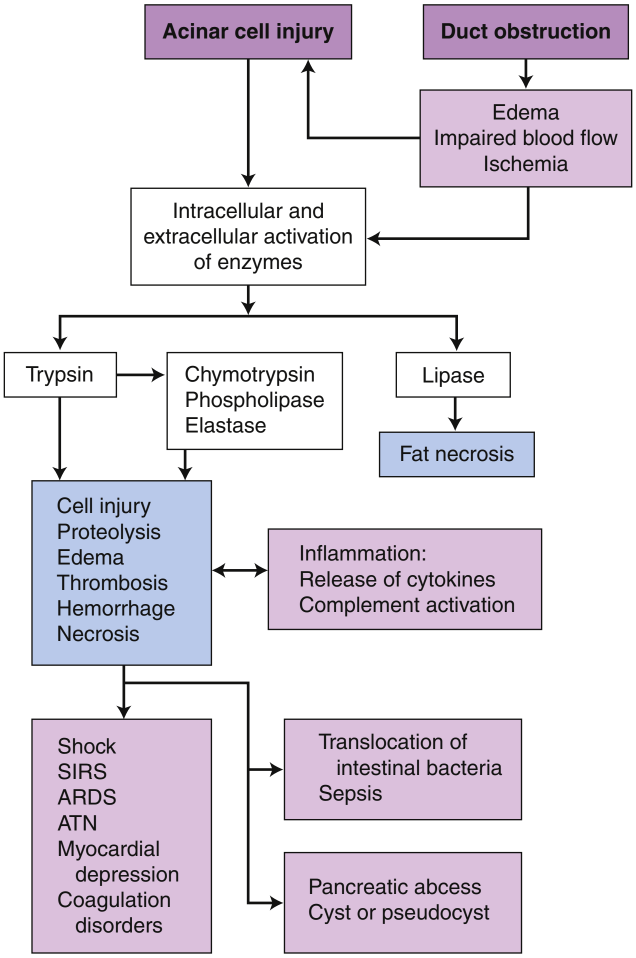

FIGURE 41-25 Pathophysiology of Acute Pancreatitis. *ARDS,* Acute respiratory distress syndrome; *ATN,* acute tubular necrosis; *SIRS,* systemic inflammatory response syndrome.

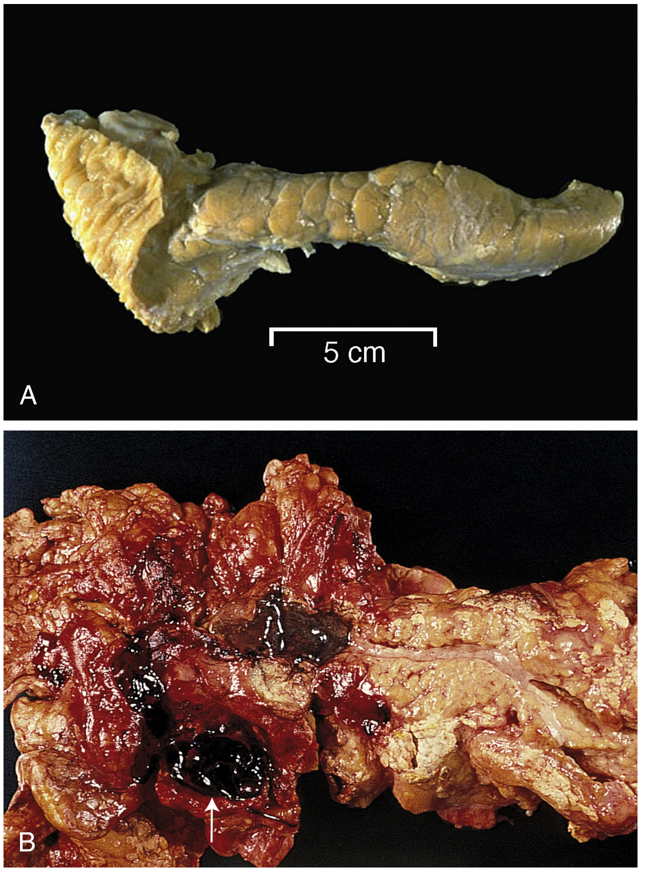

FIGURE 41-26 Acute Severe Pancreatitis with Hemorrhage. **A,** Normal pancreas. **B,** Acute hemorrhagic pancreatitis. The pancreas has hemorrhage, fat necrosis *(white patches),* and a pseudocyst filled with blood *(white arrow).* (**A** from Klatt EC, editor: *Robbins and Cotran atlas of pathology,* Philadelphia, 2006, Saunders. **B** from Damjanov I, Linder J, editors: *Pathology: a color atlas,* St Louis, 2000, Mosby.)

the pancreas. The pain is caused by edema, which distends the pancreatic ducts and capsule; chemical irritation and inflammation of the peritoneum; and irritation or obstruction of the biliary tract. Fever and leukocytosis accompany the inflammatory response. Nausea and vomiting are caused by hypermotility or paralytic ileus secondary to the pancreatitis or peritonitis.

Abdominal distention accompanies bowel hypermotility or paralytic ileus and the accumulation of fluids in the peritoneal cavity (ascites). Hypotension and shock occur with hypovolemia and SIRS.[309] Tachypnea and hypoxemia are indicative of ascites, diaphragmatic irritation, or respiratory complications.[310] In severe cases, hypovolemia decreases renal blood flow sufficiently to impair renal function.[311-313] Transient hyperglycemia also can occur if glucagon is released from damaged A cells in the pancreatic islets. SIRS and multiple organ failure account for most deaths with severe pancreatitis.[307] In severe acute pancreatitis, some individuals develop flank or periumbilical ecchymosis, a sign of poor prognosis.

EVALUATION AND TREATMENT. Diagnosis of pancreatitis is based on clinical findings, identification of associated disorders, laboratory studies, and imaging techniques (CT scan, MRI, and ultrasonography). Elevated serum lipase level is the primary diagnostic marker for acute pancreatitis. Serum lipase levels increase within 4 to 8 hours of clinical symptom onset and decrease within 8 to 14 days. Serum amylase level is elevated but is not diagnostic of severity or specificity of disease. Serum trypsin levels are very specific for pancreatitis but the test is not widely available.[314] C-reactive protein, procalcitonin, blood urea nitrogen, and Bedside Index of Severity in Acute Pancreatitis are predictors of severity.[315,316]

Acute pancreatitis is difficult to diagnose because several other disorders can cause similar clinical and laboratory findings (e.g., perforating duodenal ulcer, acute cholecystitis, and kidney stones). Intra-abdominal pressure monitoring assesses risk for abdominal compartment syndrome[317] (see What's New? Abdominal Compartment Syndrome).

There is no specific treatment for acute pancreatitis. The goal of treatment is to stop the process of autodigestion and prevent systemic complications. Hemodynamic monitoring and parenteral fluids are essential to restore blood volume and prevent hypotension and shock, particularly in the first 24 hours. Narcotic medications may be needed to relieve pain. Meperidine hydrochloride (Demerol) is used instead of morphine because it causes less spasm of the sphincter of Oddi than morphine. Nasogastric suction may not be necessary with mild pancreatitis but may help relieve pain and prevent

WHAT'S NEW?

Abdominal Compartment Syndrome

Abdominal compartment syndrome (ACS), also known as *intra-abdominal hypertension,* develops when there is abnormally high intra-abdominal pressure associated with organ dysfunction. It occurs in 20% to 40% of intensive care unit patients. ACS is associated with abdominal injury, including trauma, ruptured aortic aneurysm, acute pancreatitis, sepsis, significant thermal injury, liver failure with ascites, and massive fluid volume replacement with mechanical ventilation. Increased intra-abdominal pressure increases intrathoracic, intracardiac, and intracranial filling pressures and results in decreased cardiac output, atelectasis, pulmonary edema, oliguria, compromise of splanchnic and hepatic blood flow, and translocation of bacteria from the gut. The end consequence is multiple organ failure.

Normally intra-abdominal pressure is slightly greater than atmospheric pressure (5 to 7 mmHg, up to 12 mmHg). Organ dysfunction develops at pressures greater than 20 mmHg that last for more than 6 hours. ACS is difficult to detect from physical diagnosis alone. Automated serial or continuous monitoring of pressure inside the bladder provides a reliable estimate of intra-abdominal pressure. Gastric monitoring is not always feasible and inferior vena cava monitoring is more invasive. Treatment is tiered medical management and decompressive laparotomy, which may be performed at the bedside if the individual is too unstable to move. Elevating the head of the bed to 30 degrees is helpful for some individuals.

Data from Luckianow GM et al: *Crit Care Res Pract* 2012:908169, 2012; Starkopf J, Tamme K, Blaser AR: *Ann Intensive Care* 2(Suppl 1):S9, 2012; Yi M et al: *J Crit Care* 27(2):222.e1e–6, 2012.

paralytic ileus in individuals who are nauseated and vomiting. Feeding is usually initiated within 24 to 48 hours if ileus is not present. In severe acute pancreatitis, enteral nutrition with use of jejunal tube feeding is usually well tolerated and may decrease pancreatic enzyme secretion, prevent gut bacterial overgrowth, and maintain gut barrier function. Parenteral hyperalimentation should be initiated only when enteral feeding is not tolerated. Drugs that decrease gastric acid production (e.g., H2 receptor antagonists) can decrease stimulation of the pancreas by secretin. Necrotizing pancreatitis requires surgical resection, and antibiotics may control infection. The risk of mortality increases significantly with the development of pulmonary, cardiac, and renal complications.[318]

Chronic Pancreatitis

Chronic alcohol abuse is the most common cause of **chronic pancreatitis** because repeated exacerbations of acute pancreatitis can lead to chronic changes. Obstruction from gallstones, autoimmune disease, gene mutations, smoking, occupational chemical exposure, and obesity are associated with chronic pancreatitis. The disease is idiopathic in about 25% of cases. Toxic metabolites and chronic release of inflammatory cytokines contribute to the destruction of acinar cells and islets of Langerhans. The pancreatic parenchyma is destroyed and replaced by fibrous tissues, strictures, calcification, ductal obstruction, and pancreatic cysts. The cysts are walled-off areas or pockets of pancreatic juice, necrotic debris, or blood within or adjacent to the pancreas. Continuous or intermittent abdominal pain is the classic symptom. Pain is associated with increased intraductal pressure, increased tissue pressure, ischemia, neuritis, ongoing injury, and changes in central pain perception. Weight loss and, less commonly, steatorrhea and diabetes mellitus accompany disease progression and require treatment with oral lipase and insulin. Autoimmune chronic pancreatitis is treated with corticosteroids. Preventing disease progression includes lifestyle modification to stop alcohol use and smoking. Pain management is complex with use of analgesics, endoscopic therapy, nerve block, and surgical drainage of cysts or partial resection of the pancreas.[319-321] Chronic pancreatitis is a risk factor for pancreatic cancer.[322]

CANCER OF THE DIGESTIVE SYSTEM

Cancer occurs throughout the alimentary tract and the accessory organs of digestion (liver, gallbladder, and pancreas) (Table 41-8). A genetic predisposition is being evaluated.[323]

Cancer of the Gastrointestinal Tract

Cancer of the Esophagus

Carcinoma of the esophagus is a rare disease with 17,990 new cases and 15,210 deaths in 2013 in the United States.[324] Squamous cell carcinoma is more prevalent in China, Iran, South America, and South Africa. Squamous cell carcinoma is found in the upper two thirds of the esophagus and is associated with smoking and alcohol ingestion. Adenocarcinoma accounts for about 58% of esophageal carcinoma cases in the United States and is increasing. Adenocarcinoma is found in the distal one third of the esophagus and is associated with risk factors that include smoking, abdominal obesity, reflux esophagitis, and sliding hiatal hernia. Carcinomas are most common at the gastroesophageal junction.[325]

PATHOGENESIS. The pathogenesis of esophageal carcinoma is facilitated by (1) chronic inflammation, metaplasia, and dysplasia caused by gastroesophageal reflux (**Barrett esophagus);** and (2) long-term exposure to irritants, such as alcohol and tobacco, that cause neoplastic transformation (see Chapter 12). Both genomic and epigenomic events are associated with Barrett esophagus and mutation of the *TP53* gene is an early event.[326,327] The *CagA*-positive strain of *H. pylori* may be a protection against esophageal adenocarcinoma.[328]

CLINICAL MANIFESTATIONS. Early stages of esophageal carcinoma are asymptomatic. The two main manifestations of esophageal carcinoma are chest pain and dysphagia. The most common type of pain is heartburn (pyrosis). It is initiated by eating spicy or highly seasoned foods and by lying down. Dysphagia (pain on swallowing), another common symptom, is usually pressure-like and may radiate posteriorly between the scapulae. Some individuals with esophageal cancer complain of a constant retrosternal pain that radiates to the back. Dysphagia usually progresses rapidly.

EVALUATION AND TREATMENT. Individuals who present with dysphagia undergo endoscopy so that specimens can be examined for neoplastic change and type of carcinoma. CT studies of the thorax also are used for diagnosis. Treatment of gastroesophageal reflux is essential for the prevention of Barrett esophagus. Barrett esophagus with high-grade dysplasia is treated with endoscopic radiofrequency ablation, cryotherapy, or resection.[329]

TABLE 41-8 CANCER OF THE GUT, LIVER, AND PANCREAS*

ORGAN	PERCENTAGE OF DEATHS OF ALL CANCERS	RISKS	CELL TYPE	COMMON MANIFESTATIONS
Esophagus	2	Malnutrition Alcohol Tobacco Chronic reflux	Squamous cell Adenocarcinoma	Chest pain Dysphagia

Amended with permission from the American Cancer Society: *Cancer facts and figures, 2009,* Atlanta, GA, 2009, Author.
***Note:** Esophageal (men), colorectal, liver, and pancreatic cancers are within the top 10 causes of death from cancer.

Untreated esophageal cancer metastasizes rapidly and has a poor prognosis. At the time of diagnosis, 50% of esophageal cancers present with metastatic disease. The lymphatic vessels of the esophagus are continuous with vital mediastinal structures (trachea, heart, and great vessels) and drain to the celiac lymph nodes, making it impossible to remove all the lymph nodes with the tumor. Removal of the primary lesion and the local lymph nodes, however, can benefit the individual with esophageal cancer and cure is likely if there is no metastasis. If spread has occurred, treatment is combined radiation, chemotherapy, and palliative care (e.g., self-expanding metal stents).[330]

Cancer of the Stomach

Although the incidence of gastric cancer has declined in the United States, it still represents about 2% (21,600 cases) of all new cancer cases and 10,990 deaths in 2013.[324] The majority of cases are adenocarcinoma. The incidence of gastric cancer is greater in men than in women. In countries such as Eastern Asia, Eastern Europe, and South America, the incidence of stomach cancer has remained consistently high.[331] Nonenvironmental risk factors include a family history of gastric adenocarcinoma; blood type (blood group A); type A atrophic gastritis; and pernicious anemia, which is associated with atrophy of the gastric mucosa in the same locations where gastric tumors arise.[332-334]

The most important environmental risk factors in causing gastric cancer are: (1) infection with *H. pylori* that carries the *CagA* gene product cytotoxin-associated antigen A (80% of cases); (2) dietary factors, such as salt added to food, food additives (e.g., nitrates) in pickled or salted foods (e.g., bacon), and low intake of fruits and vegetables; and (3) lifestyle, such as alcohol consumption and cigarette smoking. Infection with *H. pylori* and severe chronic gastritis change the mucosal cell proliferation pattern, destroy cell junctions, inhibit cell proliferation, and promote cell invasive ability, increasing the risk for gastric and duodenal carcinoma.[335-337]

H. pylori also is causatively linked to **mucosa-associated lymphoid tissue (MALT) lymphoma** (a low-grade B-cell lymphoma) that can originate in the stomach. Dietary salt enhances the conversion of nitrates to carcinogenic nitrosamines in the stomach. Salt is also caustic to the stomach and can cause chronic atrophic gastritis. Hypertonic salt solutions delay gastric emptying. Delayed emptying increases the time during which carcinogenic nitrosamines can exert their effects on the stomach mucosa. Nitrates interact with amino acids in the stomach to form nitrosamines. The conversion of these carcinogenic nitrosamines is enhanced at a low pH by iodides and thiocyanates. Nitrates are thought to be active only when converted to nitrites and to cause stomach cancer once atrophic gastritis has occurred. Smoking decreases the production of prostaglandins that maintain gastric mucosal integrity, and smokers have a higher incidence of *H. pylori* infection.[338]

PATHOGENESIS. Gastric adenocarcinoma usually begins in the glands of the stomach mucosa. Approximately 50% of all gastric cancers develop in the prepyloric antrum (Figure 41-27). Atrophic gastritis and intestinal metaplasia are strongly linked to the development of gastric cancer. Insufficient acid secretion by the atrophic mucosa creates a relatively alkaline environment that permits bacteria to multiply and act on nitrates. The resulting increase in nitrosoamines damages the deoxyribonucleic acid (DNA) of mucosal cells further, promoting metaplasia and neoplasia. Duodenal reflux also may contribute to intestinal metaplasia. The reflux contains caustic bile salts that destroy the mucosal barrier that normally protects the stomach. Epigenetic alterations (DNA methylation, histone methylation, and histone acetylation) and multiple genes are involved in gastric cancer including oncogenes, tumor-suppressor genes, DNA repair genes, and cell cycle regulator genes. Genetics also can distinguish well-differentiated (intestinal) from undifferentiated (diffuse) gastric adenocarcinomas. About 10% to 15% of gastric cancers are familial.[339,340]

CLINICAL MANIFESTATIONS. The early stages of gastric cancer are generally asymptomatic or produce vague symptoms such as loss of appetite (especially for meat), malaise, and unexplained weight loss. Later manifestations include upper abdominal pain, vomiting, change in bowel habits, and anemia caused by persistent occult bleeding. The prognosis is poor because symptoms usually do not occur until the tumor has penetrated the muscle layers of the stomach, spread to surrounding tissues, and entered the draining lymph nodes and veins, causing distant metastases. Generally the first manifestations of carcinoma are caused by distant metastases.

EVALUATION AND TREATMENT. The choice of diagnostic tests depends on the clinical manifestations at the time of presentation. Most symptoms suggest a problem in the upper gastrointestinal tract. Direct endoscopic visualization and biopsy usually establish the diagnosis, or microscopic examination of exfoliated cells obtained by lavage during endoscopy.

Surgery is the treatment for gastric cancer. Staging is determined by pathologic findings after resection. Chemotherapy combined with chemoradiotherapy may provide the best postoperative outcomes. Five-year survival is less than 20%. Screening and eradication of *H. pylori* infection is the best preventive approach to gastric cancer and remission of gastric MALT lymphoma.[341] Dietary modifications include high intake of fruits and vegetables, vitamin C, carotenoids, and fiber and reduced intake of salt, salted food, and red meat.[342]

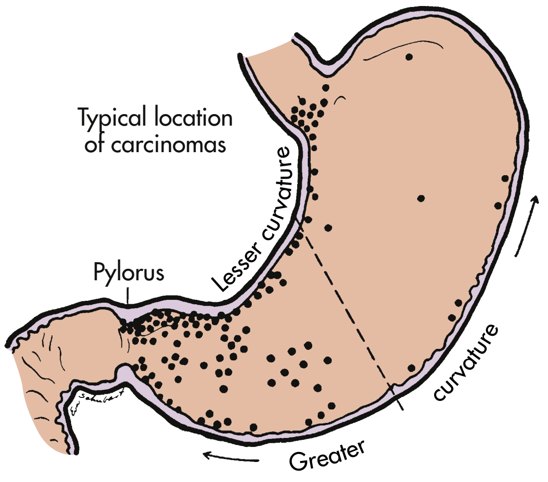

FIGURE 41-27 Typical Sites of Stomach Cancer. (From del Regato JA, Spjut HJ, Cox JD: *Cancer: diagnosis, treatment, and prognosis,* ed 2, St Louis, 1985, Mosby.)

Cancer of the Small Intestine

Small intestine carcinoma is rare and represents less than 3% of gastrointestinal cancers (8810 estimated new cases and 1170 deaths in 2013).[324] Adenocarcinoma is the most common tumor type followed by carcinoid (neuroendocrine) tumors.[343] Carcinoma occurs more frequently in familial adenomatous polyposis and Crohn disease.[344] Long-term management includes frequent screening and endoscopic surveillance.[345]

Cancer of the Colon and Rectum

Cancer of the lower intestinal tract (colon [78%], rectum [28%]) is the third most common cause of cancer death in the United States for men and women. Colon and rectal cancer (CRC) accounted for an estimated 102,480 colon and 40,340 rectal new cancer cases, and 50,830 deaths (colon and rectal combined) in 2013. The median age at diagnosis was 69 years in 2009. It is more common in blacks[324] worldwide, and the prevalence of colorectal cancer is highest in populations with high socioeconomic standards.[346,347] CRC develops in individuals with an acquired or inherited genetic predisposition who are exposed to a combination of environmental risk factors (Box 41-7).

BOX 41-7 SELECTED RISK FACTORS AND COLORECTAL CANCER

Higher Risk
- Family history of colorectal cancer
- Familial adenomatous polyposis
- Inflammatory bowel disease
- Smoking or chewing tobacco
- Obesity
- Alcohol consumption
- Red meat consumption
- Type 2 diabetes mellitus
- High-fat, low-fiber diet

Lower Risk
- Diets high in cereal grains, vegetables, milk; fish; folic acid, calcium, and vitamin D; magnesium and selenium
- Postmenopausal estrogen use
- Physical activity
- Use of NSAIDs

Data from Aune D et al: *Ann Oncol* 23(1):37–45, 2012; Aune D et al: *BMJ* 343:d6617, 2011; Avivi D et al: *Exp Opin Ther Targets* 16(Suppl 1): S51–S62, 2012; Bardou M et al: *Gut* 62(6):933–947, 2013; Kennedy DA et al: *Cancer Epidemiol* 35(1):2–10, 2011; Méplan C, Hesketh J: *Mutagenesis* 27(2):177–186, 2012; Meyerhardt JA: *Semin Oncol* 38(4):533–541, 2011; Schrör K: *Best Pract Res Clin Gastroenterol* 25(4-5):473–484, 2011; Wu S et al: *Am J Med* 125(6):551–559, 2012; Yuhara H et al: *Am J Gastroenterol* 106(11):1911–1921, 2011; Zhang X, Giovannucci E: *Best Pract Res Clin Gastroenterol* 25(4-5):485–494, 2011.

PATHOGENESIS. Genetic and environmental factors (epigenetics, see Chapter 6)[348] are associated with the development of CRC (Figure 41-28). CRC can develop through molecular pathways, gene mutations, and genomic instability (the cell cycle loses control of the gene mutation rate). Gene mutations may be inherited or acquired after birth (somatic mutations). Family history of CRC occurs in about 25% of cases but only 5% to 6% of these are related to highly penetrating gene mutations, mostly autosomal dominant (e.g., familial adenomatous polyposis [FAP] and hereditary nonpolyposis colorectal cancer

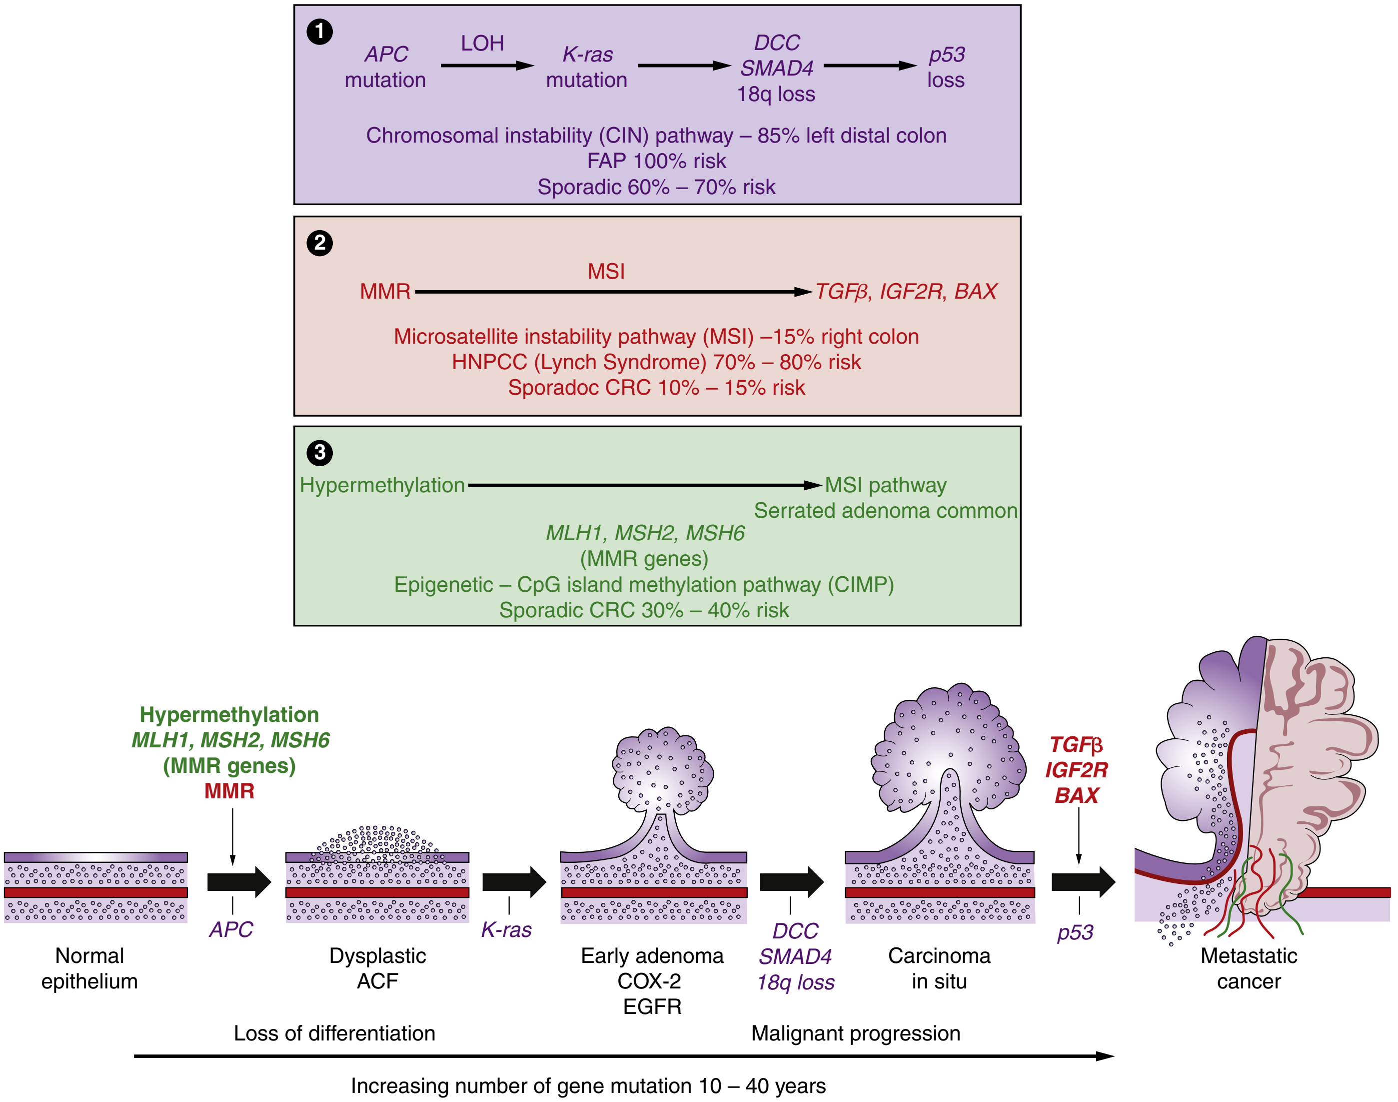

FIGURE 41-28 **Multistage Development of Colonic Cancer.** Colorectal carcinoma develops from the sequential progression of genetic abnormalities in different pathways. These pathways overlap in many tumors. **1,** Most CRC arises in the CIN pathway with imbalances in chromosomal numbers (aneuploidy) and loss of heterozygosity. Abnormalities in oncogenes and tumor-suppressor genes activate the pathways for CRC initiation and progression. Mutations in the *APC* gene are the earliest known event and inactivation of *APC* accelerates cell cycle progression. *K-ras* overexpression leads to loss of *p53* and transforms an adenoma into a metastatic carcinoma. *p53* loss occurs in ≈75% of colorectal carcinomas, but occurs infrequently in benign lesions. Growth factors COX-2 and EGFR promote tumor growth and angiogenesis in response to inflammatory cytokines and proto-oncogenes. **2,** The microsatellite instability *(MSI)* pathway involves the epigenetic mutation of DNA mismatch repair genes *(MMR)* that encode key molecules that repair DNA, resulting in replication errors and deactivation of proteins from other downstream mutations (*TGFβ, IGF2R, BAX*). **3,** The epigenetic pathway, CpG island methylator phenotype *(CIMP),* involves early hypermethylation of DNA with gene silencing of *MMR* genes that then transform into the MSI pathway. *ACF,* Aberrant crypt foci; *APC, APC* gene (a tumor-suppressor gene); *BAX,* Bcl-2-associated X protein (apoptosis-related protein); *CIN,* chromosomal instability; *COX-2,* cyclooxygenase-2; *CpG,* cytosine-phosphodiester bond-guanine DNA region; *CRC,* colorectal cancer; *DCC,* deleted in colorectal cancer (located at chromosome 18q); *EGFR,* epidermal growth factor receptor; *FAP,* familial adenomatous polyposis; *HNPCC,* hereditary nonpolyposis colorectal cancer; *IGF2R,* insulin growth factor type II receptor; *K-ras,* a proto-oncogene (promotes cell growth); *LOH,* loss of heterozygosity; *MLH1, MSH2, MSH6,* deoxyribonucleic acid (DNA) mismatch repair genes; *MMR,* mutation mismatch repair; *MSI,* microsatellite instability; *p53,* protein 53 or tumor protein 53 (a tumor-suppressor protein); *SMAD4,* a tumor-suppressor gene; *TGFβ,* transforming growth factor-beta.

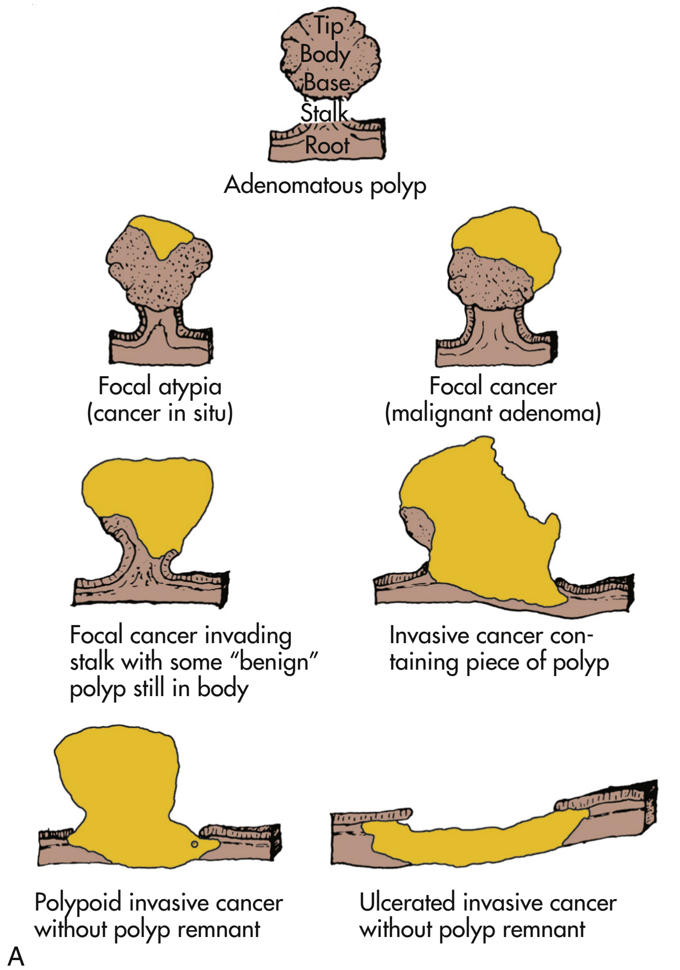
[HNPCC or Lynch syndrome]). The remainder of inherited CRCs are related to less penetrant genes, and environmental interactions increase risk.[349] About 75% of CRC is sporadic (nonhereditary or acquired) and the environment contributes to multiple somatic mutations.

Most CRCs arise from epithelial tissue in the form of adenomatous polyps. Progression from polyps to colon cancer (adenocarcinoma) involves a multistep cascade of genetic mutations. The gene mutations include: (1) activation of proto-oncogenes (promote cell growth; e.g., *K*-ras [retrovirus-associated DNA sequence] and *BRAF*); (2) loss of tumor-suppressor gene activity (inhibit cell growth [e.g., *APC, TP53, TFTB* and *SMAD4, DCC*]); and (3) abnormalities in DNA mismatch repair (MMR) genes (fix errors in DNA replication and recombination, e.g., *TGF, EGFR, hMSH1, hMSH2, hMSH6*).

Three molecular subtypes of genomic instability have been recognized and they can overlap in tumor development[350-352] (see Figure 41-28). *Chromosomal instability* (CIN or the suppressor pathway or adenoma-carcinoma sequence) includes the autosomal dominant inherited syndrome known as *familial adenomatous polyposis (FAP)* coli. Tumors associated with CIN are primarily located on the left side in the distal colon (50% to 85% of tumors). *Microsatellite instability* (MSI) is associated with epigenetic methylation of DNA MMR genes. These tumors are located in the right colon proximal to the splenic flexure and are associated with autosomal dominant hereditary polyposis colorectal cancer (HNPCC) or sporadic epigenetic alterations in 15% to 20% of CRCs. *CpG (cytosine-phosphate-guanine) island methylator phenotype* (CIMP) involves epigenetic DNA methylation of promoter CpG islands silencing genes involved in tumor suppression, cell cycle control, DNA repair, apoptosis, and invasion. It is found in 35% to 40% of CRCs and serrated adenomas are associated with this pathway. Cyclooxygenase-2 (COX-2) is variably expressed in right-sided and left-sided colorectal cancer, but the mechanism of expression is not clear. COX-2 may participate in regulation of apoptosis, angiogenesis, and invasiveness of adenomatous polyposis coli[353] (see Figure 41-28). Understanding the molecular events associated with CRC is allowing more targeted detection, diagnosis, and prognosis prediction, and more specific and personalized treatment approaches.[354,355]

Most CRC develops from adenomatous polyps (Figure 41-29). A **polyp** is a mass or fingerlike projection arising from the intestinal mucosal epithelium. Most polyps are benign. Grossly, they are described as pedunculated (with a stalk) or sessile (flat, without a stalk). Histologically, they are classified as tubular with branched tubular glands (the most prevalent), villous with fingerlike projections of the epithelium (more related to CRC), or tubulovillous adenomas. Sessile serrated polyps have a serrated crypt and include hyperplastic polyps. They generally lack atypia but when they are large (greater than 1 cm), numerous (more than 20), and located in the right colon they are associated with cancer (Figure 41-30). The adenomatous polyp forms in an area of epithelial cell hyperproliferation and crypt dysplasia. Once the adenoma traverses the muscularis mucosae, it becomes invasive and highly malignant. Adenomas can be detected early, however, and the submucosa may not be penetrated for several years. The larger the polyp and the greater the degree of dysplasia, the greater the risk of CRC. Thus, screening colonoscopy with polypectomy is important when polyps are found. Table 41-9 gives other conditions commonly confused with colorectal cancer.



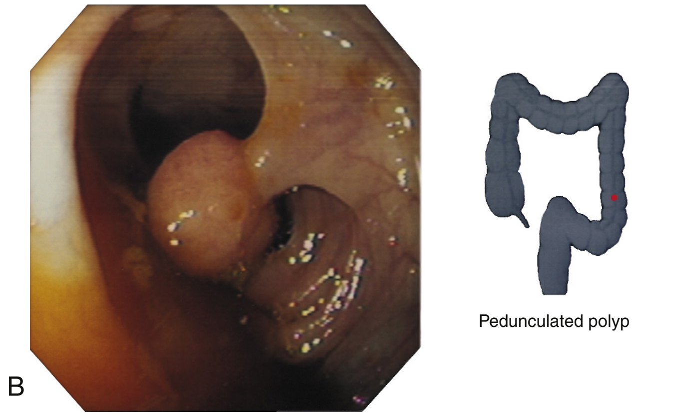


FIGURE 41-29 Development of Cancer of the Colon from Adenomatous Polyps. **A,** The tumor becomes invasive if it penetrates the muscularis mucosae and enters the submucosal layer. **B,** Endoscopic image of pedunculated polyp in descending colon. (**A** from del Regato JA, Spjut HJ, Cox JD: *Cancer: diagnosis, treatment, and prognosis,* ed 2, St Louis, 1985, Mosby. **B** courtesy David Bjorkman, MD, Department of Gastroenterology, University of Utah School of Medicine, Salt Lake City, UT.)

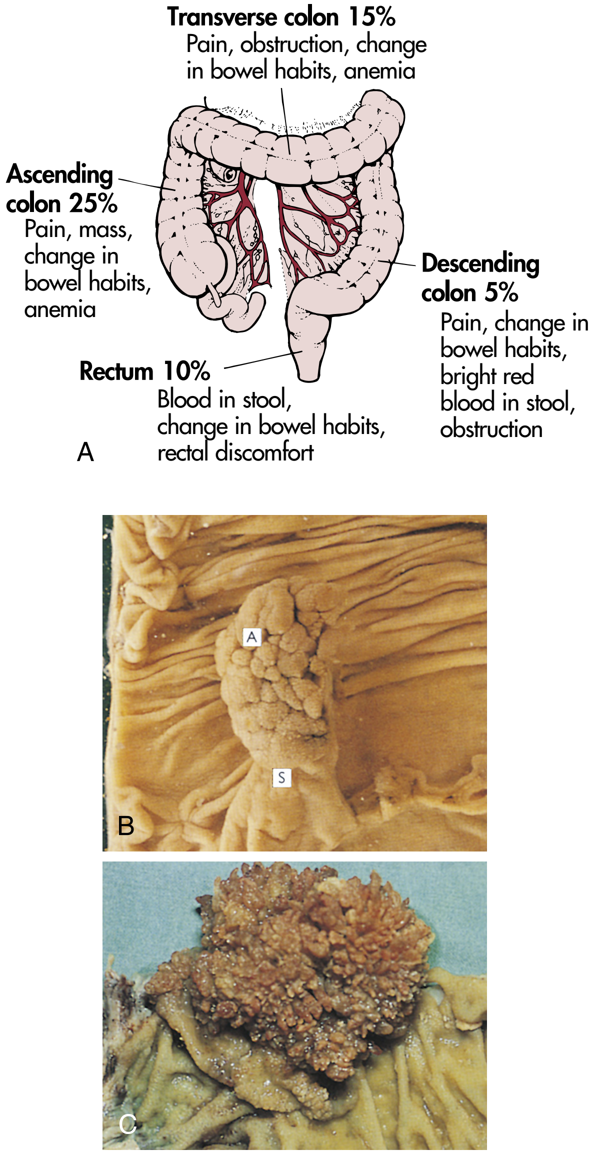

FIGURE 41-30 Signs and Symptoms of Colorectal Cancer by Location of Primary Lesion. **A,** Clinical manifestations are listed in order of frequency for each region (lymphatics of colon also shown). **B,** Tubular adenomas *(A)* are rounded lesions 0.5 to 2 cm in size that are generally red and sit on a stalk *(S)* of normal mucosa that has been dragged up by traction of the polyp in the bowel lumen. **C,** Villous adenomas are frondlike lesions about 0.6 cm thick that occupy a broad area of mucosa generally 1 to 5 cm in diameter. (**B** and **C** from Stevens A, Lowe JS, Scott I: *Core pathology,* ed 3, London, 2009, Mosby.)

Most colorectal cancers are moderately differentiated adenocarcinomas. These tumors have a long preinvasive phase, and when they invade they tend to grow slowly (10 to 15 years). Because the lymphatic channels are located underneath the muscularis mucosae, the lesions must traverse this layer before metastasis can occur. Systemic lymphatic spread occurs along the aorta to the mesenteric and pancreatic lymph nodes. Liver metastasis follows invasion of the mesenteric veins (left colon) or superior veins (right colon), which drain into the portal circulation.

Rectal carcinomas are defined as tumors occurring up to 15 cm from the anal opening. Tumors of the rectum can spread through the rectal wall to nearby structures: the prostate in men and the vagina in women. Penetration occurs more readily in the lower third of the rectum because it has no serosal covering. Systemic and pulmonary metastases occur through the hemorrhoidal plexus, which drains into the vena cava.

CLINICAL MANIFESTATIONS. Symptoms of colorectal cancer depend on the location, size, shape, and metastasis of the lesion. Tumors of the right (ascending) and left (descending) colon evolve into two distinct types. On the right side the lesions are polypoid and extend along one wall of the cecum and ascending colon. These tumors may be silent, evolving to pain, with a palpable mass in the lower right quadrant, anemia, fatigue, and dark red or mahogany-colored blood mixed with the stool (see Figure 41-30). These tumors can become large and bulky with necrosis and ulceration, contributing to persistent blood loss and anemia. Obstruction is unusual because the growth does not encircle the colon.

Tumors of the left, or descending, colon are small, elevated, button-like masses. This type grows circumferentially, encircling the entire bowel wall, and eventually ulcerating in the middle as the tumor penetrates the blood supply. Obstruction is common but occurs slowly and stools become narrow and pencil shaped. Manifestations include progressive abdominal distention, pain, vomiting, constipation, need for laxatives, cramps, and bright blood on the surface of the stool. In 8% to 29% of cases, bowel obstruction is the primary symptom at diagnosis.[356] Other symptoms can develop related to distant organ metastasis.

EVALUATION AND TREATMENT. Individuals with hereditary polyposis or a strong family history of CRC should begin screening at an early age (10 to 12 years) using colonoscopy and biopsy with a consideration of prophylactic surgery.[357] Fecal immunochemical testing (FIT) may be more accurate than stool occult blood testing.[358,359] Screening for nonhereditary CRC in asymptomatic individuals older than age 50 years includes fecal occult blood and immunochemical tests, stool DNA and sigmoidoscopy, colonoscopy, virtual colonoscopy, or double-contrast barium enema.[360,361]

The staging of colorectal cancer involves preoperative testing and operative exploration. Preoperative testing begins with physical examination of the abdomen to detect liver enlargement and ascites and palpation of appropriate lymph nodes. Elevations in the level of carcinoembryonic antigen (CEA) are often detected in the sera of individuals with colorectal carcinoma. The amount of CEA in the serum is a function of the stage of the disease and the type of tumor. Operative staging consists of careful exploration during surgery and biopsy of possible metastases. The National Cancer Institute[362] classification is widely used for staging of colorectal cancer and is as follows:

Stage 0 (carcinoma in situ): involves only the mucosal lining; also known as carcinoma in situ

Stage I: extension of cancer to the middle layers of the colon wall, no spread to lymph nodes; stage I colon cancer is sometimes called Dukes' A colon cancer

Stage II: extension beyond the colon wall to nearby tissues around the colon or *rectum,* and/or through the *peritoneum*; stage II colon cancer is sometimes called Dukes' B colon cancer

TABLE 41-9 CONDITIONS COMMONLY CONFUSED WITH COLORECTAL CANCER

CONDITION	SIGNIFICANT CHARACTERISTICS
Diverticulitis	Left-sided pain similar to that of appendicitis; tender lower left quadrant; associated findings: nausea, vomiting, fever, obstruction, anorexia, and leukocytosis; mucosa is intact, and perforation, peritonitis, and abscesses occur more often than in cancer; ultrasound, CT scan, MRI, and proctosigmoidoscopy are used to distinguish from cancer
Ulcerative colitis	Younger people with chronic attacks of bloody diarrhea, crampy abdominal pain, fever, malnutrition, and dehydration; usually involves the left colon and rectum; endoscopy, barium enema, and biopsy performed for definitive diagnosis
Crohn disease (granulomatous colitis)	Generally involves the right colon; chronic diarrhea with abdominal cramps, fever, weight loss, and often a palpable abdominal mass; difficult at times to distinguish Crohn disease from ulcerative colitis; endoscopic examination and CT scan used to distinguish from cancer
Appendicitis	Vague abdominal symptoms, often with a tender or nontender mass in the lower right quadrant; associated symptoms: mild fever and leukocytosis; CT scan used to distinguish cancer of the cecum from appendiceal abscess
Thrombosed hemorrhoids	Examination shows a tender, swollen, bluish painful mass in the anus; individual has a history of hemorrhoids

Stage III: spread beyond the colon into lymph nodes and nearby organs and/or through the *peritoneum;* stage III colon cancer is sometimes called Dukes' C colon cancer

Stage IV: spread to nearby *lymph nodes* and has spread to other parts of the body, such as the *liver* or *lungs;* stage IV colon cancer is sometimes called Dukes' D colon cancer

Treatment for cancer of the colon is always surgical. The location and amount of colon resected depend on the site of the cancer. Resection and anastomosis can be performed for early stage tumors and is usually curative. These surgeries are performed using laparoscopic techniques or through abdominal incisions, and natural defecation is preserved. Growths in the lower portion of the rectum require removal of the entire rectum with formation of a permanent colostomy. Prognosis after surgery depends on the stage and location of the tumor. TNM classifications are available from the National Cancer Institute.[363]

Radiation therapy is often given before surgery in the hope that it will shrink the tumor, alter the malignant cells, or both so that these cells will not survive after surgery. Adjuvant chemoradiotherapy is used to treat metastatic disease and cases with a high risk of recurrence. Monoclonal antibody therapy may be added.[364-366] Vaccines for colon cancer are in clinical trials.[367,368] Treatment of rectal cancer includes preoperative chemoradiotherapy, total mesorectal excision surgery, and adjuvant chemotherapy with fluorouracil.[369]

Anal carcinoma is rare (estimated 7060 cases and 880 deaths in 2013).[324] The most common tumor type is squamous cell carcinoma, about 80%; other anal cancers are adenocarcinoma, lymphoma, or sarcoma. The most common risk factor is infection with human papillomavirus (93%) and less commonly anal involvement in Crohn disease.[370] Squamous cell anal carcinoma is more common among the human immunodeficiency virus–infected population.[371]

Cancer of the Accessory Organs of Digestion

Cancer of the Liver

Hepatocellular carcinoma represented about 2% of new cancers (30,640) and 3.6% of cancer deaths (21,670) in 2013. The overall 5-year survival rate is 14%.[324] Blacks and Hispanics are almost twice as likely to develop these cancers as whites.[372] In the United States, the incidence of primary hepatocellular carcinoma is increasing as a result of chronic hepatitis C infection. Liver cancer is common in densely populated parts of Southeast Asia and sub-Saharan Africa where hepatitis B virus infection is endemic.[324] Primary liver cancer is rare before the age of 40 years and most common during the sixth decade. Cancer in the liver is usually caused by metastatic spread from a primary site elsewhere in the body.

Risk factors for primary liver cancer include the following[373-376]:

1. Infection with HBV, HCV, and HDV, particularly in conjunction with cirrhosis, acts either as a carcinogen or as a co-carcinogen in chronically infected hepatocytes[377]
2. Chronic alcoholic liver disease and nonalcoholic liver disease that results in cirrhosis
3. Exposure to mycotoxins; the most significant mycotoxins are the aflatoxins, particularly those produced by *Aspergillus flavus,* a mold found on spoiled corn, peanuts, and grain; aflatoxins cause mutation of the *TP53* suppressor gene and activation of WNT signal transduction pathway
4. Long duration of heavy smoking (greater than 20 years)
5. Nonalcoholic fatty liver disease
6. Hepatic iron overload

PATHOGENESIS. Primary carcinomas of the liver are hepatocellular or cholangiocellular. Hepatocellular carcinoma develops in the hepatocytes, whereas cholangiocellular carcinoma (cholangiocarcinoma) develops in the bile ducts. **Hepatocellular carcinoma (hepatocarcinoma) (HCC)** can be nodular (consisting of multiple, discrete nodules), massive (consisting of a large tumor mass having satellite nodules), or diffuse (consisting of very small nodules distributed throughout most of the liver). HCC is the type of primary liver cancer that is closely associated with cirrhosis (Figure 41-31). Chronic hepatitis B and hepatitis C and cirrhosis give rise to HCC repetitive cellular proliferation that occurs in the inflamed liver in response to growth factor and cytokine stimulation and oxidative stress–induced DNA damage. Numerous genetic and epigenetic alterations, including activation of oncogenes, failure of tumor-suppressor genes, and signaling pathways, combine to promote carcinogenesis.[378] Because carcinoma of the liver invades the hepatic and portal veins, it often spreads to the heart and lungs. Other sites of metastases are the brain, kidney, and spleen.

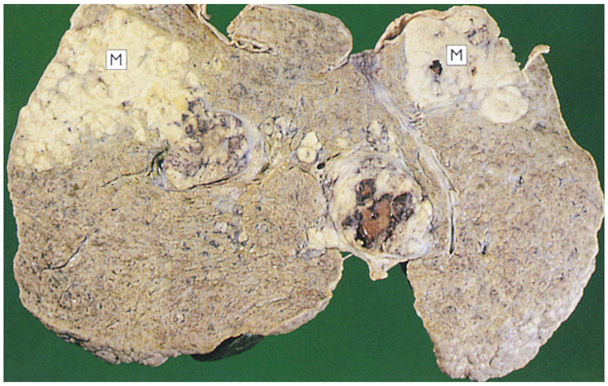

FIGURE 41-31 Hepatocellular Carcinoma. Macroscopically, hepatocellular carcinomas may be single or multifocal. They usually develop in a liver already affected by cirrhosis. Tumor appears as an abnormal mass *(M)* within the liver. (From Stevens A, Lowe JS, Scott I: *Core pathology,* ed 3, London, 2009, Mosby.)

Cholangiocellular carcinomas (**cholangiocarcinoma**) occur less often than hepatocellular carcinomas in the United States and represent about 10% to 25% of hepatobiliary malignancies. The disease predominates in men. Incidence demonstrates geographic variation and is common in Southeast Asia where liver fluke infestation is prevalent. The mechanism by which fluke infestation causes cholangiocellular carcinoma is multifactorial and includes parasite secretions, immunopathology, and mechanical damage. Other risk factors include primary sclerosing cholangitis, hepatolithiasis, and choledochal cysts.[379] Intrahepatic cholangiocellular carcinoma also is associated with cirrhosis, HBV and HCV infection, obesity, and diabetes. However, most individuals diagnosed with cholangiocellular carcinoma do not have an identifiable risk factor except age.[380,381] Cholangiocellular carcinoma can occur anywhere along the bile duct, both within and outside the liver, and usually is a solitary lesion. It is difficult to distinguish an invasion of cholangiocellular carcinoma from a metastatic adenocarcinoma except by neoplastic changes found in nearby ducts.

CLINICAL MANIFESTATIONS. The clinical presentation of liver cancer in adults is characterized by vague abdominal symptoms, such as nausea and vomiting, fullness, pressure, dull ache in the right hypochondrium, and weight loss. Manifestations of hepatocellular carcinoma can occur slowly or abruptly. In individuals with cirrhosis, deepening jaundice or abrupt lack of appetite is a sign of hepatocellular carcinoma. Obstruction by the tumor can cause sudden worsening of portal hypertension and development of ascites. As the tumor enlarges, it causes pain. Cholangiocellular carcinoma more commonly presents insidiously as pain, loss of appetite, weight loss, and gradual onset of jaundice. Some carcinomas of the liver rupture spontaneously, causing hemorrhage. Others are discovered accidentally during evaluation of a bone fracture or surgical exploration.

EVALUATION AND TREATMENT. There is no specific test for the diagnosis of liver cancer. For HCC high-risk individuals, alpha fetoprotein and abdominal ultrasound are common screening tools and can be used for screening in individuals with cirrhosis.[382] Additional serum markers are being evaluated.[383] The diagnosis is based on additional laboratory findings, radiologic examination, biopsy findings, and exploratory laparotomy. Serum levels of alkaline phosphatase, aspartate aminotransferase (AST), and alanine aminotransferase (ALT) are commonly elevated in individuals with HCC.

Staging of HCC is important to guiding treatment but does not accurately predict postoperative outcome. Surgical resection is possible with solitary tumors and the absence of portal hypertension.[384] Radiofrequency (thermal) ablation has emerged as the most effective method for local tumor destruction. Tyrosine kinase inhibitors (e.g., sorafenib) and monoclonal antibodies are improving survival; many new therapies are in clinical trials.[385] Transarterial embolization and radiation is used for management of pain and to reduce tumor size.[384] Surgical resection or liver transplantation is the only alternative for cure; however, very early stage HCC is difficult to diagnose.[382] Primary prevention of HCC is vaccination against HBV and antiviral therapy for HCV.[386]

Cholangiocarcinoma causes duct obstruction, and radiotherapy, chemotherapy, photodynamic therapy, and stenting can temporarily relieve the blockage for unresectable disease.[387-390]

Cancer of the Gallbladder

Cancer of the gallbladder and biliary tract is a rare but lethal disease. An estimated 10,310 new cases and 3230 deaths were recorded in 2013.[324] It rarely occurs before age 40 and is most common between the ages of 50 and 60 years. Risk factors include gallstones, advancing age, female gender (2:1), anomalous pancreaticobiliary ductal junction, and obesity. Native populations in North and South America have greater risk of gallbladder cancer, and it is more common in Chile, Poland, India, Japan, and Israel.[391-394] Most cancerous tumors in the gallbladder are caused by metastasis.

PATHOGENESIS. Most primary cancers of the gallbladder are adenocarcinomas and, less commonly, squamous cell carcinomas. The mechanisms of tumorigenesis are not clear. Multiple genes and oncogenes are involved in the initiation and progression of gallbladder cancer. Research is in progress to target these genes for diagnosis and treatment.[395] Infiltrative tumors are associated with gallstones, and invasion of the liver and lymph nodes occurs early. Spreading extends to the pancreas and retroperitoneal lymph nodes. Direct invasion of the stomach and the duodenum can cause pyloric obstruction. Infection often accompanies cancer of the gallbladder. Generalized peritonitis, gangrene, perforation, and liver abscesses are potential complications of infection.

CLINICAL MANIFESTATIONS. Early stages of gallbladder carcinoma are asymptomatic. A typical presentation is steady upper right quadrant pain for about 2 months. Other symptoms mimic benign gallbladder disease, including diarrhea, belching, weakness, loss of appetite, weight loss, and vomiting. Obstructive jaundice can occur if an enlarging tumor presses on the extrahepatic ducts.

EVALUATION AND TREATMENT. Early diagnosis of gallbladder cancer is rare and the disease is often found incidentally when removing gallstones or when an individual presents with an advanced stage of disease.[396] Individuals with gallstones, especially older women, are evaluated carefully. Inflammatory disorders, such as cholangitis (bile duct inflammation) and

peritonitis, often obscure an underlying malignancy. The most specific diagnostic procedures include ultrasonography, CT, and MRI.

Complete surgical resection of the gallbladder is the only effective treatment. Because advanced malignancies cannot be resected, gallbladders containing stones are removed as a preventive measure. Palliative chemotherapy or chemoradiation provides symptom improvement but does not improve survival.[397] The prognosis of gallbladder cancer is extremely poor; most individuals die within 1 to 2 years after surgery.[398,399]

Cancer of the Pancreas

Pancreatic cancer represents about 2.6% of all new cancers. There are 45,220 new cases and 38,460 deaths estimated for 2013.[324] The incidence of pancreatic cancer rises steadily with age. Men are affected slightly more often than women and blacks more often than whites.[324] Mortality is about 95% within 12 months. Risk factors include cigarette smoking, heavy alcohol use, family history of pancreatic cancer, and non-O blood group.[400] Chronic pancreatitis is associated with about 4% to 5% of pancreatic cancers.[401,402]

PATHOGENESIS. Cancer of the pancreas can arise from exocrine or endocrine cells. Most pancreatic tumors arise from exocrine cells in the ducts and are called *ductal adenocarcinomas.* Tumors arising in small ducts invade nearby glandular tissue, penetrate the covering of the pancreas, and extend into surrounding tissues.[403] Pancreatic cancer is a disease of inherited and acquired mutations in cancer-related genes associated with chronic inflammation.[403a] A *K-ras* mutation is the most common genetic alteration; tumor-suppressor gene alterations are also found, including *TP53, CDKN2A, SMAD4, BRCA2,* and *PALB2.*[404] Growth factors are overexpressed in ductal cancer.[405,406]

Ductal adenocarcinomas are the most common tumor and can occur in the head, body, or tail of the pancreas. Tumors of the head quickly spread to obstruct the common bile duct and portal vein (Figure 41-32). These tumors can then infiltrate the superior mesenteric artery, the vena cava, and the aorta. Cancer cells that enter the blood vessels can form emboli. Tumors of the body and tail infiltrate the posterior abdominal wall. Lymphatic invasion occurs early and rapidly and involves local and regional lymph nodes. Venous invasion causes metastases to the liver. Tumor implants on the peritoneal surface can obstruct veins and promote development of ascites.

Ductal adenocarcinomas arising in the head of the pancreas cause biliary obstruction somewhat early in the disease. Individuals with such tumors survive slightly longer than those with cancer of the body and tail, presumably because they seek medical attention earlier.

Tumors of the endocrine pancreas are rare neoplasms of the islets of Langerhans known as *apudomas.* The first four letters in *apudoma* derive from *amine precursor uptake* and *decarboxylation.* The apudomas are so named because they contain neurosecretory granules. Endocrine neoplasms secrete abnormal amounts of hormones, such as insulin.

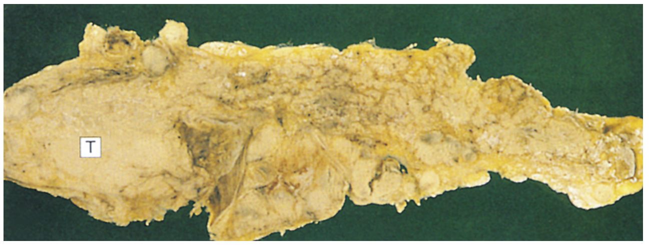

FIGURE 41-32 **Pancreatic Carcinoma.** Tumors appear as gritty, gray, hard nodules *(T)* irregularly invading the adjacent gland and local structures. (From Stevens A, Lowe JS, Scott I: *Core pathology,* ed 3, London, 2009, Mosby.)

CLINICAL MANIFESTATIONS. Cancer of the body and tail of the pancreas is generally asymptomatic until there is intraductal obstruction or the tumor invades adjacent tissue. Often vague, abdominal or mid-back pain is an initial symptom.[407] Jaundice develops in most cases, usually caused by obstruction of the bile duct. Because obstruction impairs enzyme secretion and flow to the duodenum, pancreatic cancer causes fat and protein malabsorption, resulting in weight loss. Some individuals develop diabetes mellitus. Distant metastases are found in the cervical lymph nodes, the lungs, and the brain. Most individuals die of hepatic failure, malnutrition, or systemic complications.

EVALUATION AND TREATMENT. Pancreatic cancer is usually diagnosed at an advanced stage and has a poor prognosis. The most effective screening method for those at risk is endoscopic ultrasound because it detects small lesions; the search for biomarkers is continuing.[408] *Autoimmune pancreatitis* is a rare, fibroinflammatory disorder of the pancreas that mimics and must be differentiated from pancreatic cancer.[409] Contrast CT scans, contrast MRI, and abdominal and endoscopic ultrasound (EUS) are used for initial diagnosis. EUS also provides opportunity for biopsy, or CT-guided fine needle aspiration can confirm diagnosis although this is not necessary when cancer suspicion is high.[410] Laparotomy is used to establish a definitive diagnosis, evaluate the extent of disease, and determine whether palliative bypass surgery (i.e., cholecystojejunostomy and gastrojejunostomy) is needed.

Individuals with small tumors and complete resection have the best possibility of cure (15% to 20% of cases). Pancreaticoduodenectomy (Whipple procedure) is the most common procedure and portal or superior mesenteric vein resection and reconstruction may be performed. Some surgeons recommend a total pancreatectomy because cancer of the pancreas seldom consists of a single lesion.[411] The dense stromal structure of the tumor impairs chemotherapeutic drug delivery, resulting in poor response to chemotherapy.[412] Adjuvant chemotherapy is used for curative attempts in resected low-grade tumors. Chemoradiation therapy is used for advanced disease in some centers. Treatments with molecular targets are in clinical trials.[413-415] Palliative care, including pain management and nutrition, are important.[416]

SUMMARY REVIEW

Disorders of the Gastrointestinal Tract

1. Anorexia (loss of appetite), vomiting, constipation, diarrhea, abdominal pain, and evidence of gastrointestinal bleeding are clinical manifestations of many disorders of the gastrointestinal tract.
2. Vomiting is the forceful emptying of the stomach effected by gastrointestinal contraction and reverse peristalsis of the esophagus. It is usually preceded by nausea and retching with the exception of projectile vomiting, which is associated with direct stimulation of the vomiting center in the brain.
3. Primary constipation is defined in three categories: functional, associated with low-residue, low-fluid diet; slow-transit, related to impaired colonic motor function; and pelvic floor dyssynergia-anismus. Secondary constipation results from a neurogenic disease, drugs that decrease intestinal motility, endocrine or metabolic disorders, or obstruction.
4. Diarrhea can be caused by excessive fluid drawn into the intestinal lumen by osmosis (osmotic diarrhea), excessive secretion of fluids by the intestinal mucosa (secretory diarrhea), or excessive gastrointestinal motility.
5. Abdominal pain is caused by stretching, inflammation, or ischemia and originates in the peritoneum (parietal pain) or in the organs themselves (visceral pain). Visceral pain is often referred to the back.
6. Gastrointestinal bleeding can occur in the upper or lower gastrointestinal tract. Obvious manifestations of gastrointestinal bleeding are hematemesis (vomiting of blood), melena (dark, tarry stools), and hematochezia (frank bleeding from the rectum). Occult bleeding can be detected only by testing stools or vomitus for the presence of blood.
7. Dysphagia is difficulty in swallowing. It can be caused by a mechanical or functional obstruction of the esophagus. Functional obstruction is an impairment of esophageal motility.
8. Achalasia is a form of functional dysphagia caused by loss of esophageal innervation or relaxation of the lower esophageal sphincter.
9. Gastroesophageal reflux disease is the regurgitation of chyme from the stomach into the esophagus, causing esophagitis from repeated exposure to acids and enzymes in the regurgitated gastric contents.
10. Hiatal hernia is the protrusion of the upper part of the stomach through the hiatus (esophageal opening in the diaphragm) at the gastroesophageal junction. Hiatal hernia can be sliding, paraesophageal, or mixed.
11. Pyloric obstruction is the narrowing or blockage of the pylorus, which is the opening between the stomach and the duodenum. It can be caused by a congenital defect, inflammation and scarring secondary to a gastric ulcer, or tumor growth.
12. Intestinal obstruction prevents the normal movement of chyme through the intestinal tract. It is usually mechanical—that is, caused by torsion, herniation, or tumor. Functional obstruction is caused by paralytic ileus.
13. The most severe consequences of intestinal obstruction are fluid and electrolyte losses, hypovolemia, shock, intestinal necrosis, and perforation of the intestinal wall.
14. Gastritis is an acute or a chronic inflammation of the gastric mucosa.
15. Regurgitation of bile, use of anti-inflammatory drugs or alcohol, *H. pylori* infection, and some systemic diseases are associated with gastritis.
16. Chronic fundal gastritis is rare and associated with autoantibodies to parietal cells and intrinsic factor, resulting in gastric atrophy and causing pernicious anemia.
17. Chronic antral gastritis is the most common and is associated with *H. pylori* and NSAIDs.
18. Alkaline reflux gastritis is stomach inflammation caused by the reflux of bile and pancreatic secretions from the duodenum into the stomach. These substances disrupt the mucosal barrier and cause inflammation.
19. A peptic ulcer is a circumscribed area of mucosal inflammation and ulceration caused by excessive secretion of gastric acid, disruption of the protective mucosal barrier, or both.
20. The three types of peptic ulcers are duodenal, gastric, and stress ulcers and they are usually caused by *H. pylori* infection or NSAIDs.
21. Duodenal ulcers, the most common peptic ulcers, are associated with increased numbers of parietal (acid-secreting) cells in the stomach, elevated gastrin levels, and rapid gastric emptying. Pain occurs when the stomach is empty, and pain is relieved with food or antacids. Duodenal ulcers tend to heal spontaneously and recur frequently.
22. Gastric ulcers develop near parietal cells, generally in the antrum, and tend to become chronic. Gastric secretions may be normal or decreased, and pain may occur after eating.
23. Zollinger-Ellison syndrome is associated with a gastrinoma, chronic secretion of gastric acid, and gastric and duodenal ulcers.
24. Stress ulcer (stress-related mucosal disease) is an acute form of peptic ulcer associated with severe illness or extensive trauma.
25. Ischemic stress ulcers develop suddenly after severe illness, systemic trauma, neural injury, or burns (Curling ulcer). Ulceration follows mucosal damage caused by ischemia (decreased blood flow to the gastric mucosa).
26. Cushing ulcer is a stress ulcer caused by head trauma. Ulceration follows hypersecretion of hydrochloric acid caused by overstimulation of the vagal nuclei.
27. Malabsorption syndromes result in impaired digestion or absorption of nutrients.
28. Pancreatic insufficiency causes malabsorption associated with insufficient amounts of the enzymes that digest protein, carbohydrates, and fats into components that can be absorbed by the intestine.
29. Deficient lactase production in the brush border of the small intestine inhibits the breakdown of lactose. This prevents lactose absorption and causes osmotic diarrhea.
30. Bile salt deficiency causes fat malabsorption, including fat-soluble vitamins, and steatorrhea (fatty stools). Bile salt deficiency can result from inadequate secretion of bile, excessive bacterial deconjugation of bile, or impaired reabsorption of bile salts caused by ileal disease.

SUMMARY REVIEW—cont'd

31. Dumping syndrome causes malabsorption by the rapid emptying of hypertonic chyme from the surgically created residual stomach into the small intestine. It causes an osmotic shift of fluid from the vascular compartment to the intestinal lumen, which decreases plasma volume.
32. Ulcerative colitis is an inflammatory bowel disease that causes ulceration, abscess formation, and necrosis of the colonic and rectal mucosa. Cramping pain, bleeding, frequent diarrhea, dehydration, and weight loss accompany severe forms of the disease. A course of frequent remissions and exacerbations is common.
33. Crohn disease is similar to ulcerative colitis, but it affects the large and small intestines, and ulceration tends to involve all the layers of the lumen. "Skip lesion" fissures and granulomas are characteristic of Crohn disease. Abdominal tenderness, nonbloody diarrhea, and weight loss are the usual symptoms.
34. Diverticula are outpouchings of colonic mucosa through the muscle layers of the colon wall. Diverticulosis is the presence of these outpouchings; diverticulitis is inflammation of the diverticula.
35. Appendicitis is the most common surgical emergency of the abdomen. Obstruction of the lumen leads to increased pressure, ischemia, and inflammation of the appendix. Without surgical resection, inflammation may progress to gangrene, perforation, and peritonitis.
36. Vascular insufficiency in the intestine is associated most often with acute or chronic occlusion or obstruction of the mesenteric vessels or insufficient mesenteric arterial blood flow. The resulting ischemia and necrosis produce abdominal pain, fever, bloody diarrhea, hypovolemia, and shock.
37. Obesity is defined as a BMI greater than 30 kg/m^2 and usually results from energy intake exceeding expenditure.
38. Single-gene and polygenetic disorders are associated with obesity, as well as social, cultural, economic, exercise, and metabolic factors.
39. Increases in body fat mass are associated with macrophage infiltration of adipocytes with release of inflammatory mediators, increased adipocyte lipolysis, increased leptin (leptin resistance) and RBP4 levels, and decreased adiponectin level. Insulin resistance may develop. Increased levels of ghrelin and endocannabinoids and decreased levels of PYY and GLP1 are associated with obesity. Alterations in the expression of these hormones and neurotransmitters affect appetite and metabolic rate at the level of the hypothalamus.
40. The eating disorders include anorexia nervosa, bulimia nervosa, and binge eating disorder. They are psychogenic disorders that can lead to malnutrition. Anorexia nervosa is the most serious and can be fatal.
41. Short-term starvation, or lack of dietary intake for 3 or 4 days, stimulates mobilization of stored glucose by two metabolic processes: glycogenolysis (splitting of glycogen into glucose) and gluconeogenesis (formation of glucose from noncarbohydrate molecules).
42. Long-term starvation triggers the breakdown of ketone bodies and fatty acids. Eventually proteolysis (protein breakdown) begins, and death ensues if nutrition is not restored.

Disorders of the Accessory Organs of Digestion

1. Portal hypertension, ascites, hepatic encephalopathy, jaundice, and hepatorenal syndrome are complications of many liver disorders.
2. Portal hypertension is an elevation of portal venous pressure to at least 10 mmHg. It is caused by increased resistance to venous flow in the portal vein and its tributaries, including the sinusoids and hepatic vein.
3. Portal hypertension is the most serious complication of liver disease because it can cause fatal complications, such as bleeding varices, ascites, hepatic encephalopathy, and renal failure.
4. Varices are distended, tortuous, collateral veins associated with portal hypertension.
5. Splenomegaly is an enlargement of the spleen resulting from increased splenic vein pressure caused by portal hypertension.
6. Hepatopulmonary syndrome is pulmonary hypertension related to the release of vasodilators that effect pulmonary arterioles and is associated with portal hypertension and severe liver disease.
7. Ascites is the accumulation and sequestration of fluid in the peritoneal cavity, often as a result of portal hypertension, decreased concentrations of plasma proteins, and sodium retention.
8. Hepatic encephalopathy (portosystemic encephalopathy) is impaired cerebral function caused by blood-borne toxins (particularly ammonia) not metabolized by the liver.
9. Jaundice (icterus) is a yellow or greenish pigmentation of the skin or sclera of the eyes caused by increases in plasma bilirubin concentration (hyperbilirubinemia).
10. Obstructive jaundice is caused by obstructed bile canaliculi (intrahepatic obstructive jaundice) or obstructed bile ducts outside the liver (extrahepatic obstructive jaundice). Bilirubin accumulates proximal to sites of obstruction, enters the bloodstream, and is deposited in the skin and other connective tissues.
11. Hemolytic jaundice is caused by destruction of red blood cells at a rate that exceeds the liver's ability to metabolize unconjugated bilirubin.
12. Hepatorenal syndrome is functional renal failure caused by advanced liver disease, particularly cirrhosis with portal hypertension. Renal failure is caused by a sudden decrease in blood flow to the kidneys, usually as a result of massive gastrointestinal hemorrhage or liver failure. Its chief clinical manifestation is oliguria.
13. Autoimmune hepatitis is T cell mediated with hypergammaglobulinemia and absence of viral hepatitis.
14. Viral hepatitis is an infection of the liver caused by strains of the hepatitis virus: HAV, HBV, HCV, HDV, and HEV. HAV and HEV are transmitted via the fecal-oral route. The hepatitis viruses are blood-borne and can cause hepatic cell necrosis, Kupffer cell hyperplasia, and infiltration of liver tissue by mononuclear phagocytes. These changes obstruct bile flow and impair hepatocyte function.

SUMMARY REVIEW—cont'd

15. The clinical manifestations of viral hepatitis depend on the stage of infection. Fever, malaise, anorexia, and liver enlargement and tenderness characterize the prodromal phase (stage 1). Jaundice and hyperbilirubinemia mark the icteric phase (stage 2). During the recovery phase (stage 3), symptoms resolve. Recovery takes several weeks.
16. Chronic active hepatitis can occur with HBV and HCV with predisposition to cirrhosis and hepatocellular carcinoma.
17. Fulminant hepatitis is a complication of hepatitis B (with or without hepatitis D infection) or hepatitis C. It causes widespread hepatic necrosis and is often fatal.
18. Cirrhosis is an irreversible inflammatory disease of the liver that causes disorganization of lobular structure, fibrosis, and nodular regeneration. Bile obstruction causes jaundice. Vascular obstruction causes portal hypertension, shunting, and varices. Cirrhosis can result from hepatitis or exposure to toxins, such as acetaldehyde (a product of alcohol metabolism). The disease causes progressive irreversible liver damage, usually over a period of years.
19. Alcoholic liver disease impairs the hepatocytes' ability to oxidize fatty acids, synthesize enzymes and proteins, degrade hormones, and clear portal blood of ammonia and toxins. The disease is progressive and includes steatosis, steatohepatitis, and alcoholic cirrhosis.
20. Nonalcoholic fatty liver disease is fat infiltration of hepatocytes associated with obesity.
21. Primary biliary cirrhosis is an autoimmune disease with inflammatory destruction of intrahepatic bile ducts. Mitochondrial autoantibodies are found in this disease.
22. Secondary biliary cirrhosis develops from prolonged obstruction of bile flow (e.g., gallstones) with increased pressure in the hepatic bile ducts that causes pooling of bile and necrosis of tissue. Relief of obstruction alleviates symptoms of jaundice and pruritus. Continued obstruction causes cirrhosis and liver failure.
23. Primary sclerosing cholangitis is a fibrotic disease of medium and large sized bile ducts outside the liver.
24. Cholelithiasis (the formation of gallstones) is a result of bile aggregation of cholesterol crystals (cholesterol stones) or precipitates of unconjugated bilirubin (pigmented stones). Gallstones that fill the gallbladder or obstruct the cystic, or common, bile duct cause abdominal pain and jaundice.
25. Cholecystitis is an inflammation of the gallbladder. It is usually associated with obstruction of the cystic duct by gallstones.
26. Acute pancreatitis (pancreatic inflammation) is a serious but relatively rare disorder associated with biliary obstruction and alcoholism. Injury permits leakage of digestive enzymes into pancreatic tissue, where they become activated and begin the process of autodigestion, inflammation, and destruction of tissues. Release of pancreatic enzymes into the bloodstream or abdominal cavity causes damage to other organs.
27. Chronic pancreatitis results from structural or functional impairment of the pancreas usually related to alcoholism or recurrent acute pancreatitis. It causes recurrent abdominal pain and digestive disorders.

Cancer of the Digestive System

1. Cancer of the esophagus is rare and tends to occur in people older than 60 years. Alcohol and tobacco use, reflux esophagitis, radiation exposure, and nutritional deficiencies are associated with esophageal carcinoma.
2. Dysphagia and chest pain are the primary manifestations of esophageal cancer. Early treatment of tumors that have not spread into the mediastinum or lymph nodes results in a good prognosis.
3. Gastric carcinoma is associated with *H. pylori (CagA)*, high salt intake, food preservatives (nitrates and nitrites), and atrophic gastritis.
4. Approximately 50% of all gastric cancers are located in the prepyloric antrum. Clinical manifestations (weight loss, upper abdominal pain, vomiting, hematemesis, anemia) develop only after the tumor has penetrated the wall of the stomach.
5. Cancer of the colon and rectum (colorectal cancer) is the second most common type of cancer death in the United States. Small intestinal cancers are rare. Familial adenomatous polyposis coli is an inherited form of colon cancer. Preexisting large and numerous polyps are highly associated with sporadic adenocarcinoma of the colon.
6. Tumors of the right (ascending) colon are usually large and bulky; tumors of the left (descending, sigmoid) colon develop as small button-like masses. Manifestations of colon tumors include pain, bloody stools, and change in bowel habits.
7. Rectal carcinoma is located up to 15 cm from the opening of the anus. The tumor spreads transmurally to the vagina in women or to the prostate in men.
8. Metastatic invasion of the liver is more common than primary cancer of the liver.
9. Primary liver cancers are associated with chronic liver disease (cirrhosis and hepatitides B and C). Hepatocellular carcinomas arise from the hepatocytes, whereas cholangiocellular carcinomas arise from the bile ducts. Primary liver cancer spreads to the heart, lungs, brain, kidney, and spleen through the circulation.
10. Cancer of the gallbladder is relatively rare and tends to occur in women older than 50 years. Adenocarcinoma is most common. Because clinical manifestations occur late in the disease, metastases to lymph channels have usually occurred by the time of diagnosis, and the prognosis is poor.
11. Cancer of the pancreas ranks fifth as a cause of cancer deaths. The one known risk factor is heavy cigarette smoking. Most tumors are adenocarcinomas that arise in the exocrine cells of ducts in the head, body, or tail of the pancreas. Symptoms may not be evident until the tumor has spread to surrounding tissues. Treatment is palliative, and mortality is nearly 100%.

CHAPTER OUTLINE

Disorders of the gastrointestinal tract, liver, and pancreas in children include congenital anomalies with structural and functional alterations, enzyme deficiencies, and infections. These disorders lead to impairment of motility, digestion, nutrition, and normal growth and development.

DISORDERS OF THE GASTROINTESTINAL TRACT

Congenital Impairment of Motility

Cleft Lip and Cleft Palate

Cleft lip (harelip) and cleft palate (CLP) are developmental anomalies of the first branchial arch (Figure 42-1). The incidence of CLP is estimated at 1 in 1000 live births in the United States.[1] Incidence is lower in black populations and higher in Asian populations.[2] Cleft lip, with or without cleft palate, is more common in males and isolated cleft palate is more common in females. Both anomalies can be unilateral or bilateral, partial or complete and may also be associated with other malformations. *Nonsyndromic (isolated) CLP* is a malformation with an incomplete separation between nasal and oral cavities without any associated anomaly. Syndromic CLP is associated with other malformations (e.g., Crouzon syndrome [craniofacial dysostosis], Treacher Collins syndrome [mandibulofacial dysostosis], hemifacial microsomia).[3]

In most cases, cleft lip and cleft palate are caused by multiple gene-environmental interactions, including maternal deficiency of B vitamins (B_6, folic acid, and B_{12}), maternal smoking and alcohol use, maternal hyperhomocysteinemia, and maternal diabetes mellitus as well as genetic variations of interferon regulatory factor-6, fibroblast growth factor, tumor growth factor-alpha, and other growth factors.[4] (This phenomenon, called *multifactorial inheritance,* is discussed in Chapter 4.) Together these factors reduce the amount of neural crest mesenchyme that migrates into the area that will develop into the face of the embryo.[5]

PATHOPHYSIOLOGY. Cleft lip (harelip) is caused by the incomplete fusion of the nasomedial and intermaxillary processes beginning during the fourth week of embryonic development,[6] a period of rapid fetal growth. The cleft causes structures of the face and mouth to develop without the normal restraints of encircling lip muscles. The facial cleft may affect not only

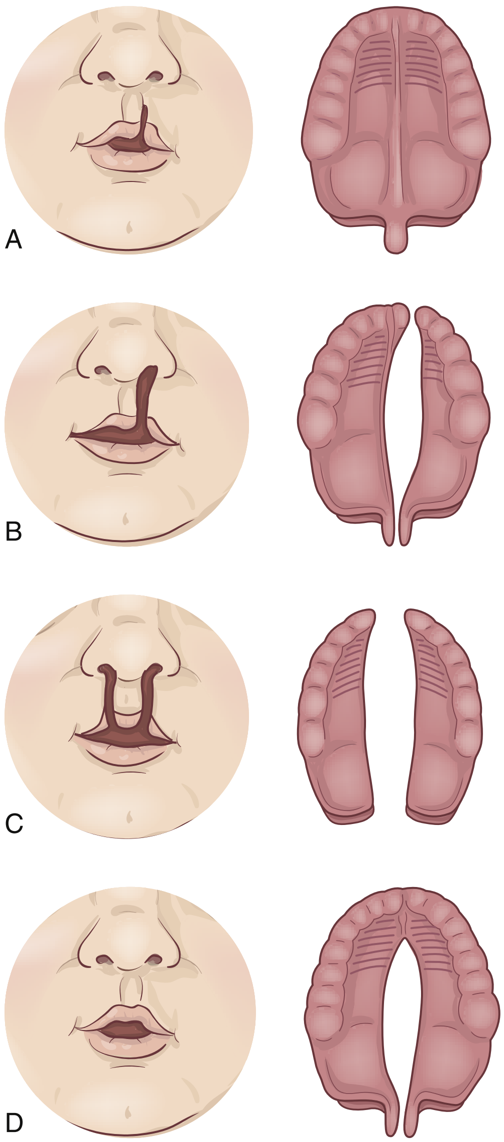

FIGURE 42-1 Variations in Clefts of the Lip and Palate. **A,** Notch in vermilion border. **B,** Unilateral cleft lip and palate. **C,** Bilateral cleft lip and cleft palate. **D,** Cleft palate.

the lip but also the external nose, the nasal cartilages, the nasal septum, and the alveolar processes (bony ridge of maxilla that contains the tooth sockets).

The cleft is usually just beneath the center of one nostril. The defect may occur bilaterally and may be symmetric or asymmetric. The cleft can range in severity from a slight indentation of the lip to a fissure that extends to the nostril, causing a sagging and flattening of the nose. The failure of lip fusion by 35 days of gestation may impair closure of the palatal shelves. The more complete the cleft lip, the greater the chance that teeth in the line of the cleft will be missing or malformed.

Cleft palate is often associated with cleft lip but may occur without it. Cleft palate results from the failure of the primary palatal shelves, or processes, to fuse during the third month of gestation. The fissure may affect only the uvula and soft palate, or it may extend forward to the nostril and involve the hard palate and the maxillary alveolar ridge. It may be unilateral or bilateral, with the cleft occupying the midline posteriorly and as far forward as the alveolar process, where it deviates to the involved side. Clefts involving the palate only are usually but not necessarily in the midline. In some cases the vomer and nasal septum are partly or completely undeveloped. When these facial bones are involved, the nasal cavity may freely communicate with the oral cavity. Teeth in the cleft palate area may be missing or deformed.[7]

CLINICAL MANIFESTATIONS. Feeding the infant with cleft lip usually presents no difficulty if the cleft lip is simple and the palate intact. Nursing at breast or bottle depends on suction developed by pressing the nipple against the hard palate with the tongue. Closure of the lips is not necessary, but the tongue must work harder if the lips cannot be pursed. A baby with cleft palate usually requires large, soft nipples with cross-cut openings and better tolerates feeding when in an upright position to prevent milk escaping through the nose. Although most infants with cleft palate can be successfully breast-fed, it may be impossible for some because of an unproductive suck and difficulty swallowing.[8] An orthodontic prosthesis for the roof of the mouth may facilitate sucking for some infants.[9]

EVALUATION AND TREATMENT. Prenatal diagnosis is made by ultrasound; facial x-ray films confirm the extent of bone deformity. Soft tissue alterations are evaluated by history and physical examination.[10] The nature and extent of the cleft, the infant's condition, and the method of surgical correction proposed determine the course of treatment. Surgical correction is planned as soon as possible and may be in stages.[11] The aim of surgery is to obtain an airtight closure of the palatal cleft and to preserve the mobility and length of the soft palate without compromising mid-facial growth.[12] Children with cleft palate tend to have repeated infections of the paranasal sinuses and middle ear both before and after surgery, which require treatment. The child should be evaluated for hearing loss.[13] Excessive dental decay is not unusual. Speech training and special attention by a prosthodontist and orthodontist are almost always required.[14] Periconceptual B vitamins, folate, and folic acid intake and reduced tobacco and alcohol use may prevent orofacial clefts.[5] Surgical correction facilitates feeding and normal growth and development.[15]

Esophageal Malformations

Congenital malformations of the esophagus are rare and occur in about 1 in 3000 live births, depending on geographic region.[16] **Esophageal atresia** is a condition in which the esophagus ends in a blind pouch and is usually accompanied by a fistula between the esophagus and the trachea. This connection is called a **tracheoesophageal fistula (TEF).** Either defect can occur alone or in association with other defects (Figure 42-2). Many genes have been implicated.[17]

PATHOPHYSIOLOGY. The pathogenesis of esophageal abnormalities is unknown. They are thought to arise from defective differentiation as the trachea separates from the esophagus during the fourth to sixth weeks of embryonic development. Defective growth of endodermal cells leads to atresia. Incomplete fusion of the lateral walls of the foregut leads to incomplete closure of the laryngotracheal tube and fistula formation.[18]

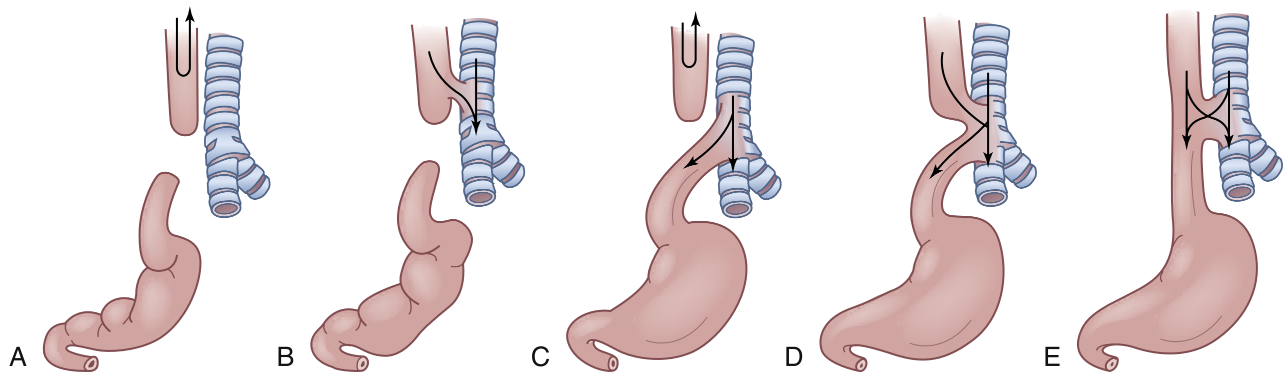

FIGURE 42-2 Five Types of Esophageal Atresia and Tracheoesophageal Fistulae. **A,** Simple esophageal atresia. Proximal esophagus and distal esophagus end in blind pouches, and there is no tracheal communication. Nothing enters the stomach; regurgitated food and fluid may enter the lungs. **B,** Proximal and distal esophageal segments end in blind pouches, and a fistula connects the proximal esophagus to the trachea. Nothing enters the stomach; food and fluid enter the lungs. **C,** Proximal esophagus ends in a blind pouch, and a fistula connects the trachea to the distal esophagus. Air enters the stomach; regurgitated gastric secretions enter the lungs through the fistula. **D,** Fistula connects proximal and distal esophageal segments to the trachea. Air, food, and fluid enter the stomach and the lungs. **E,** Simple tracheoesophageal fistula between otherwise normal esophagus and trachea. Air, food, and fluid enter the stomach and the lungs. Between 85% and 90% of esophageal anomalies are type C; 6% to 8% are type A; 3% to 5% are type E; and less than 1% are type B or D. **Note:** Type F, esophageal stenosis, is not shown.

CLINICAL MANIFESTATIONS. Polyhydramnios (excessive amniotic fluid) is reported to occur in 14% to 90% of mothers of affected infants.[19] The blind end of the proximal esophagus has a capacity of only a few milliliters. Normally swallowed amniotic fluid is absorbed into the placental circulation, and it accumulates in the uterus if the fetus cannot swallow. As the infant with esophageal atresia swallows oral secretions, the pouch fills and overflows into the pharynx, resulting in drooling and occasionally in aspiration (see Figure 42-2, *A* and *C*).

If a fistula connects the trachea with the distal esophagus, the abdomen fills with air and becomes distended. The distention may be great enough to interfere with breathing (see Figure 42-2, *C* to *E*). If the fistula connects the proximal esophagus to the trachea, the first feeding after birth will be problematic (see Figure 42-2, *B, D,* and *E*). As the infant drinks, the blind end of the esophagus and the mouth fill with fluid. When the infant tries to take a breath, the fluid is aspirated into the lungs, which triggers protective cough and choke reflexes. Intermittent cyanosis may result. Plain water or glucose is recommended for the initial feeding to minimize the dangers associated with aspiration. If an abnormality of the esophagus is indicated, oral feedings are withheld until a diagnosis is confirmed.

Pulmonary complications are compounded by reflux of air and gastric secretions into the tracheobronchial tree through the fistula (see Figure 42-2, *D* and *E*), causing severe chemical irritation. The upper lobe of the right lung is most commonly involved because of its proximity to the tracheoesophageal (TE) fistula. Infants with esophageal atresia but no fistula have a scaphoid (boat-shaped), gasless abdomen. In fistula without atresia (see Figure 42-2, *E*), the usual symptoms are recurrent aspiration, pneumonia, and atelectasis that remains "silent" for days or even months. Late complications of esophageal atresia or tracheal esophageal fistula include stricture, reflux, dysphagia, chronic cough, and dyspnea on exertion.[20]

Other congenital anomalies are present in at least 50% of infants with esophageal defects. They are known as the VACTERAL association with the letters representing *v*ertebral anomalies, *a*nal atresia, *c*ardiovascular malformations, *TE* fistula and/or esophageal atresia, *r*enal *a*nomalies, and *l*imb anomalies.[21]

EVALUATION AND TREATMENT. Prenatal diagnosis may include ultrasound imaging but the findings of polyhydramnios and small stomach bubble are often nonspecific and associated with other problems.[22] Esophageal atresia is usually diagnosed at birth, when attempts to pass a small-bore orogastric or nasogastric tube into the stomach fail. Imaging will show displacement of the tube.[23]

Initial postnatal treatment is to prevent aspiration. Surgery restores esophageal continuity, and the fistula is eliminated. Surgery is usually undertaken after birth, sometimes in stages. The child may continue to have problems with aspiration, gastroesophageal reflux, and esophagitis after surgical repair. The overall survival rate for infants with esophageal defects exceeds 90%.[24]

Pyloric Stenosis

Pyloric stenosis is an obstruction of the pyloric sphincter caused by hypertrophy of the sphincter muscle. It is one of the most common disorders of early infancy and affects infants between the ages of either 1 and 2 weeks or 3 and 4 months.[25] The incidence of pyloric stenosis among males is approximately 5 in 1000, whereas among females it is only 1 in 1000.[26] Whites are affected more often than blacks or Asians, and full-term infants are affected more often than premature infants. The cause is unknown but increased gastrin secretion by the mother in the last trimester of pregnancy raises the likelihood of pyloric stenosis in the infant. The overproduction of gastric secretions in the infant may be caused by stress-related factors in the mother. Exogenous administration of prostaglandin E is associated with an increased incidence of pyloric stenosis. There is an increased incidence of pyloric stenosis in those children

who have a family member with pyloric stenosis, suggesting a genetic predisposition.[27]

PATHOPHYSIOLOGY. The circular muscle of the pylorus is grossly enlarged because of an increase in cell size (hypertrophy) and an increase in cell number (hyperplasia).[27] The mucosal lining of the pyloric opening is folded and the lumen is narrowed by the encroaching muscle. Because of the extra peristaltic effort necessary to force the gastric contents through the narrow pylorus, the muscle layers of the stomach may become hypertrophied as well.

CLINICAL MANIFESTATIONS. Between 2 and 3 weeks after birth, an infant who is fed well and gained weight begins to vomit without apparent reason and the vomiting becomes more forceful. The forceful, or projectile, vomiting usually occurs immediately after eating, and the vomitus consists of the bulk of the feeding plus some food retained from previous feedings but is almost always free of bile. Usually infants are hungry and want to eat again after vomiting.

Prolonged retention of food in the stomach is a characteristic feature of pyloric stenosis and food is present after 4 hours unless vomiting has occurred. Constipation is the rule because most food does not reach the intestine.

In severe untreated cases, increased gastric peristalsis and vomiting lead to severe fluid and electrolyte imbalances (hypokalemic, hypochloremic metabolic alkalosis), chronic malnutrition, and weight loss that can be fatal within 4 to 6 weeks. Infants with pyloric stenosis are irritable because of hunger, and they may have esophageal discomfort caused by repeated vomiting and esophagitis. The vomitus may be blood streaked because of rupture of gastric and esophageal vessels.

EVALUATION AND TREATMENT. Diagnosis is based on the history of clinical manifestations. Occasionally, gastric peristalsis is observable over the abdomen. A firm, small, movable mass, approximately the size of an olive, is felt in the right upper quadrant in 70% to 90% of infants with pyloric stenosis. A visible gastric peristaltic wave after eating is observed in some infants. Ultrasound clearly shows the hypertrophied pyloric muscles and narrowed pyloric channel.

The standard treatment for hypertrophic pyloric stenosis is a pyloromyotomy, in which the muscles of the pylorus are split and separated. The procedure can be completed with an open technique or with laparoscopy. The mortality associated with surgical correction is less than 0.5%. Fluid and electrolyte losses are managed before surgical intervention and children usually can tolerate feeding several hours after surgery.[28]

Intestinal Malrotation

During the tenth week of embryonic development, the emerging ileum and cecum normally rotate, so that the cecum moves into the lower right quadrant of the abdomen and is fixed there by the mesentery. **Intestinal malrotation** is a condition in which rotation does not occur and the colon remains in the upper right quadrant, where an abnormal membrane or band may press on and obstruct the duodenum. The obstructing band over the duodenum, called a **periduodenal band (Ladd's band),** is one of the most significant findings in malrotation (Figure 42-3). Genetic factors associated with malrotation are being identified and most occur with other malformations or abnormalities.[29]

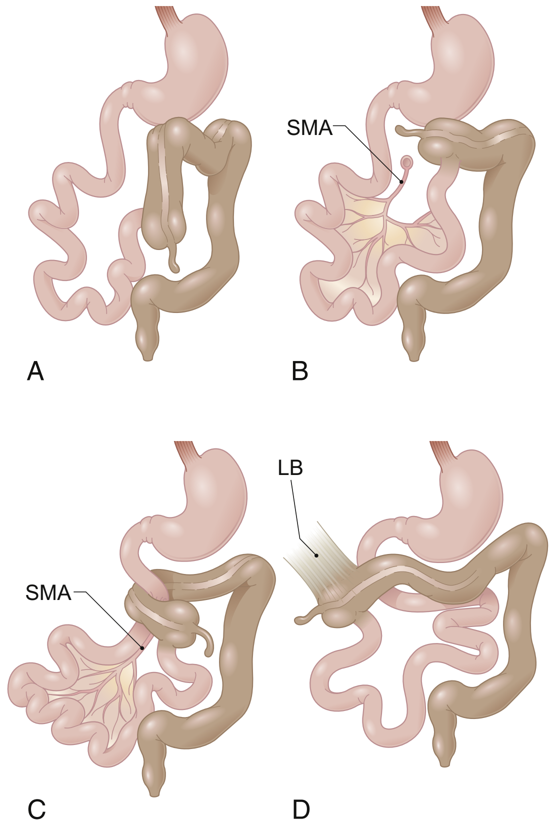

FIGURE 42-3 Variations of Intestinal Malrotation. **A,** Nonrotation. **B,** Incomplete rotation. **C,** Midgut volvulus with duodenal obstruction and obstruction of superior mesenteric artery blood flow. **D,** Incomplete rotation with Ladd's bands extending from the lateral and posterior abdominal wall to the subhepatic cecum. *LB,* Ladd's band; *SMA,* superior mesenteric artery. (From Gilbert-Barness E et al: *Potter's pathology of the fetus, infant and child,* ed 2, Philadelphia, 2007, Mosby.)

Associated abnormalities include 50% of children with duodenal atresia and 33% of those with jejunal atresia, as well as biliary or pancreatic malformations and heart defects.[30]

PATHOPHYSIOLOGY. The small intestine lacks a normal posterior fixation in malrotation because it has only a rudimentary attachment near the origin of the superior mesenteric artery. Therefore, the entire mass can twist when the mobile loops of intestine from the duodenojejunal junction to the middle of the transverse colon twist on themselves. The twisting is termed *volvulus.* Intestinal twisting around the rudimentary mesentery angulates and obstructs the intestinal lumen and partly or completely occludes the superior mesenteric artery, causing infarction and necrosis of the entire midgut.

CLINICAL MANIFESTATIONS. Although most cases of malrotation-associated volvulus and infarction develop during the neonatal period or infancy (younger than 1 year), some develop during childhood or even adulthood. In one study, 48% of individuals first diagnosed with malrotation were adults.[31] In infants the obstruction causes intermittent or persistent bile-stained vomiting after feedings. Abdominal distention is limited initially to the epigastrium because only the stomach and duodenum are dilated. The degree of distention depends on the pressure of swallowed air and the degree of obstruction caused by the volvulus. Dehydration and electrolyte imbalance may

occur rapidly because large amounts of pancreatic juice, bile, and gastric secretions are lost through vomiting. Fever usually ensues. Pain, scanty stools, diarrhea, bloody stools, and severe dehydration are associated with progressive volvulus, vascular compression, and infarction of the intestine in infants.[32] Intermittent or partial volvulus may be seen in older children and adults. This may be asymptomatic (25% to 50% of the time) and discovered during unrelated abdominal surgery, or it may cause minor abdominal complaints, such as nausea after meals, recurrent episodes of vomiting, or abdominal pain.[33]

EVALUATION AND TREATMENT. Diagnosis of malrotation with volvulus and infarction is based on a review of the clinical manifestations, upper gastrointestinal contrast imaging, and explorative laparoscopy.[34]

Treatment includes laparoscopic or open surgery to reduce the volvulus.[35] Necrotic bowel is resected and a primary anastomosis performed. An enterostomy may be created. Most children have a good outcome; however, there is risk for adhesion-related bowel obstruction in about 15% of cases.[36]

Meconium Ileus

Meconium is a substance that fills the entire intestine before birth. It consists of intestinal gland secretions and some amniotic fluid. Normally, meconium is passed from the rectum during the first 12 to 72 hours after birth.

Meconium ileus (MI) is intestinal obstruction caused by meconium formed in utero that is abnormally sticky and adheres firmly to the mucosa of the small intestine, resisting passage beyond the terminal ileum. The cause is usually a lack of digestive enzymes during fetal life. This meconium is also found to contain albumin, which is not normally found in meconium. MI is associated with cystic fibrosis.[37] In the cases *not* associated with cystic fibrosis, genes other than *CFTR* mutations have been identified.[38] The cause usually is unknown. Partial aplasia of the pancreas is an associated factor, however, and one fifth of infants with meconium ileus are premature or have a history of maternal hydramnios (excessive amniotic fluid). After intestinal atresia and malrotation with volvulus, meconium ileus is the most common cause of small intestinal obstruction in newborns.

PATHOPHYSIOLOGY. The terminal ileum is plugged with thick, viscous meconium resulting from the formation of an insoluble, calcium-glycoprotein compound in abnormal mucus. The segment of the ileum proximal to the obstruction is distended with liquid contents, and its walls may be hypertrophied. The segment distal to the obstruction is collapsed and filled with small pellets of pale-colored stool. Meconium in the obstructed segment has the consistency of thick syrup or glue. Peristalsis fails to propel this viscous material through the ileum, so it becomes impacted. Volvulus, atresia, or perforation of the bowel sometimes accompanies meconium ileus.

CLINICAL MANIFESTATIONS. Abdominal distention usually develops during the first few days after birth. The infant does not pass meconium and begins to vomit within hours or days of birth. Infants with cystic fibrosis may have signs of pulmonary involvement, such as tachypnea, intercostal retractions, and grunting respirations. The distended abdomen shows patterns of dilated intestinal loops that feel doughlike when palpated. Some of the loops contain scattered, firm, movable masses. Despite hyperactive peristalsis, the rectal ampulla is empty.

EVALUATION AND TREATMENT. All women of reproductive age should be offered preconception and prenatal cystic fibrosis (CF) carrier screening. Prenatal diagnosis of MI can be made by ultrasound. Radiologic imaging is used to confirm the presence of MI.[39] The sweat test is performed to detect or rule out cystic fibrosis. It is considered the "gold standard" and is accurate in 90% of infants. The treatment of choice for cases not complicated by volvulus or perforation is a hyperosmolar enema (e.g., metglutamine diatrizoate [Gastrografin]) performed under fluoroscopy. The fluid is drawn into the meconium mass, hydrating and softening it. Transient osmotic diarrhea follows. A warm saline enema containing 4% *N*-acetylcysteine may be given to help complete the evacuation. Surgical management includes tube enterostomy (a percutaneous drain), open enterostomy, or resection to remove the meconium mass. Survival of infants with meconium ileus is improving, with survival rates approaching 100%.[40] The mortality increases if obstruction is complicated by peritonitis.[41]

Distal Intestinal Obstruction Syndrome

Distal intestinal obstruction syndrome (DIOS), formerly called *meconium ileus equivalent,* affects approximately 15% of children and adults with cystic fibrosis.[42] DIOS is the partial or complete obstruction of the colon or the terminal ileum by abnormally viscous intestinal contents, particularly after episodes of dehydration or lack of pancreatic enzymes. It can occur in children or adults. The child displays signs and symptoms of intestinal obstruction. In most cases the obstruction is relieved by hypertonic enemas.[43]

Obstructions of the Duodenum, Jejunum, and Ileum

Congenital obstruction of the duodenum can be caused by intrinsic malformations (atresia or stenosis) or external pressure. The obstruction may be partial or complete and usually is located at or near the major duodenal papilla. Extrinsic obstructions can be caused by peritoneal bands that constrict the duodenum. The duodenum can be obstructed by an annular pancreas—a defect in which the head of the pancreas surrounds part of the duodenum. Congenital obstructions of the jejunum and ileum can be attributable to atresia, stenosis, meconium ileus, megacolon (Hirschsprung disease), intussusception, Meckel diverticulum, intestinal duplication, or strangulated hernia.

In **ileal atresia** or **jejunal atresia**, the intestine ends blindly proximal and distal to an interruption in its continuity, with or without a gap in the mesentery. Stenosis (narrowing of the lumen) causes dilation proximal to the obstruction and luminal collapse distal to it.

Meckel Diverticulum

Meckel diverticulum is an outpouching of all layers of the small intestinal wall (usually in the ileum) and is the most common congenital malformation of the gastrointestinal tract. The rules of 2 are cited in association with Meckel diverticulum: it occurs in about 2% of the population, 2% develop complications

usually before 2 years of age, there are 2 types of common ectopic tissue (gastric and pancreatic), and it is located within 2 feet of the ileocecal valve. Meckel diverticulum develops when there is failure to obliterate the omphalomesenteric duct, which normally leaves a fibrous band that connects the small intestine to the umbilicus during the first months of fetal development. Ectopic gastric mucosal cells are contained in the diverticuli and may cause peptic ulcer. Although most Meckel diverticuli are asymptomatic, the most common symptom is painless rectal bleeding. Intestinal obstruction, intussusception, and volvulus occur more commonly in adults. Diagnosis is made by symptom presentation and radionucleotide scintingraphy. The scan shows the gastric mucosal cells in the diverticuli. Treatment in those with symptoms is surgical resection.[44]

Congenital Aganglionic Megacolon

Congenital aganglionic megacolon (**Hirschsprung disease**) is a functional obstruction of the colon caused by the absence of the enteric ganglia along a variable length of the colon with inadequate motility. The incidence is approximately 1 in 5000 live births with an increased incidence in males, siblings of children with Hirschsprung disease, and children with Down syndrome or other congenital malformations.[45] The exact cause is unknown but multiple interacting factors and a complex inheritance pattern with mutations in multiple genes are involved.[46]

PATHOPHYSIOLOGY. Congenital aganglionic megacolon is caused by a malformation of the parasympathetic nervous system. It is characterized by abnormalities of the basement membrane and extracellular matrix and absence of the intramural ganglion cells in the enteric nerve plexuses (Meissner and Auerbach plexuses) along variable lengths of the colon, and there may be skipped segments. Lacking neural stimulation, the muscle layers of the colon wall fail to propel feces through the colon, leading to functional obstruction. In 80% of cases the aganglionic segment is limited to the rectosigmoid region (short-segment); in 3% the entire colon lacks ganglion cells and the ileum may be involved. The abnormally innervated colon impairs fecal movements, causing the proximal colon to become distended, hence the term *megacolon* (Figure 42-4).

The ganglia normally develop from an advancing neural crest between the muscle layers (tunica muscularis) in the submucosal area (muscularis mucosae) of the intestinal wall. In cases of congenital megacolon, neurologic development is blocked and large, nonmyelinated fibers develop in place of these ganglion cells. The segment of colon that lacks ganglion cells has a relatively normal lumen caliber and wall thickness. In the segment of the colon proximal to it, the lumen is dilated and the muscle hypertrophied. Therefore, the abnormal portion of the colon appears to be normal and the normal portion appears to be diseased.[47]

CLINICAL MANIFESTATIONS. The extent of the aganglionic portion of the colon determines the severity of the symptoms of congenital aganglionic megacolon. The most distal part of the rectum is always involved. This is the extent of the aganglionic portion in some children, and the child is said to have "ultrashort-segment" Hirschsprung disease and generally has only mild constipation as a symptom. These individuals may not be diagnosed until

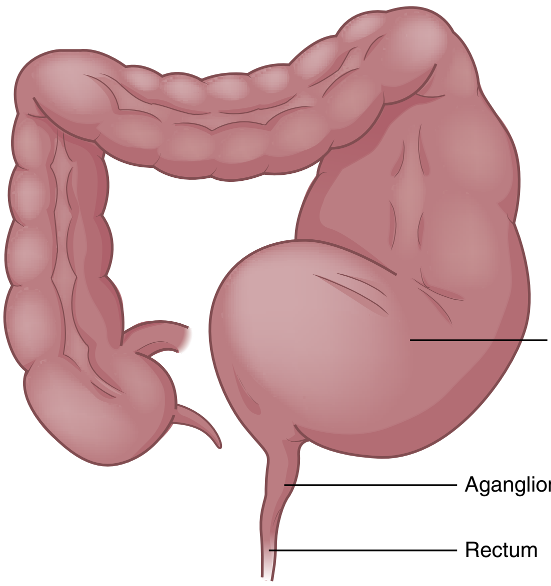

FIGURE 42-4 Congenital Aganglionic Megacolon (Hirschsprung Disease).

adulthood. Symptoms of chronic constipation, poor feeding, poor weight gain, and progressive abdominal distention increase in severity as the aganglionic portion extends proximally. Diarrhea may be the first sign, however, because only water can travel around the impacted feces.

In the neonate there is delayed passage of meconium and abdominal distention, with or without bilious vomiting. Bowel dilation stretches and partly occludes the encircling blood and lymphatic vessels, causing edema, ischemia, infarction of the mucosa, and significant outflow of fluid into the bowel lumen. Copious, liquid stools result. In severe cases infarction and destruction of the mucosa enable enteric microorganisms to penetrate the bowel wall. Frequently, gram-negative sepsis occurs, accompanied by fever and vomiting. Severe and rapid electrolyte changes may take place, causing collapse and rapid death.[48]

EVALUATION AND TREATMENT. Hirschsprung disease in usually diagnosed in the newborn period and should be suspected with failure to pass meconium within 24 to 48 hours after birth. Radiocontrast enema, anorectal manometry, and rectal suction biopsy are screening tools for the diagnosis of Hirschsprung disease. Serial manometry measurements may be required in neonates.[49] This test has uncovered ultrashort-segment Hirschsprung disease in older children with a history of constipation.[50] The definitive diagnosis is made by rectal suction biopsy showing an absence of ganglion cells in the submucosa of the colon.[51]

The involved segment is usually resected within the first few months of life using a "pull-through" procedure that anastomoses the proximal and distal segments of remaining bowel or rectum. Laparoscopic or open approaches may be used. In skipped segment disease, the area of normal bowel may be preserved.[52] For children with short-segment Hirschsprung disease, enemas are given to relieve impaction, and laxatives with a dietary and bowel training program are used in preference to surgical intervention.[50] The child is not treated for diarrhea.

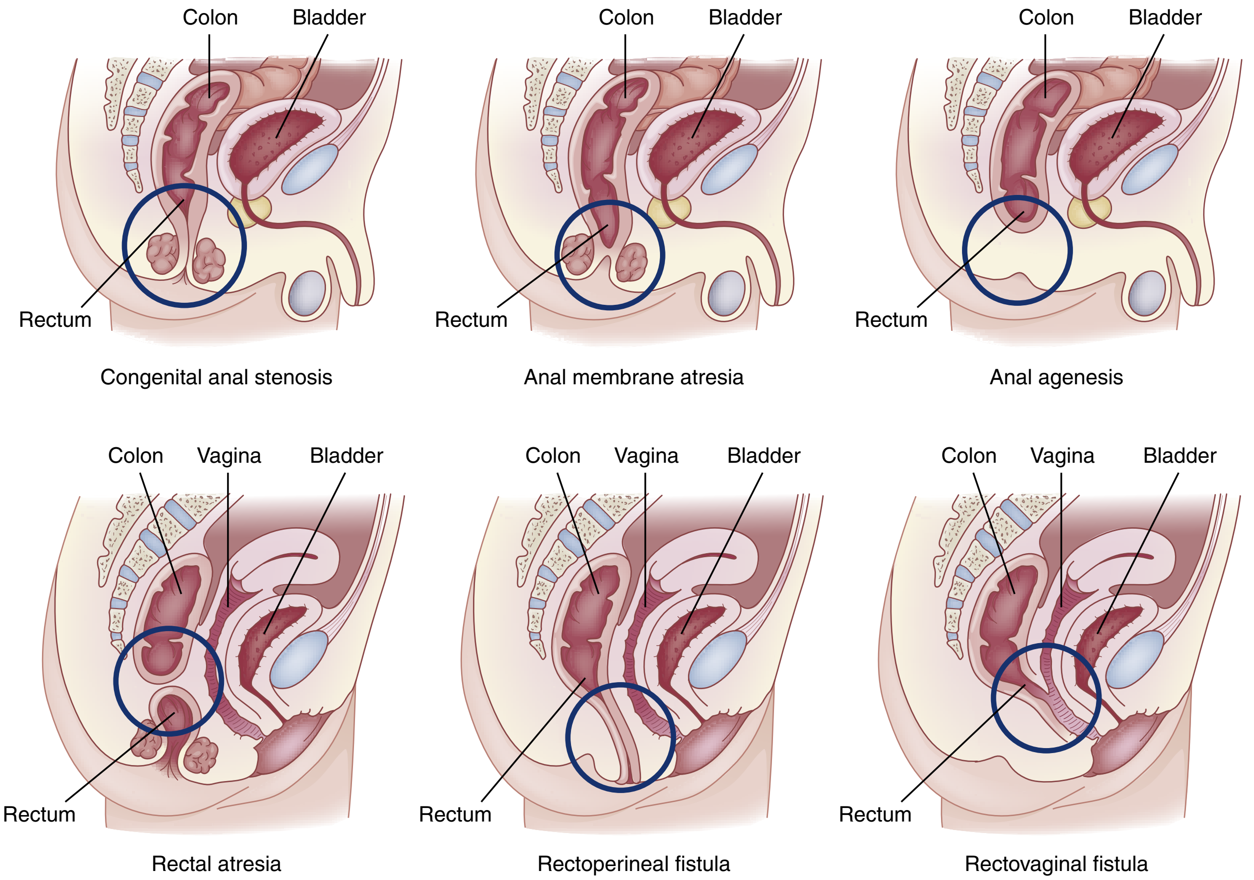

FIGURE 42-5 Anorectal Stenosis and Imperforate Anus.

Hirschsprung-associated enterocolitis is a postsurgical complication that sometimes recurs. If postoperative enterocolitis is allowed to persist, pseudopolyps may appear. Because these are essentially identical to the lesions of ulcerative colitis, they have malignant potential. Therefore, a colectomy is indicated if pseudopolyps develop.

In general, the prognosis of congenital megacolon is satisfactory for children who undergo surgical treatment. Bowel training may be prolonged; however, most children achieve bowel continence before puberty whereas others have long-term constipation or fecal incontinence.[53]

Anorectal Malformations

Congenital anorectal malformations (ARMs) are rare birth defects of unknown etiology that range from mild anal stenosis, which is corrected by simple dilation, to complex deformities, such as anal or rectal agenesis, atresia, and rectourethral fistula (Figure 42-5). Deformities that cause complete obstruction are known collectively as **imperforate anus.** The cause is unknown.[54] ARM occurs in approximately 1 in 2500 to 1 in 5000 newborn babies.[55]

Approximately 40% of infants with ARMs have other developmental anomalies, including Down syndrome, congenital heart disease, renal and urologic abnormalities, cryptorchidism, esophageal atresia, and malformations of the spine.[56] Imperforate anus may not be obvious. It can be detected by gentle insertion of a rectal tube; x-ray films show dilations throughout the intestinal tract. Anal stenosis can be treated by dilations, but all other anorectal malformations require surgical correction. The overall death rate is approximately 10%. More than 90% of children with a low (anal) anomaly and intact sacrum achieve bowel continence with stenosis as a common complication. Children with very high anomalies or anomalies associated with genitourinary fistulae have more difficulty achieving continence.[57,58]

Acquired Impairment of Motility

Intussusception

Intussusception is the telescoping or invagination of one portion of the intestine into another. It is the most common cause of acquired intestinal obstruction in infants between 5 and 10 months of age, although it can occur at any age. The ileum usually invaginates the cecum and part of the ascending colon by collapsing through the ileocecal valve (ileocolic intussusception). It can occur anywhere from the duodenum to the rectum. Intussusception is more common in males and can be idiopathic, can be associated with lead points (polyps or tumors, Meckel diverticulum, intestinal adhesions) or cystic fibrosis, or can develop immediately after abdominal surgery.[59]

PATHOPHYSIOLOGY. Most commonly, the proximal portion of the intestine, the intussusceptum, collapses into the distal portion, the intussuscipiens, in the direction of peristaltic flow (Figure 42-6). As this occurs, the intussusceptum drags its mesentery into the enveloping lumen. Initially, the mesentery

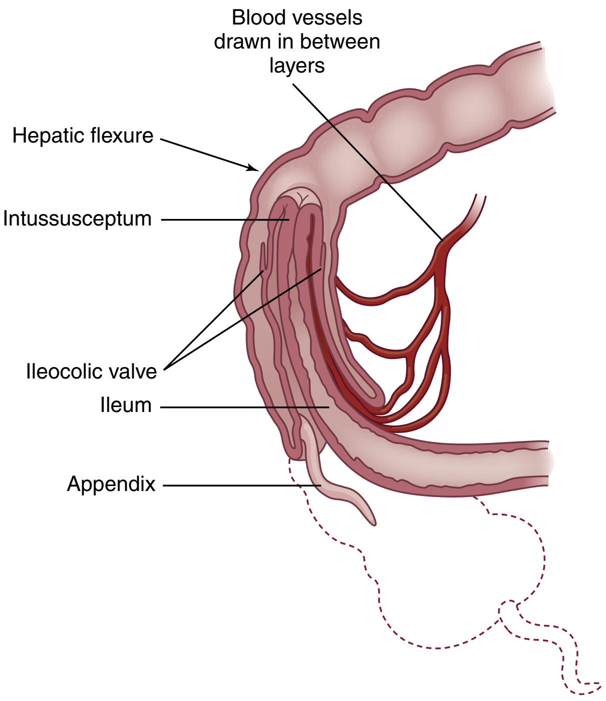

FIGURE 42-6 Ileocolic Intussusception.

is constricted, obstructing venous return. Compression of the mesenteric vessels between the two layers of intestinal wall and at the U-shaped angle at either end of the intussusceptum leads within hours to venous stasis, engorgement, edema, exudation, and further vascular compression. Unless the intussusception is treated, bleeding, necrosis, bowel perforation, and gangrene ensue. The tension of the mesentery on the intussusceptum tends to arch the bowel in a curve with its center at the mesenteric root. Edema and compression obstruct the flow of chyme through the intestine.

CLINICAL MANIFESTATIONS. The affected infant suddenly develops *abdominal pain,* becomes irritable (colicky), and flexes the knees. *Vomiting* occurs soon afterward. A single normal stool may be passed, evacuating the colon distal to the apex of the intussusception. Following the passage of normal stool, 60% of infants pass *"currant jelly" stools,* which appear dark and gelatinous because of their blood and mucus content. In one study, less than one third of children had this clinical triad of vomiting, colicky abdominal pain, and bloody stools.[60] Most infants have a tender, sausage-shaped *abdominal mass*. Abdominal tenderness and distention develop as intestinal obstruction becomes more acute.

EVALUATION AND TREATMENT. Diagnosis is based on clinical manifestations and onset of symptoms. Ultrasound of the abdomen, computed tomography (CT), and magnetic resonance imaging (MRI) are commonly completed for diagnosis.[61] More than 82% of children have positive ultrasound results in ileocolic and jejunointestinal intussusception. Reduction is an emergency procedure involving hydrostatic pressure generated by an air or a barium enema given using fluoroscopic guidance. This technique is successful most of the time with about a 10% to 13% recurrence rate. Surgical reduction is done on children who fail or, in rare cases, have perforation.[62,63] Untreated intussusception in infants is nearly always fatal. Most infants recover if the intussusception is reduced within 24 hours. Spontaneous reduction of intussusception may occur in symptomatic or asymptomatic children.[64]

Gastroesophageal Reflux Disease

Gastroesophageal reflux (GER) is the return of stomach contents into the esophagus because of relaxation or incompetence of the lower esophageal sphincter. In newborns, gastroesophageal reflux is normal (physiologic reflux) because neuromuscular control of the gastroesophageal sphincter is not fully developed. The frequency of reflux is highest in premature infants and decreases during the first 6 to 12 months of life. Children usually outgrow their reflux. **Gastroesophageal reflux disease (GERD)** occurs when protective mechanisms are ineffective and persistent reflux results in complications such as mucosal erosion, bleeding, dysphagia, or failure to thrive.

PATHOPHYSIOLOGY. GERD in children may be related to delayed maturation of the lower esophageal sphincter or impaired hormonal or neurotransmitter response mechanisms (i.e., vasoactive intestinal peptide and nitric oxide). Factors that maintain lower esophageal sphincter integrity in children include location of the gastroesophageal junction in a high-pressure zone within the abdomen, mucosal gathering within the sphincter, and the angle at which the esophagus is inserted into the stomach. Reflux persists if any of these pressure-maintaining factors is altered. Irritation of the mucosa by acidic gastric contents results in inflammation of the esophageal epithelium (esophagitis) and stimulation of the vomiting reflex.[65]

GERD may be a factor in the stimulation of reactive airway disease and otitis media with effusion in some children but the exact relationships are yet to be defined.[66,67] The relationship between apnea of prematurity caused by GERD and laryngospasm is controversial.[68]

Eosinophilic esophagitis is differentiated from GERD (see Chapter 41) and can occur in children. It is thought to be an atopic disease involving immediate as well as delayed hypersensitivity reactions to food ingestion. A mast cell, eosinophil, and T lymphocyte infiltrate are associated with inflammation of the entire esophagus that is nonresponsive to acid-suppression therapy. Eosinophilic inflammation may lead to *progressive subepithelial fibrosis* with esophageal strictures, narrowing, and dysphagia. The esophageal mucosa can appear normal in children at endoscopy. Dysphagia, food impaction, and vomiting are common symptoms and other atopic diseases, such as asthma and eczema, may be present. Treatment includes elimination diets and oral corticosteroids.[69,70]

CLINICAL MANIFESTATIONS. The signs and symptoms of GERD are caused by exposure of the esophageal epithelium to refluxed gastric contents; 85% of affected infants vomit excessively during the first week of life and usually have other symptoms by 6 weeks, including feeding difficulty, feeding refusal, and failure to thrive.

Vomiting may be forceful and must be differentiated from pyloric stenosis. Aspiration pneumonia develops in one third of infants with gastroesophageal reflux (GER). In cases that persist into childhood, chronic cough, wheezing, hoarseness, and

recurrent pneumonia are common.[71,72] Repeated vomiting leads to inadequate retention of nutrients, adversely affecting growth and weight gain. Esophagitis from exposure of the esophageal mucosa to acidic gastric contents is manifested by pain, bleeding, and eventually stricture formation and abnormal motility. Approximately 10% to 25% of children with GERD also have iron deficiency anemia caused by frank or occult blood loss.[73]

EVALUATION AND TREATMENT. The clinical manifestations are often adequate to confirm a diagnosis of GERD. However, irritability, crying, feeding refusal, and regurgitation can be common problems in infants and not specific to GERD. Esophageal pH monitoring with a probe for 24 hours and endoscopy with biopsy are routinely used for diagnosis.[74-76] Mild GER resolves without treatment. Thickened feedings may help some infants[77]; however, this has not been shown to be consistently helpful. Techniques for managing infant reflux include small, frequent feedings; prolonged feeding duration and slower flow rate; and frequent burping.[78,79]

Medications are used to treat erosive esophagitis and prokinetic agents must be used with caution.[80] If no improvement is seen with medical management or the child has life-threatening events with reflux, an antireflux surgical procedure, including gastropexy and fundoplication, is performed. A fundoplication recreates a valve by wrapping the fundus of the stomach around the lower esophagus and can be completed using laparoscopic techniques.[65, 81]

Impairment of Digestion, Absorption, and Nutrition

Cystic Fibrosis

Classic gastrointestinal manifestations of cystic fibrosis include meconium ileus at birth, which is usually pathognomonic for cystic fibrosis (CF). Approximately 15% to 20% of individuals with CF present with this symptom. Rectal prolapse is an occasional presenting sign that should always prompt testing for CF. About 10% of CF patients do not experience gastrointestinal problems and are termed "pancreatic sufficient." Several specific *CFTR* mutations are predictive of this milder phenotype. Males with CF are typically infertile (98%).

Cystic fibrosis of the pancreas, which is also called *mucoviscidosis* or *fibrocystic disease* of the pancreas, is a genetically transmitted disease (mutation of the long arm of chromosome 7) that involves many organs and systems and usually causes death in childhood or young adulthood. It is the most common cause of chronic suppurative lung disease in children and is the most common life-threatening inherited disease in the white population. This section focuses on the deficiency of pancreatic enzymes. (Chapter 36 discusses the pulmonary consequences of cystic fibrosis.)

PATHOPHYSIOLOGY. The pathophysiologic triad that is the hallmark of CF includes: (1) pancreatic enzyme deficiency, which causes maldigestion; (2) overproduction of mucus in the respiratory tract and inability to clear secretions, which cause progressive chronic obstructive pulmonary disease; and (3) abnormally elevated sodium and chloride concentrations in sweat. Exocrine secretions tend to be abnormally thick and precipitate in the glandular ducts, obstructing flow. Almost all clinical manifestations of CF are a result of overproduction of extremely viscous mucus and pancreatic enzyme deficiency. The full spectrum of involvement is summarized in Table 42-1.

Pancreatic function may range from normal to completely ablated. Approximately 85% of patients have pancreatic insufficiency. Obstruction of the pancreatic ducts with thick mucus blocks the flow of pancreatic enzymes and causes degenerative and fibrotic changes in the pancreas. Pancreatic damage eventually can affect the beta cells, resulting in diabetes mellitus (10% to 25%). The incidence of diabetes mellitus and cirrhosis (13% to 17%) in this population has increased as larger numbers of people with cystic fibrosis have moved into young and middle adulthood. Severe problems with maldigestion of proteins, carbohydrates, and fats occur because of insufficient secretion of pancreatic enzymes. Failure to thrive, growth failure, malabsorptive symptoms, metabolic abnormalities, trace element deficiencies, fat-soluble vitamin alterations, electrolyte imbalances, and decreased bone mineral density can occur early in the disease.[82-84]

CLINICAL MANIFESTATIONS. Clinical manifestations are presented in Table 42-1.

EVALUATION AND TREATMENT. To determine the extent of pancreatic function 72-hour stool fat measurements are used. Stools also may be examined for absence of pancreatic enzymes, particularly fecal elastase, trypsin, and chymotrypsin. To optimize treatment, the carbon-13 (^{13}C) mixed triglyceride breath test offers a simple, noninvasive way of assessing the need for pancreatic enzyme supplementation in children with cystic fibrosis.[85] Pancreatic replacement enzymes are administered before or with meals and high-calorie, high-protein diets with frequent snacks and vitamin supplements are used to treat malnutrition.[86] However, anorexia is not uncommon in this group secondary to pulmonary disease and frequently large sputum output. To combat the worsening problem of growth failure in children with cystic fibrosis, nasogastric or gastrostomy tube feedings are used to supplement oral intake and promote weight gain. Monitoring of growth and body mass index is critical to treatment evaluation.[87,88]

Gluten-Sensitive Enteropathy

Gluten-sensitive enteropathy, formerly called *celiac sprue* or *celiac disease,* is an autoimmune disease of the small intestinal villous epithelium when there is ingestion of the cereal protein gluten (gliadin) found in wheat, rye, barley, and oats in genetically susceptible individuals. The disease has a prevalence of about 1% worldwide and about 0.71% in the United States; many cases are undiagnosed.[89] Although gluten-sensitive enteropathy is widely perceived as a malabsorption syndrome of childhood, the diagnosis is usually made in adulthood. It is not known why disease presentation varies so widely.[90] Numerous genes have been identified and other autoimmune diseases can be associated with the autoantibodies of gluten-sensitive enteropathy, including type 1 diabetes mellitus, autoimmune thyroiditis, and Addison disease.[91]

PATHOPHYSIOLOGY. The disease is complex and involves the interaction of genetic, immune, and environmental factors. Both cellular immunity and humoral immunity are implicated.[92] The major pathophysiologic characteristic is T-cell–mediated

TABLE 42-1 PATHOPHYSIOLOGY, CLINICAL MANIFESTATIONS, AND COMPLICATIONS OF CYSTIC FIBROSIS

ORGAN INVOLVED	SECRETORY DYSFUNCTION	CLINICAL MANIFESTATIONS	COMPLICATIONS
Sweat glands	Elevated concentrations of sodium and chloride in sweat	Hyponatremia; hypochloremia	Heat prostration; shock
Intestine			
Newborn	Viscid meconium	Meconium ileus with intestinal obstruction	Meconium peritonitis
Older child and adult	Inspissated (dried out) mucofecal masses (intestinal sludging)	Partial intestinal obstruction with severe cramping pains	Gastroesophageal reflux Volvulus (obstruction), intussusception (prolapse) Distal intestinal obstruction syndrome
Pancreas (enzyme deficiency)	Inspissation and precipitation of pancreatic secretions, causing obstruction of pancreatic ducts	Absence of pancreatic enzymes, causing malabsorption of food; fatty, bulky stools	Hypoproteinemia; iron deficiency anemia; malnutrition
		Decreased vitamins A, D, E, and K absorption	Vitamins A, D, E, and K deficiency and rectal prolapse
		Growth failure	Decreased bone density and risk of fractures in adolescents and adults
	Insulin deficiency	Glucose intolerance	Diabetes mellitus
Liver	Inspissation and precipitation of bile in biliary system	Focal biliary cirrhosis; shrunken, "hobnail" liver	Portal hypertension with esophageal varices, hematemesis and hypersplenism Steatorrhea from lack of bile salts
Salivary glands	Inspissation and precipitation of secretions in small ducts of submaxillary and sublingual salivary glands	Mild patchy fibrosis of salivary glands	None
Paranasal structures	Viscid mucus	Retention of mucus; clouding seen on sinus roentgenograms	Mucopyoceles (pus accumulations) with nasal deformity or orbital cavity extension
Nose	Nasal polyps	Obstruction of nasal airflow	None
Lungs	Viscid mucus in bronchioles and bronchi	Obstruction of bronchioles causing bronchiolectasis, bronchiectasis, and chronic lung infection	Hemoptysis; pneumothorax; cor pulmonale; atelectasis; chronic bacterial infection; respiratory failure
Reproductive tract			
Male	Viscid genital tract secretions during embryologic development, causing failure of formation of normal vas deferens	Sterility	None
Female	Distention of endocervical epithelial cells with cytoplasmic mucin	Decreased fertility	Polypoid cervicitis (cervical inflammation) while taking oral contraceptives

Data from Gelfond D, Borowitz D: *Clin Gastroenterol Hepatol* 11(4):333–342, 2013; Javier RM, Jacquot J: *Joint Bone Spine* (5):445–450, 2011; Rudolph CD et al: *Rudolph's pediatrics,* ed 21, New York, 2003, McGraw-Hill.

autoimmune injury to the intestinal epithelial cells.[91] Transglutaminase 2 (TG2) and endomysial autoantibodies closely correlate with the acute phase of the disease in the presence of gluten.[93] T-cell infiltration results in mucosal cell destruction with inflammation, atrophy, and flattening of villi in the upper small intestine (Figures 42-7 and 42-8). The atrophy is caused by accelerated shedding of epithelial cells from the villi. To compensate for this loss, epithelial cell production increases, causing hypertrophy of the crypts of Lieberkühn. Increased cell production is not sufficient to keep pace with cell loss, and the cells are not mature enough to sustain absorptive functions. The microvilli and brush border disappear, leaving patches of bald mucosa. The loss of mucosal surface area and brush-border enzymes leads to severe malabsorption. The pathologic process is most pronounced in the duodenum and jejunum. The ileum may be spared. The severity of disease correlates with the length of the small intestinal mucosa involved.[94,95]

Damage to the mucosa of the duodenum and jejunum has secondary effects that exacerbate malabsorption. The secretion of intestinal hormones, such as secretin and cholecystokinin, may be diminished. Because these chemical messengers are scarce, secretion of pancreatic enzymes and expulsion of bile from the gallbladder decrease.

Destruction of mucosal cells causes inflammation, and water and electrolytes are secreted, leading to watery diarrhea. In addition, absorption that normally occurs by sodium-dependent

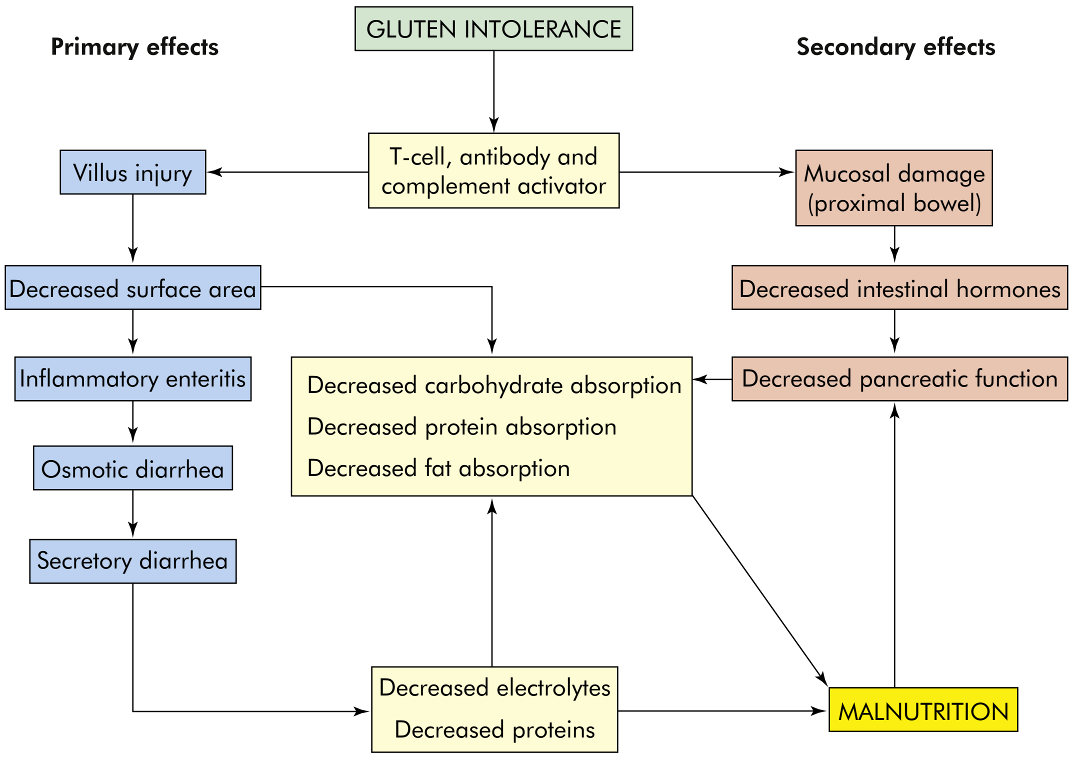

FIGURE 42-7 Pathophysiology of Gluten-Sensitive Enteropathy.

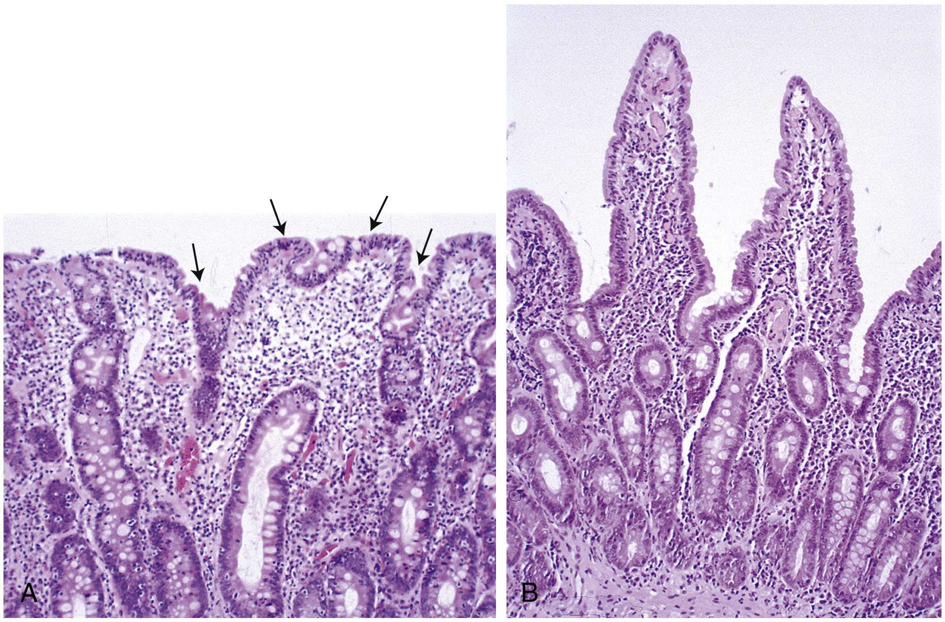

FIGURE 42-8 Gluten-Sensitive Enteropathy. **A,** Atrophy of villi and elongation of crypts that result in malabsorption *(arrows).* **B,** Recovery of normal villus structure after 6 months of gluten-free diet. (From Damjanov I, Linder J: *Pathology: a color atlas,* St Louis, 2000, Mosby.)

active transport or facilitated diffusion is impaired. Carbohydrates, amino acids, dipeptides, water-soluble vitamins, bile salts, and cations are not absorbed from the intestinal lumen. Potassium loss, which is more severe than sodium loss, leads to muscle weakness. Magnesium and calcium malabsorption can cause seizures or tetany. Unabsorbed fatty acids combine with calcium, and secondary hyperparathyroidism increases phosphorus excretion, resulting in bone reabsorption. Calcium is no longer available to bind oxalate in the intestine and is absorbed, which causes hyperoxaluria. Gallbladder function may be abnormal, and bile salt conjugation may be decreased.

Fat malabsorption in the jejunum is the major cause of steatorrhea (fatty stools). Malabsorption may be mild early in the disease. Fecal nitrogen level is elevated because peptidase

deficiencies impair protein absorption. Pancreatic function is decreased, not only because of decreased hormonal levels but also because of malnutrition.

Deficiencies of fat-soluble vitamins are common in children with gluten-sensitive enteropathy. Vitamin K malabsorption leads to hypoprothrombinemia. In one third of cases, iron and folic acid malabsorption is manifested as cheilosis; anemia; and a smooth, red tongue. Vitamin B_{12} absorption is impaired in those with extensive ileal disease. Because the absorption of folate and iron is greatest in the proximal small intestine, deficiencies of these substances are common.

Dermatitis herpetiformis is a cutaneous manifestation of gluten-sensitive enteropathy that involves transglutaminase 3 IgA autoantibodies. They circulate to the skin and interact with antigens produced by keratinocytes. The antigen-antibody complex activates neutrophils in the papillary dermis, causing blister formation. The lesions present with a symmetric distribution on the extensor surfaces of the elbows (90%), knees (30%), shoulders, middle line of the back, or buttocks. The sacral region, scalp, nuchal area, face, and groin also may be involved.[96]

CLINICAL MANIFESTATIONS. The onset of clinical manifestations of gluten-sensitive enteropathy depends on the age of the infant when gluten-containing substances are added to the diet. In 50% of affected children, onset occurs by 18 months of age, with latent intervals varying from months to years. Severity of symptoms can vary tremendously, and children older than 3 years of age can present with mild to severe gastrointestinal symptoms.[97]

Diarrhea is an early sign in most infants accompanied by failure to thrive and anemia. The stools are pale, bulky, greasy, and foul smelling, and may contain oil droplets. Three to five such movements occur daily. As early as 3 or 4 months of age, growth failure, anorexia, and constipation can begin. In older children constipation is occasionally seen despite steatorrhea. Vomiting and abdominal pain are prominent in infants but unusual in older children. Anorexia is prevalent. The classic physical manifestations of organic failure to thrive, such as abdominal protuberance, wasted buttocks and limbs, and hypotonia, occur in less than 50% of infants with gluten-sensitive enteropathy. Growth is usually diminished.[98]

Manifestations of malabsorption, such as rickets, tetany, frank or occult bleeding, or anemia, may be obvious. Some children urinate more at night. The tongue is smooth and red, and the child may bruise and bleed easily. Hypomagnesemia and hypocalcemia cause irritability, tremor, convulsions, tetany, bone pain, osteomalacia, and dental abnormalities. If vitamin D deficiency is prolonged, rickets and clubbing of the terminal phalanges are likely. Eighty-six percent of older children have fingerprint changes (ridge atrophy). In older children, delayed puberty and infertility may be a manifestation of otherwise subtle gluten-sensitive enteropathy.[99]

EVALUATION AND TREATMENT. Diagnosis includes confirmation with serologic antiendomysial and antitransglutaminase IgA antibodies and HLA-type DQ2 or DQ8 (human leukocyte antigen class II haplotypes that regulate immunity). Intestinal biopsy detects the classic mucosal changes caused by gluten-sensitive enteropathy and confirms the diagnosis. The initial biopsy may be followed by a second intestinal biopsy to demonstrate regeneration of intestinal villi after treatment with a gluten-free diet.[100] Most children with celiac disease remain undiagnosed.

Treatment consists of the immediate and permanent institution of a gluten-free diet. Lactose (milk sugar) intolerance is presumed because of damage to the villi; therefore, lactose is excluded from the diet. With removal of gluten and healing of the mucosa, lactose may be reintroduced at a later point.[101] Infants are routinely given vitamin D, iron, and folic acid supplements to treat deficiencies. Breast-feeding at the time of gluten introduction in the diet delays the appearance of celiac disease.[102]

Most children have complete remission of symptoms with clearing of serologic markers and an excellent prognosis. Approximately 25% of children experience recurrent relapses that interfere with growth. There is an increased incidence of malignant disease, particularly T-cell lymphoma, in individuals who fail to respond to gluten-free diets.[103]

Severe Acute Malnutrition

Kwashiorkor (nutritional edema) and marasmus, or a combination of both, are the most common types of malnutrition in children. These disorders are known collectively as **severe acute malnutrition (SAM),** previously known as **protein-energy malnutrition (PEM).** Both are states of starvation associated with food shortages (see Chapter 41). **Kwashiorkor** is severe protein deficiency, and **marasmus** is severe deficiency of all nutrients. Kwashiorkor is a widespread nutritional problem among children in developing countries and economically destitute populations particularly when associated with human immunodeficiency virus (HIV) infection.[104] The disease usually occurs in infants or children from 1 to 4 years of age who have been weaned from breast milk to a high-starch, protein-deficient diet.

Marasmus can occur at any age, but it is common in children younger than 1 year. In marasmus, starvation is attributable to lack of protein and carbohydrates. One third of the world's children suffer from PEM, with the highest concentrations in Asia, Africa, Latin America, and the Carribbean.[105]

The mortality risk for children in developing countries has been found to be inversely related to anthropometric indicators (height, weight, head circumference, skinfold thickness, midarm muscle circumference). There is elevated risk even in the mild to moderate range of malnutrition.[106] Poor sanitation, early weaning of breast-fed infants, use of overdiluted commercial formulas, and infection (measles, malaria, pneumonia, HIV, tuberculosis, and diarrheal disease) are major risk factors for SAM.

SAM is a complication of some diseases, such as chronic fever, malignancy, digestive and malabsorptive disorders, and psychogenic illness. Radiation therapy, chemotherapy and long-term dialysis also can contribute to SAM. Acute and chronic malnutrition is common in hospitalized children.[107]

PATHOPHYSIOLOGY. In kwashiorkor, the deficit of dietary amino acids reduces protein synthesis in all tissues. Physical growth

and mental growth are stunted, and maintenance of minimal life processes is in jeopardy. The lack of sufficient plasma proteins, particularly albumin, causes systemic pressure changes that result in generalized edema. The volume of total body water and extracellular fluid increases. Life-threatening hypokalemia, hyponatremia, and hypophosphatemia can occur.[108] The liver swells with stored fat because no hepatic proteins are synthesized to form and release lipoproteins. Pancreatic atrophy and fibrosis may be present. Kwashiorkor also causes malabsorption, reduced bone density, and impaired renal function. If the condition is not reversed, the prognosis is very poor.

Because the intake of all dietary nutrients is reduced to a minimum in marasmus, metabolic processes, including liver function, are preserved but growth is severely retarded. Caloric intake is too low to support protein synthesis for growth or the storage of fat. If more protein is needed than is ingested, muscle wasting occurs. Fat wasting and anemia are common and can be severe. The volume of total body water is high. Serum triglyceride and phospholipid levels increase with increasing severity of malnutrition, but other serum values, such as cholesterol, are normal or slightly reduced. High fasting phospholipid and triglyceride concentrations are predictive of a poor prognosis for these children.[109] Severe vitamin A deficiency contributes to blindness.[110]

CLINICAL MANIFESTATIONS. Retarded physical, mental, and psychologic development; muscle wasting; diarrhea; dermatosis; low hemoglobin level; and infection characterize marasmus. The presence of subcutaneous fat, hepatomegaly, and fatty liver distinguishes kwashiorkor from marasmus. These manifestations are missing in marasmus because caloric intake is not sufficient to support fat synthesis and storage.[111]

EVALUATION AND TREATMENT. Evaluation of SAM is based on nutritional history and clinical manifestations. Providing deficient nutrients resolves clinical symptoms in 4 to 6 weeks. Physical and mental retardation may not be reversible, however. Nutritional rehabilitation with appropriate environmental stimulation for infants and young children resolves or improves cerebral shrinkage, physical growth, and psychomotor development.[112,113] Advances are being made in the local preparation of ready-to-use therapeutic food for both home- and community-based malnutrition management.[114] Breast-feeding needs to be encouraged and some infants and children require intensive inpatient treatment.[115] High morbidity and mortality occur in some regions of the world.[116] Routine use of antibiotics for uncomplicated SAM needs investigation.[116a]

Failure to Thrive

Failure to thrive (FTT) is the inadequate intake, insufficient absorption, or excessive expenditure of calories. It is manifested as a deceleration in weight gain, a low weight/height ratio, or a low weight/height/head circumference ratio. FTT is a common problem and can present at any time in childhood.

PATHOPHYSIOLOGY. **Organic FTT** has a pathophysiologic cause, such as GERD, pyloric stenosis, gastroenteritis, cystic fibrosis, malabsorption syndromes, infection by intestinal parasites, congenital anomalies, very low birth weight, or chronic diseases of major body systems. All these factors either reduce the availability of nutrients for maintenance and growth or increase nutrient requirements, particularly when there is chronic infection. A chronic disease or congenital anomaly that causes weakness or reduced stature can create developmental, psychosocial, and emotional problems for the child.

Nonorganic FTT occurs in the absence of any gastrointestinal, endocrine, or other chronic diseases. It is usually associated with psychosocial deprivation, although behavioral problems may contribute to its occurrence in the absence of maternal pathologic findings. Behavioral and psychosocial problems may be compounded by inadequate economic resources and lack of knowledge. Generally the problem in nonorganic FTT is ineffective nurturing or neglect by parents and primary caregivers. A variety of parental stressors may be involved and include the following:

- Lack of nurturance in the parents' own childhood
- Unwanted pregnancy
- Inability to bond with the infant because of health or other problems
- Postpartum or maternal depression
- Family crisis, such as a death or marital problems
- Stress caused by single parenthood or social isolation
- Mental, emotional, or physical illness

The first few postnatal months appear to be a sensitive period in the relationship between growth and mental development, suggesting a critical need for early diagnosis and aggressive interventions.[117-119]

CLINICAL MANIFESTATIONS. Clinical manifestations of organic FTT are delayed growth accompanied by manifestations of the underlying disease (e.g., diarrhea). Manifestations of nonorganic FTT are delayed growth plus reduced energy level, reduced responsiveness and interaction with the environment, social isolation, spasticity or rigidity when held or touched, inability to make eye contact or smile, refusal to eat, and rejection of foods. Weight loss and decelerated growth are accompanied by restricted development in many areas. Nonorganic FTT is a complex syndrome involving psychosocial, emotional, and parent-child problems that compound the pathophysiologic abnormalities.[120,121] Children with primarily organic FTT have been found to have lower developmental skills, and their parents have been found to have higher emotional distress. Infant stress, vomiting, feeding disorders, and psychosocial factors have been noted in children with organic and inorganic FTT, making the distinction between the two complex.[122]

EVALUATION AND TREATMENT. Failure to thrive is suggested if a child falls below the third percentile on the growth curve or is lagging in a previously established growth curve. Organic FTT is manifested in infancy by weight, height, and head circumference growth that may be parallel to but below the normal ranges. If no genetic, endocrine, or other systemic disorder is identified and if the physical and laboratory examinations show no abnormalities other than delayed growth, an environmental cause is indicated.[123]

Hospital admission is recommended if the diagnosis is unclear or the child is in nutritional or emotional jeopardy. Eating patterns, food preferences, caloric intake, and family interactions can be assessed during the hospital stay. If the cause is environmental, the hospitalized child with FTT usually begins

to gain weight. Organic and nonorganic FTT can coexist, making the distinction between them more difficult.

If an organic problem has been identified, management of FTT consists of treating the cause. Management of nonorganic FTT involves the immediate total care of the child and measures to address: (1) the psychosocial and emotional problems of the caregivers, (2) parent-child interactions, and (3) access to adequate nutritional resources. Counseling, parental modeling, and long-term family support are sometimes required. Clinical manifestations of organic FTT have inorganic components in the majority of children. The most successful interventions not only treat the underlying organic cause but also address ways to assist parents with feeding practices and management of psychosocial symptoms.[124,125]

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is an ischemic, inflammatory condition that causes bowel necrosis and perforation, and infant death if untreated. It is the most common gastrointestinal emergency in the newborn. The overall death rate is between 12% and 30% and is higher for infants requiring surgery.[126] The incidence of NEC is increasing, causing 1500 to 2000 infant deaths every year in the United States.[127] NEC primarily occurs in premature very low birth weight infants.[128] The risk of NEC decreases as the gastrointestinal tract matures.

PATHOPHYSIOLOGY. The exact etiology of NEC is unclear. Multiple factors contribute to the development of NEC including premature birth (<28 weeks), low birth weight, immature immunity, immature intestinal motility and barrier function, abnormal bacterial colonization, infections, maternal age greater than 35 years, maternal hypertensive disease of pregnancy, perinatal stress and low Apgar scores, effects of medications, enteral feeding, and genetic predisposition.[129,130] The immature mucosal barrier delays digestion and motility is slower, allowing for the accumulation of noxious substances that damage the intestine and increase permeability and increase the risk for infection. Translocation of intestinal bacteria and other substances contributes to injury, inflammation, and development of systemic inflammatory disease. Immature intestinal innate immunity and an unfavorable balance between normal and pathogenic bacteria promote intestinal inflammation and release of proinflammatory mediators.[131] Accumulation of gas in the intestine can cause pressure that decreases blood flow and an imbalance between vasodilator and vasoconstrictor inputs in the immature gut may lead to vasoconstriction, promoting ischemia, necrosis, and perforation. Injury to Paneth cells located in the intestinal crypts has also been proposed.[131a] The terminal ileum and proximal colon are most often involved.[132,133]

CLINICAL MANIFESTATIONS. Manifestations of NEC appear suddenly and usually within 2 weeks of birth after introduction of enteral feeding. Symptoms may appear earlier in full-term infants (5.3 days compared with 15.3 days in premature infants).[134] They range from mild abdominal distention to bowel perforation, sepsis, and death. Abdominal pain, unstable temperature, bradycardia, and apnea are nonspecific signs. Affected infants have abdominal distention, occult or grossly bloody stools, retained gastric contents, and septicemia with elevated white blood cell and falling platelet counts. The more premature the infant, the greater the incidence of NEC and related diseases of prematurity, such as respiratory distress syndrome and immunocompromised status.

EVALUATION AND TREATMENT. Diagnosis is based on clinical manifestations, laboratory results, and plain films of the abdomen that show gas accumulation in the intestine. Preventive strategies include following written feeding guidelines; encouraging feeding with breast milk; ensuring judicious fluid management to prevent patent ductus arteriosus; and administering arginine, glutamine, and lactoferrin supplements, epidermal growth factor to support intestinal epithelial cell growth, and enteral prebiotics and probiotics to support commensal gut bacteria.[135-137] Treatments include cessation of feeding formula milk, avoidance of H2-receptor antagonists, use of gastric suction to decompress the intestines, maintenance of fluid and electrolyte balance, and administration of antibiotics to control sepsis.[138-140] Enteral feeding should be started as soon as possible.[141,142]

Surgical resection is the treatment of choice for intestinal perforation, and the mortality is high at about 60%, particularly for small bowel resection.[143] For very ill infants peritoneal drainage may be used as an adjunct to laparotomy.[144] Following treatment of NEC, infants treated by medical and surgical management are at risk for the following complications: intestinal obstruction related to the development of strictures, short bowel syndrome, and neurodevelopmental delay.[145] Infants who have extensive resection of necrotic bowel may develop short bowel syndrome, requiring chronic total parenteral nutrition. Preserving bowel length with stents and intestinal transplantation are available as a lifesaving option for these children.[146,147]

Diarrhea

Diarrhea is an increase in the water content, volume, or frequency of stools and can be acute or chronic. Diarrhea is a common gastrointestinal problem during infancy and early childhood, and infectious diarrhea is the leading cause of death in young children, particularly in developing countries. Severe diarrhea occurs one to three times during the first 3 years of life. Most episodes are self-limiting and resolve within 72 hours.

The pathophysiologic mechanisms of diarrhea in children are similar to those for adults, including osmotic, secretory, or increased motility (see Chapter 41). Prolonged diarrhea is more dangerous in children, because they have much smaller fluid reserves than those of adults. Therefore, dehydration can develop rapidly if any disturbance increases fluid secretion into the gastrointestinal lumen (secretory diarrhea), draws fluid into the lumen by osmosis (osmotic diarrhea), or increases motility and prevents fluid absorption in the intestine.

Infant diarrhea is of special concern because its cause may be a congenital or metabolic anomaly. Common causes of acute diarrhea in infants include infections, congenital aganglionic megacolon, milk-protein allergies, and NEC. Less common causes are adrenogenital syndrome, impaired chloride-bicarbonate exchange, congenital lactase deficiency, glucose-galactose malabsorption, and sucrase-isomaltase deficiency. Infants have low fluid reserves and relatively rapid

peristalsis and metabolism. Therefore, the danger of dehydration is great. Causes of diarrhea in young children are unknown in about 40% of cases.[148]

Acute and Chronic Diarrhea in Infants and Children

Acute infectious diarrhea in infants and young children is usually associated with acute viral or bacterial gastroenteritis. Viral causes of diarrhea include rotaviruses, noroviruses, astroviruses, and certain types of adenoviruses. **Rotavirus** is the leading cause of severe diarrhea in infants and young children worldwide. Rotavirus invades enterocytes of the intestinal mucosa and releases an enterotoxin that damages these cells. Damage decreases viable absorptive surface area, causing an imbalance of secretion and absorption, and increases motility, resulting in diarrhea and dehydration. Recovery from mucosal damage may take several weeks. Rotavirus is transmitted by the fecal-oral route among humans. Rotavirus vaccine is an effective preventive strategy and is reducing disease burden in both developed and developing countries. Monitoring is ongoing to evaluate resistant strains.[149] By 5 years of age most children have developed resistance to rotavirus infection. Viral gastroenteritis tends to be self-limiting.

Bacterial causes of diarrhea include *Escherichia coli*, *Klebsiella*, staphylococci, *Salmonella*, *Shigella*, and *Vibrio cholerae. Giardia intestinalis*, *Cryptosporidium parvum* or *hominis*, and *Strongyloides stercoralis* are parasites that cause diarrhea in tropical areas. Infectious diarrhea has a rapid onset, and acidosis and shock can occur quickly. *Clostridium difficile* is often associated with previous antibiotic therapy and can cause acute, profuse, watery diarrhea, and symptoms of colitis (pseudomembranous colitis). The symptoms are more severe in immunosuppressed children. Use of probiotics can be helpful in preventing *C. difficile*–associated diarrhea.[150,151]

Bacterial gastroenteritis is treated with antibiotics if the causal pathogen can be identified. Other causes of acute diarrhea in the older child include antibiotic therapy, appendicitis, chemotherapy, inflammatory bowel disease, parasitic infestation, and ingestion of toxic substances. Children with acute gastroenteritis often remain mildly symptomatic for up to 2 weeks; therefore, diarrhea that persists longer than 2 weeks is considered to be chronic.

Causes of **chronic diarrhea in children** include persistent infectious diarrhea (viral, bacterial, or parasitic), chronic osmotic diarrhea (lactose intolerance or ingestion of large amounts of poorly absorbable sugars), and disease that impairs absorption (e.g., celiac disease, pancreatic insufficiency, or inflammatory bowel disease). Persistent diarrhea is a significant factor in causing malnutrition and growth failure.

Treatment of diarrhea requires rehydration with fluids, electrolytes, and glucose; maintenance of nutrition; and treatment of associated conditions and antibiotics as indicated. Intravenous solutions are used only when oral rehydration solutions are not tolerated. Antiemetics can facilitate oral rehydration.[152] Zinc supplements (not used in children less than 6 months of age), yogurt-based or amino acid–based diets, and probiotics may accelerate recovery[153-155] (see What's New? Pediatric Inflammatory Bowel Disease).

WHAT'S NEW?

Pediatric Inflammatory Bowel Disease

Pediatric inflammatory bowel disease (IBD) includes both Crohn disease (CD) and ulcerative colitis (UC) (see Chapter 41). The incidence in children is unknown, but CD appears to be increasing across the world. It is often diagnosed in late childhood or during adolescence. The etiology is unknown, but there are suspected genetic, epigenetic, and environmental factors involved, and children with IBD are more likely to have parents with the disease. Male children more commonly develop CD; the disease is more extensive and progressive than in adults, involving both the ileum and the colon; growth failure is common and associated with corticosteroid treatment; there are higher rates of hospitalizations and surgery; and growth failure is more common. A recent large population-based study of IBD in children reported an increased risk associated with any antianaerobic antibiotic exposure in a dose-response manner, further emphasizing the need for caution in prescribing antibiotics for children. Fecal calprotectin (FC) level is elevated in IBD and can be used as a marker for IBD diagnosis in children. Treatment for childhood IBD is currently the same as that for adults, but new treatment approaches are needed. Nutritional management is required to maintain normal growth and development. The risk of cancer and death is low in children with IBD.

Data from Abraham BP, Mehta S, El-Serag HB: *J Clin Gastroenterol* 46(7):581–589, 2012; Benchimol EI et al: *Inflamm Bowel Dis* 17(1): 423–439, 2011; Henderson P et al: *Am J Gastroenterol* 107(6):941–949, 2012; Kronman MP et al: *Pediatrics* 130(4):e794–e803, 2012; Sauer CG, Kugathasan S: *Gastroenterol Clin North Am* 38(4):611–628, 2009; Sherlock ME, Griffiths AM: *Curr Gastroenterol Rep* 14(2):166–173, 2012; Tsang J et al: *BMC Pediatr* 12:162, 2012.

Primary Lactose Intolerance. **Lactose intolerance** is the inability to digest lactose (milk sugar). It is caused by inadequate production of lactase and is a common cause of diarrhea in children, particularly nonwhite children younger than 7 years of age. The malabsorption of lactose results in osmotic diarrhea, in which fluids move by osmosis from the vascular compartment into the intestinal lumen. The undigested sugar is processed by the colonic bacteria, and intestinal gas is produced. The diarrhea is accompanied by abdominal pain, bloating, and flatulence. Diagnosis includes elimination of dietary lactose or hydrogen breath testing. Treatment consists of using lactase-treated dairy products or lactase supplements or reducing dairy product consumption. Other sources of dietary calcium or supplements need to be provided if dairy products are eliminated. Some children can tolerate lactose in fermented forms, such as cheese and yogurt.[156-158]

DISORDERS OF THE LIVER

Disorders of Biliary Metabolism and Transport

Neonatal Jaundice

Physiologic jaundice (hyperbilirubinemia) of the newborn is usually a transient, benign icterus that occurs during the first week of life in otherwise healthy full-term infants. It is caused by mild unconjugated (indirect-reacting) hyperbilirubinemia. **Pathologic jaundice** appears within 24 hours after birth with total serum bilirubin level greater than 20 mg/dl or an indirect bilirubin level greater than 15 mg/dl. Risk factors include fetal-maternal blood type incompatibility (ABO and Rh incompatibility), prematurity,

exclusive breast-feeding, maternal age greater than or equal to 25 years, an infant of male gender, delayed meconium passage, and excessive birth trauma such as bruising or cephalhematomas.[159] Prediction tools for hyperbilirubinemia are available to reduce risk associated with early hospital discharge (within 48 hours) when hyperbilirubinemia may not yet be evident.

PATHOPHYSIOLOGY. Pathologic jaundice results from the complex interaction of factors that cause: (1) increased bilirubin production (e.g., hemolysis), (2) impaired hepatic uptake or excretion of unconjugated bilirubin, and (3) delayed maturation of liver conjugating mechanisms.[160] The most common cause is hemolytic disease of the newborn, also known as erythroblastosis fetalis (ABO blood incompatibility; see Chapters 9 and 30). Unconjugated bilirubin (indirect bilirubin) is lipid soluble, bound to albumin in the blood, and in the free form readily crosses the blood-brain barrier in infants. Chronic bilirubin encephalopathy **(kernicterus)** is caused by the deposition of toxic, unconjugated bilirubin in brain cells and usually does not occur in healthy full-term infants.[161] Elevated level of conjugated bilirubin is a sign of underlying disease. A late rising indirect bilirubin level also may be a manifestation of **glucose-6-phosphate dehydrogenase** (an enzyme important in red blood cell metabolism) **deficiency,** a hereditary X-linked genetic defect.[162,163] Elevated unconjugated bilirubin levels also can cause hemolysis, further increasing neonatal jaundice.[164]

CLINICAL MANIFESTATIONS. Physiologic jaundice develops during the second or third day after birth and usually subsides in 1 to 2 weeks in full-term infants and in 2 to 4 weeks in premature infants. After this, increasing bilirubin values and persistent jaundice indicate pathologic hyperbilirubinemia. Manifestations include yellowing skin, dark urine, light-colored stools, and weight loss. Premature infants with respiratory distress, acidosis, or sepsis are at greater risk for encephalopathy. The resulting disabilities include athetoid cerebral palsy and speech and hearing impairment.[165]

EVALUATION AND TREATMENT. Total and direct (conjugated) bilirubin levels are monitored and the bilirubin/albumin ratio is being evaluated as a corollary to unbound serum bilirubin level for predicting neurotoxicity.[166] Pathologic jaundice should be suspected with serum bilirubin values that increase greater than 5 mg/dl per day, persistent jaundice (more than 7 to 10 days in the full-term infant), or conjugated bilirubin values greater than 2 mg/dl. Other causes of jaundice must be eliminated to confirm physiologic jaundice.

Treatment depends on the degree of hyperbilirubinemia. Physiologic jaundice is usually treated by phototherapy (ultraviolet light) with good eye protection. Phototherapy produces isomers of bilirubin that are water soluble, can be more rapidly excreted in the stools and urine, and do not cross the blood-brain barrier. Pathologic jaundice requires high-intensity phototherapy, exchange transfusion, and treatment of the underlying cause. Advances are being made to improve transcutaneous bilirubin monitoring and use of drugs to reduce serum bilirubin levels.[167-169]

Biliary Atresia

Biliary atresia is a rare congenital or acquired (perinatal) malformation characterized by the absence or obstruction of intrahepatic or extrahepatic bile ducts. Extrahepatic ducts may end in a blind pouch. The cause is unknown. The congenital form may be related to a chromosomal abnormality. The acquired form may be related to a viral infection (cytomegalovirus), chronic inflammatory disease, or autoimmune injury to bile duct epithelium.[170] The points of destruction are influenced by the stage of intrauterine development in which injury occurs. The atresia or progressive destruction leads to inflammation, fibrosis, and plugging of the bile canaliculi and extrahepatic biliary tree with obstruction to bile flow. Progressive obstruction may lead to biliary cirrhosis and portal hypertension (see Chapter 41), which can develop within a few weeks after birth. Liver failure can lead to death within 2 years without treatment.[171,172]

Jaundice is the primary clinical manifestation of biliary atresia. Other signs are hepatomegaly and acholic (clay-colored) stools. Fat absorption is impaired because of the lack of bile salts, and the infant may fail to gain weight and requires nutritional support.[173] Early diagnosis of biliary atresia is mandatory and is based on clinical manifestations and liver biopsy. Liver function test results are abnormal. Serum transaminase and alkaline phosphatase values are elevated and conjugated (direct) serum bilirubin levels rise progressively.

Extrahepatic atresia can be relieved by surgical drainage and correction in approximately 10% of cases. Some infants benefit from the Kasai portoenterostomy, in which a hepatic duct remnant is anastomosed to the jejunum or a jejunal segment is anastomosed to the porta hepatis if the patent hepatic duct remnant is not available (Figure 42-9). Even with initial restoration of bile flow, however, fibrosis and obliteration of intrahepatic bile ducts can continue, resulting in cirrhosis.

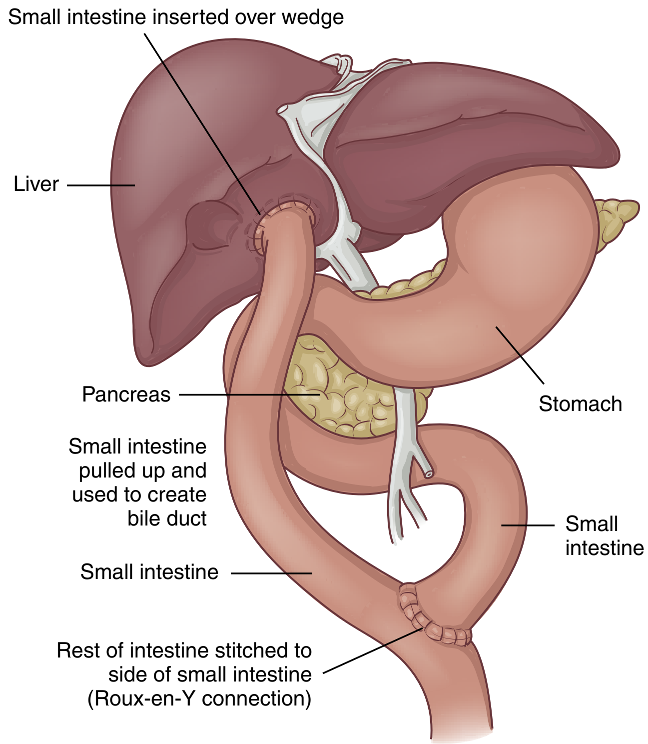

FIGURE 42-9 **Kasai Procedure.** Surgical correction for extrahepatic biliary atresia. The jejunal segment between the liver and the bowel may be externalized, creating a double-barrel portoenterostomy.

Liver transplantation is the long-term therapy when surgery fails. Approximately 40% of children with biliary atresia are immediate candidates for transplantation. Approximately 90% of children who receive transplants for biliary atresia become long-term survivors with good physical and mental development.[174] The use of reduced and split livers from living, related donors has increased the number of children who survive after transplantation.[175]

Inflammatory Disorders

Hepatitis

The pathophysiology of viral and fulminant hepatitis is described in Chapter 41 (see Table 41-7).

Hepatitis A. Approximately one third to one half of the reported cases of **hepatitis A virus (HAV)** occur in children.[176] Incidence is highest among young children of preschool age. Outbreaks tend to occur in daycare centers with large numbers of children who are not toilet trained and staff members who practice poor handwashing techniques.[177] HAV replicates in the liver and is excreted through the biliary system into the stool. HAV in young children is usually mild and asymptomatic. Clinical manifestations, however, may include nausea, vomiting, and diarrhea. Because jaundice is absent, infected children appear to have the "flu." Almost all children recover from hepatitis A without residual liver damage.[178] Vaccination for hepatitis A should begin at 12 to 23 months of age.[179]

Hepatitis B. Risk factors for **hepatitis B virus (HBV)** infection include infants of mothers who are chronic **hepatitis B surface antigen (HBsAg)** carriers, hemophiliacs who receive frequent blood transfusions, children who abuse parenteral drugs, and children who live in residences for the mentally handicapped. Of newborns infected by their mothers (vertical transmission), most develop chronic hepatitis and become carriers.[180] Hepatitis B is endemic in China and other parts of Asia where most infections occur in infants and children as a result of maternal-neonatal transmission.[181]

Chronic hepatitis may develop more often in young children because of their immature immune systems. Infected infants and children are at risk for cirrhosis and hepatocellular carcinoma. The most serious consequence of HBV infection is fulminant hepatitis, which occurs in 1% of cases. Hepatitis D virus (HDV) infection depends on active infection with HBV. There is evidence that the risk of fulminant hepatitis is higher in individuals with combined infections of HBV, HDV, HCV, or human immunodeficiency virus (HIV) than in those with HBV infection alone.[182] Infants should receive passive-active immunoprophylactic treatment at birth. Most children are treated conservatively and antivirals are used for chronic disease. Aggressive vaccination programs reduce the incidence of HBV. Maternal antiviral therapy during pregnancy and lactation is a treatment option.[183,184]

Hepatitis C. **Hepatitis C virus (HCV)** in children is most commonly transmitted vertically and is enhanced with maternal coinfection with HIV. It also is transmitted with blood transfusions. Between 10% and 50% of affected children develop chronic liver disease. Antivirals are effective in the treatment of hepatitis C and liver transplant is required for liver failure.[185] There is currently no vaccination available for hepatitis C.

Chronic Hepatitis. Hepatitis B (HBV) and hepatitis C (HCV) are the main causes of chronic hepatitis in children. Manifestations of chronic hepatitis include malaise, anorexia, fever, gastrointestinal bleeding, hepatomegaly, edema, and transient joint pain. Often there are no symptoms. Serum transaminase and bilirubin levels are elevated. There may be evidence of impairment of synthetic functions of the liver: prolonged prothrombin time and hypoalbuminemia. Diagnosis is based on the clinical manifestations and liver biopsy. There is no curative therapy for chronic HBV or chronic HCV and children are treated with antiviral drugs and should continue to be monitored. There also is an autoimmune form of chronic hepatitis that is treated with immunosuppression therapy.[186] Liver transplant may ultimately be required for chronic hepatitis.[187,188]

Cirrhosis

Cirrhosis is fibrotic scarring of the liver in response to inflammation and tissue damage (see Chapter 41). Most forms of chronic liver diseases in children can progress to cirrhosis, but they seldom do. Causes include cystic fibrosis, biliary atresia, infectious hepatitis, and Wilson disease. Nonalcoholic fatty liver disease (steatohepatitis) is increasing in children in correlation with an increase in childhood obesity and it can progress to cirrhosis and liver cancer.[189]

The complications of cirrhosis in children are the same as those in adults: portal hypertension, the opening of collateral vessels between the portal and systemic veins, and varices. In addition, children with cirrhosis experience growth failure caused by nutritional deficits and developmental delay, particularly in gross motor function because of ascites and weakness. The cause of cirrhosis may influence its severity and course. Some types of cirrhosis can be stabilized if the cause is identified and treated early.

Portal Hypertension

The two basic causes of **portal hypertension** in children are: (1) increased resistance to blood flow within the portal system, and (2) increased volume of portal blood flow. Increased resistance to flow can occur anywhere in the portal circulatory system. Portal hypertension can accompany cirrhosis, intra-abdominal infections, portal vein thrombosis, congenital anomalies of the portal vein, and congenital hepatic fibrosis.

Types of Portal Hypertension

Extrahepatic Portal Hypertension. **Extrahepatic (prehepatic) portal venous obstruction** causes 50% to 70% of extrahepatic portal hypertension in children. For at least half of these children, no specific cause can be found. Obstruction is almost always in the portal vein and is usually caused by thrombosis. Umbilical infection with or without a history of catheterization of the umbilical vein may be a cause in neonates. Portal vein thrombosis can occur as a complication of intra-abdominal infections, pancreatitis, and blunt abdominal trauma. It also has been associated with neonatal dehydration, inflammatory bowel disease, and hypercoagulable states, such as protein C and protein S deficiencies.[190] Life-threatening variceal bleeding can require banding or sclerotherapy. Mesoportal bypass (anastomosis

of mesenteric vein to portal vein) restores normal physiologic portal flow to the liver and corrects portal hypertension.[191]

Intrahepatic Portal Hypertension. Cirrhosis is the primary cause of **intrahepatic portal hypertension.** The most common finding is cirrhosis and congenital hepatic fibrosis, which increases resistance to portal blood flow by constricting and reducing the compliance of the hepatic sinusoids. No underlying cause is found in half of cases.[192]

CLINICAL MANIFESTATIONS. The clinical manifestations of portal hypertension are: (1) splenomegaly, (2) upper gastrointestinal bleeding, (3) ascites, and (4) hepatic encephalopathy (see Chapter 41). Severe liver disease is characterized by hypoalbuminemia, prolonged prothrombin times, hyperbilirubinemia, electrolyte imbalance, and hypoglycemia. **Splenomegaly** is the most common sign of portal hypertension in children. The spleen may be firm or hard, depending on the duration of portal hypertension. In children, most episodes of **gastrointestinal bleeding** are caused by rupture of esophageal varices. Hematemesis, possibly associated with abdominal pain, often accompanies sudden pallor. Melena is observed, either at the time of hematemesis or soon afterward. Clotting abnormalities caused by altered liver function promote the bleeding. If plasma volume is increased, esophageal varices readily rupture during activities that increase blood pressure, such as coughing. Acetylsalicylic acid (aspirin), which should not be administered to children, can trigger bleeding. Severe bleeding episodes can cause hypovolemic shock and death. Symptoms of **ascites** include weight gain, protruding abdomen, and reduced tidal volumes if the ascites is severe. **Hepatic encephalopathy** in children can be acute or chronic. Acute encephalopathy is characterized by major disorders of consciousness, which may progress to coma. This may follow an acute episode of variceal bleeding as the impaired liver attempts to metabolize the large protein (nitrogenous) load from the blood. Chronic, or minimal, encephalopathy is characterized by emotional or psychiatric disorders, decreased intellectual functioning, personality disorders caused by minimal brain dysfunction, and spatial disorientation.

EVALUATION AND TREATMENT. Assessment of portal hypertension in children must be thorough because the cause dictates the management. The objectives of the clinical investigation are to locate the site of the venous block and identify the disease responsible for the portal hypertension. Thorough physical examination, laboratory tests of liver function, imaging procedures, and biopsy may be included in the diagnostic evaluation (see Chapter 40). Sclerotherapy, banding, and transjugular intrahepatic portosystemic shunt (TIPS procedure) are treatments for severe esophageal varices in children.[191,193]

The indications for surgical shunting include gastrointestinal hemorrhage not responsive to sclerotherapy. Portosystemic shunts are rarely performed in children but it can be a bridge to liver transplant.[194] The outcome of portal hypertension depends almost entirely on its cause. Children with extrahepatic disease are expected to recover with little morbidity. For children with intrahepatic disease, the prognosis varies.

Metabolic Disorders

More than 5000 genetically determined metabolic pathways have been identified in liver tissue. The earliest possible identification of metabolic disorders is essential because: (1) early treatment may prevent permanent damage to vital organs, such as the liver or brain; (2) precise genetic counseling may be possible with prenatal diagnosis; and (3) complications can be minimized, even if cure is not possible. Galactosemia,[195] fructosemia, and Wilson disease are rare treatable metabolic disorders that have hepatic clinical manifestations. These disorders are summarized in Table 42-2; Wilson disease is discussed next.

TABLE 42-2 GALACTOSEMIA, FRUCTOSEMIA, AND WILSON DISEASE

	GALACTOSEMIA	FRUCTOSEMIA	WILSON DISEASE
Mechanism of disease	Deficiency of galactose and phosphate, uridyl transferase An autosomal recessive trait Cannot convert galactose to glucose Toxic accumulation of galactose in body tissues, liver, and brain	Deficiency of fructose-1-phosphate aldolase An autosomal recessive trait Cannot metabolize fructose, sucrose, or honey; occurs when breast milk is replaced with cow's milk Toxic accumulation of fructose in body tissues	Autosomal recessive: *ATP7B* gene mutation on chromosome 13 Defect in copper excretion by liver Impaired transport of copper in blood caused by diminished transport protein (ceruloplasmin) Toxic accumulations of copper in liver, brain, kidney, corneas
Clinical manifestations	High levels of blood galactose Vomiting Hypoglycemia May have failure to thrive Symptoms of cirrhosis at 2 to 6 months—jaundice Mental retardation if not treated Cataracts if not treated	High levels of blood fructose Vomiting Hypoglycemia May have failure to thrive Hepatomegaly Jaundice Seizures	Intention tremors Indistinct speech Dystonia Greenish yellow rings in cornea Hepatomegaly Jaundice Anorexia Renal tubular defects
Evaluation	Presence of reducing substances in urine when infant is receiving lactose	Detailed dietary history Liver or intestinal mucosa biopsy	Low plasma ceruloplasmin
Treatment	Galactose-free diet	Fructose-, sucrose-, honey-free diet Vitamin C supplementation	Chelation therapy to remove copper from body Decreased dietary intake of copper Liver transplant

Wilson Disease

Wilson disease (hepatolenticular degeneration) is an autosomal recessive defect of copper metabolism related to loss of *ATP7B* gene expression that causes toxic amounts of copper to accumulate in the liver, brain, kidneys, and corneas. *ATP7B* is localized on chromosome 13 and encodes copper-transporting P-type adenosinetriphosphatase (ATPase) membrane-spanning protein. It is highly expressed in the liver, kidney, and placenta and is expressed in lower levels in the brain, heart, muscle, and pancreas.[196] This defect in the uptake and excretion of copper by hepatocytes is an important cause of progressive liver disease in children and young adults. Wilson disease is very rare, with an incidence of 1 in 30,000 live births worldwide.[197] Between 1 in 200 and 1 in 500 persons are carriers.[190]

PATHOPHYSIOLOGY. Two major abnormalities in copper metabolism have been identified: (1) diminished biliary excretion of copper, and (2) failure to insert copper into ceruloplasmin (a glycoprotein that transports copper in the blood). A positive copper balance is present from birth in children with Wilson disease, despite increased excretion of copper in the urine. Copper toxicity with accumulation in the liver and brain is the major abnormality. Excesses of copper generate free radicals that disrupt cellular organelles, deoxyribonucleic acid (DNA), microtubules, enzymes, and proteins. Copper overload is related to impaired biliary excretion of copper and may be related to failure of hepatocyte lysosomes to eliminate copper by exocytosis.[198]

Early in the disease, intestinal absorption of copper is normal, as is hepatic clearance of albumin-bound absorbed copper. As copper-binding proteins in the liver become saturated, hepatic uptake of copper diminishes, with elevated serum copper levels and biochemical and clinical evidence of liver damage caused by copper accumulation. In later stages of the disease, copper accumulates in extrahepatic tissues, including the eyes, brain, and kidneys.

When cerebral copper-binding proteins become saturated, a characteristic pattern of brain damage develops, particularly in the basal ganglia. Neural effects include intention tremor, unsteady gait, dystonia, and behavioral changes. Manifestations of renal tubular injury usually appear simultaneously. The uptake of copper by red blood cells is thought to cause hemolytic anemia, a condition sometimes seen early in the clinical course of Wilson disease.

CLINICAL MANIFESTATIONS. The clinical manifestations of Wilson disease may begin as young as 4 years of age, when control mechanisms responsible for copper homeostasis and biliary excretion should have matured. The classic clinical presentation of Wilson disease is a triad of neuromuscular abnormalities, intention tremors, dysarthria (indistinct speech), and dystonia (disordered muscular tonicity): (1) Kayser-Fleischer rings (accumulation of copper in the limbus of the cornea, causing a greenish yellow ring), (2) cirrhosis associated with elevated serum copper levels, and (3) low ceruloplasmin levels.[199] Initial symptoms vary from malaise and abdominal pain to jaundice. Changes in mental and motor performance may develop at age 6 years or into adult life. The earliest signs of liver involvement include enlargement of the liver and spleen, jaundice, and anorexia. Edema and ascites may develop suddenly, or gastrointestinal hemorrhage may be the initial sign of the disease. Occasionally Wilson disease begins with a hemolytic crisis caused by the toxic effects of copper on the red blood cells. Cirrhosis develops in all untreated cases. Copper deposition in the kidneys causes a proximal renal tubular defect that results in losses of glucose, amino acids, phosphate, and uric acid in the urine and renal tubular acidosis. All untreated individuals will develop behavioral or psychiatric disorders.

EVALUATION AND TREATMENT. Because Wilson disease is rare and has broad clinical manifestations, it may not be diagnosed until older childhood or adulthood. The mean age at diagnosis in one large study was 15.5 years.[200] Laboratory tests detect a serum ceruloplasmin concentration less than 30 mg/dl. Serum copper values may be normal or high, and urine copper values are elevated. Liver biopsy is used to assess structural changes and measure copper concentrations. *ATP7B* gene sequencing can avoid the need for liver biopsy.[201] The goal of therapy is to decrease copper accumulation by decreasing dietary copper intake and intestinal copper absorption, and increasing renal excretion of copper. Medical treatments include D-penicillamine, trientine, zinc (reduces intestinal copper absorption), and ammonium tetrathiomolybdate.[202] Liver transplantation is the only therapy for Wilson disease and gene therapy and hepatocyte cell transplantation are being investigated.[203]

SUMMARY REVIEW

Disorders of the Gastrointestinal Tract

1. Most alterations of digestive function in children are caused by congenital anomalies of the intestinal tract; disorders of digestion, absorption, or nutrition; or liver disease.
2. Cleft lip (harelip) and cleft palate (failure of the bony palate to fuse in the midline) may occur separately or together, and both defects are associated with multiple gene-environmental interactions and deficiency of B vitamins. The fissure may affect the uvula, soft palate, hard palate, nostril, and maxillary alveolar ridge.
3. Esophageal atresia, a condition in which the esophagus ends in a blind pouch, may occur with or without tracheoesophageal fistula, a connection between the esophagus and the trachea. As the infant swallows oral secretions or ingests milk, the pouch fills, causing either drooling or aspiration into the lungs.
4. Pyloric stenosis, an obstruction of the pyloric outlet caused by hypertrophy and hyperplasia of circular muscles in the pyloric sphincter, is more common in male infants and may require surgical correction.
5. Intestinal malrotation occurs with failure of the colon to rotate during fetal development and an obstructing band or volvulus (twisting of the bowel on itself) may partly or completely occlude the gastrointestinal tract and its blood vessels.

SUMMARY REVIEW—cont'd

6. Meconium ileus is a condition in the newborn in which intestinal secretions and amniotic waste products produce a thick tarry plug that obstructs the intestine, usually from lack of fetal digestive enzymes. From 10% to 15% of neonates with CF have meconium ileus as neonates.
7. DIOS, formerly called *meconium ileus equivalent,* can occur when intestinal contents become abnormally thick and obstruct the intestinal lumen. CF, pancreatic enzyme deficiency, and dehydration are common causes.
8. Duodenal, jejunal, and ileal obstructions can be caused by meconium ileus, atresia, peritoneal bands, or acquired obstructive disorders.
9. Meckel diverticulum is an outpouching of all layers of the small intestine caused by failure of the fibrous band that connects the small intestine to the umbilicus.
10. Congenital aganglionic megacolon (Hirschsprung disease) is caused by an absence of enteric ganglia and malformation of the parasympathetic nervous system in a segment of the colon, resulting in inadequate colon motility and functional obstruction.
11. Malformations of the anus and rectum range from mild congenital stenosis of the anus to complex deformities, all of which are classified as imperforate anus.
12. The most common cause of acquired intestinal obstruction in infants is intussusception, a condition in which one portion of the bowel telescopes or invaginates into another. It occurs most commonly in the area of the ileocecal junction.
13. GERD is caused by the relaxation or incompetence of the lower esophageal sphincter. Infants are susceptible to reflux because the sphincter is not fully mature, their diet consists of liquids, and they are seldom in an upright position.
14. Eosinophilic esophagitis involves an eosinophilic inflammation of the esophagus with dysphagia and vomiting that can be associated with asthma and eczema.
15. CF is an inherited disease with a pathophysiologic triad that includes pancreatic enzyme deficiency (which causes maldigestion), overproduction of mucus in the respiratory tract, and abnormally elevated sodium and chloride concentrations in sweat.
16. Gluten-sensitive enteropathy is an immune-mediated lifelong disease characterized by the loss of mature villous epithelium in the presence of a gluten-containing diet. It results in malabsorption and growth failure.
17. Severe acute malnutrition is a group of disorders resulting from a severe dietary deficiency of proteins (kwashiorkor), carbohydrates, or both (marasmus). Starvation causes stunted mental and physical development. Kwashiorkor occurs most often in toddlers who have stopped breast-feeding and subsist on a high-carbohydrate diet.
18. Failure to thrive is inadequate physical growth of a child. Organic failure to thrive is caused by genetic, anatomic, or pathophysiologic factors that restrict normal growth and development. Nonorganic failure to thrive is caused by nutritional deficits associated with inadequate nurturing.
19. Necrotizing enterocolitis is a disorder in neonates, particularly low birth weight or premature infants, thought to result from stress and anoxia of an immature bowel wall. Bacteria invade the mucosa and can result in colitis, necrosis, intestinal perforation, sepsis, and death.
20. Acute diarrhea in infants and children is often caused by infection and can rapidly cause dehydration and electrolyte imbalances because fluid reserves are relatively small. The most common cause of acute diarrhea in children is bacterial or viral enterocolitis.
21. Chronic diarrhea (diarrhea persisting longer than 4 weeks) can be caused by a wide variety of underlying conditions and often leads to growth failure and delayed development.
22. Lactose intolerance causes diarrhea when failure to produce lactase results in osmotic diarrhea with ingestion of lactose-containing dairy products.

Disorders of the Liver

1. Physiologic jaundice of the newborn is caused by mild hyperbilirubinemia that subsides in 1 to 2 weeks. Pathologic jaundice is caused by severe hyperbilirubinemia and can cause brain damage (**kernicterus).**
2. Biliary atresia is a congenital malformation of the bile ducts that obstructs bile flow. Atresia causes jaundice, cirrhosis, and liver failure. Biliary atresia is the most common reason for liver transplantation in children.
3. Acute hepatitis has the same clinical course in children and adults but children have milder cases of the disease. Hepatitis A is the most common form of childhood hepatitis.
4. Young children more readily develop chronic HBV or HCV hepatitis because of their immature immune system.
5. Cirrhosis is fibrotic scarring of the liver and is rare in children but can develop from most forms of chronic liver disease.
6. Portal hypertension in children usually is caused by extrahepatic obstruction. Thrombosis of the portal vein is the most common cause of portal hypertension in children and splenomegaly is the most common sign.
7. The three most common metabolic disorders that cause liver damage in children are galactosemia, fructosemia, and Wilson disease. All are rare, inherited as genetic traits, and permit the accumulation of toxins in the liver.
8. Wilson disease causes defective copper uptake and metabolism. Unexcreted copper accumulates in the liver, brain, kidney, and corneal cells. Damage from accumulated copper is gradual; the disease is usually not diagnosed before age 4 or 5 years.

- Review Questions and Answers

CHAPTER OUTLINE

The way an individual functions in daily life, moves about, or manipulates objects physically depends on the integrity of the musculoskeletal system. The musculoskeletal system is actually composed of two systems: (1) the skeleton proper, which is composed of bones and joints; and (2) skeletal muscles. Each of the systems contributes to mobility. The skeleton supports the body and provides leverage to the skeletal muscles so that movement of various parts of the body is possible. This movement is accomplished by contraction of the skeletal muscles and bending or rotation at the joints.

STRUCTURE AND FUNCTION OF BONES

Bones give form to the body, support tissues, and permit movement by providing points of attachment for muscles. Many bones meet in movable joints that determine the type and extent of movement possible. Bones also protect many of the body's vital organs. For example, the bones of the skull, thorax, and pelvis are hard exterior shields that protect the brain, heart, lungs, and reproductive and urinary organs.

Bone marrow is one of the sources of **mesenchymal stem cells** (**MSCs**) (Figure 43-1). These nonhematopoietic stem cells consist of a small proportion of the stromal cell population in the bone marrow, and can generate bone, cartilage, fat, cells that support the formation of blood, and fibrous connective tissue. Within certain bones, the marrow cavities also serve as storage site for the hematopoietic stem cells that form both blood and immune cells. In adults, blood cells originate exclusively in the marrow cavities of the skull, vertebrae, ribs, sternum, scapulae, and pelvis. Bones also have a crucial role in mineral homeostasis, and storing and releasing minerals (i.e., calcium, phosphate, carbonate, magnesium) that are essential for the proper working of many delicate cellular mechanisms.

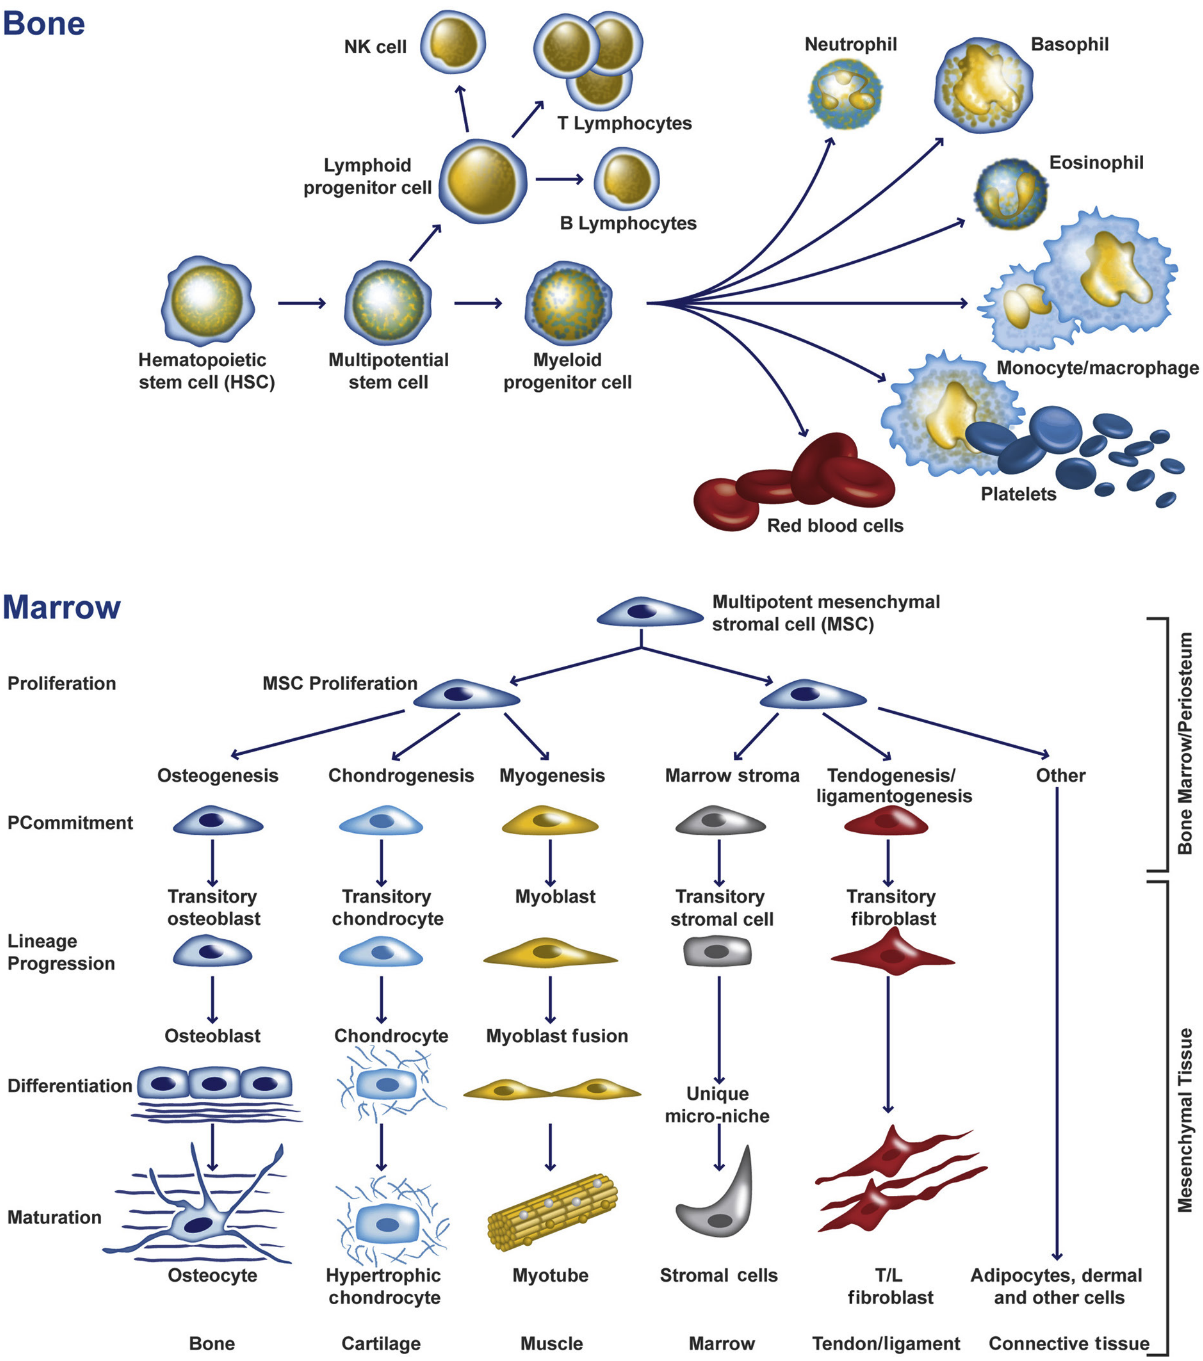

FIGURE 43-1 Hematopoietic and Mesenchymal Stromal Cell Differentiation. Undifferentiated hematopoietic and mesenchymal multipotential cells give rise to a variety of cell types with distinct functions. (Adapted from abcam.com.)

Elements of Bone Tissue

Mature bone is a rigid yet flexible connective tissue consisting of cells, fibers, a gelatinous material termed **ground substance,** and large amounts of crystallized minerals, mainly calcium, that give bone its rigidity. The structural elements of bone are summarized in Table 43-1.

Bone cells enable bone to grow, repair itself, change shape, and continuously synthesize new bone tissue and resorb (dissolve or digest) old tissue. The fibers in bone are made of collagen, which gives bone its tensile strength (the ability to hold itself together). Ground substance acts as a medium for the diffusion of nutrients, oxygen, metabolic wastes, biochemicals, and minerals between bone tissue and blood vessels.

Bone formation arises during embryonic development when mesenchymal stem cells begin differentiating into either chondrocytes or preosteoblasts. Endochondral ossification and intramembranous bone formation are the two major mechanisms responsible for normal bone development.

Endochondral ossification occurs when mesenchymal (**mesenchyme,** or loose tissue found during embryonic development) stem cells begin differentiating into chondrocytes (see Figure 43-1), which in turn develop a mineralized cartilage

TABLE 43-1 **STRUCTURAL ELEMENTS OF BONE**

STRUCTURAL ELEMENT	FUNCTION
Bone Cells	
Osteoblasts	Synthesize collagen and proteoglycans; stimulate bone formation and are also involved in some osteoclast resorptive activity
Osteocytes	Maintain bone matrix; act as mechanoreceptors; influence osteoblasts and osteoclasts
Osteoclasts	Resorb bone; major role in mineral homeostasis
Bone Matrix	
Collagen fibers	Lend support and tensile strength
Proteoglycans	Control transport of ionized materials through matrix
Bone morphogenic proteins (BMPs)*	Induce cartilage, bone, tendon, and ligament formation and repair
Glycoproteins	
Sialoprotein	Promotes calcification
Osteocalcin	Inhibits calcium-phosphate precipitation; promotes bone resorption
Laminin	Stabilizes basement membranes in bones
Osteonectin	Binds calcium in bones
Albumin	Transports essential elements to matrix; maintains osmotic pressure of bone fluid
α-Glycoprotein	Promotes calcification
Minerals (Elements)	Crystallizes to lend rigidity and compressive strength
Calcium	Regulates vitamin D and thereby promotes mineralization
Phosphate	Balance of organic and inorganic phosphate required for proper bone mineralization; regulates vitamin D
Alkaline phosphatase	Promotes mineralization
Vitamins	
Vitamin D	Assists with differentiation, mineralization of osteoblasts
Vitamin K	Increases bone calcification; reduces serum osteocalcin

*See Table 43-2 for BMP functions.

scaffold that allows formation of osteoblasts. Most bone elements are formed this way. With the second mechanism, **intramembranous bone formation,** mesenchymal stem cells differentiate into a preosteoblast line that then forms osteoblasts without any cartilage framework.[1,2]

Multiple factors influence normal bone formation, maintenance, and remodeling. The superfamily of signaling factors, containing more than 40 members including bone morphogenic proteins (BMPs), is known as the **transforming growth factor-beta (TGF-β)** family. This group is primarily responsible for initiation, differentiation, and commitment of precursor cells into osteoblasts. TGF-β signals are transmitted across the plasma membrane, combine with certain proteins that act as transcription factors (Smads), and then form specific receptors known as R-Smads. These receptors, in turn, initiate intracellular signaling, interact with other transcription factors, and regulate other factors that are important in osteoblast formation, function, and maintenance.[3] Crosstalk between signaling pathways (including TGF-β, BMPs, FGF, Wnt, Notch, MAPK, and Hedgehog) is critical in regulating osteoblasts.

BMPs have multiple crucial functions in the skeletal system. BMP activities are regulated at different molecular levels. Table 43-2 summarizes the role of several important BMPs.

Wnt genes belong to a large family of protein-signaling factors that are required for the development of body systems, including the musculoskeletal system. They play a significant role in forming bone, developing bone mass, remodeling, and fracture healing. Wnt signaling regulates production and differentiation of osteoblasts and osteoclasts, and affects bone mass and density, joint formation, fracture repair, bone remodeling, and some bone diseases. Other important elements responsible for bone formation and homeostasis are presented in Table 43-3.

In mature bone the formation of new tissue begins with the production of an organic matrix by the bone cells. This **bone matrix** consists of ground substances, collagen, and other proteins (see Table 43-1) that take part in bone formation and maintenance.

The next step in bone formation is **calcification,** when minerals are deposited and crystallize. Minerals bind tightly to collagen fibers, producing tensile and compressional strength in bone, and withstand pressure and weightbearing.

Bone Cells

Bone contains three types of cells: osteoblasts, osteocytes, and osteoclasts (Figure 43-2). Osteoblasts are the bone-forming cells, whose primary function is to lay down new bone. Once this function is complete, osteoblasts become osteocytes that are imbedded in bone. Comprising 90% to 95% of bone cells, osteocytes develop dendritic processes that extend to either the bone surface or the bone's vascular space.[4] They help maintain bone by signaling osteoblasts and osteoclasts to form and resorb bone.[5] Osteoclasts are the major bone-resorbing cells responsible for remodeling.

TABLE 43-2 BONE MORPHOGENIC PROTEINS (BMPs) AND THEIR KNOWN FUNCTIONS

BMP	KNOWN FUNCTION
BMP1	Cartilage development; is actually a metalloprotease; key role in extracellular matrix (ECM) formation
BMP2	Induces bone and cartilage formation, osteoblast differentiation, bone healing
BMP3 (osteogenin)	Induces bone formation
BMP4	Regulates formation of teeth, limbs, and bone
BMP5	Involved in cartilage development
BMP6	Found in osteoblasts; helps maintain adult joint integrity; accelerates bone repair
BMP7	Major role in osteoblast differentiation, chondrocyte formation, fracture healing; important in renal development and repair
BMP8a	Bone and cartilage development; up-regulated in fracture nonunion
BMP9	Induces osteogenesis in mature osteoblasts
BMP10	Plays role in development of the heart
BMP12 (cartilage-derived morphogenic protein-3; CDMP-3)	Tendon and ligament formation
BMP13	Cartilage development; tendon and ligament repair
BMP14	Assists in bone and tendon healing; cartilage formation

Data from Caetano-Lopes J, Canhão H, Fonseca JE: *Arthritis Res Ther* 9(Suppl 1):S1, 2007; Hojo H et al: *J Bone Miner Metab* 28(5):489–502, 2010; Fajardo M, Liu C-J, Egol K: *Clin Orthop Relat Res* 467(12):3071–3078, 2009; Li Y et al: *Zhong Nan Da Xue Xue Bao Yi Xue Ban* 37(1):1–5, 2012.

TABLE 43-3 SELECTED FACTORS AFFECTING BONE FORMATION AND HOMEOSTASIS

FACTOR	FUNCTION
Transforming growth factor-beta (TGF-β)	Superfamily of polypeptides; regulates bone formation, many other cellular processes though signaling
Platelet-derived growth factor (PDGF)	Increases number of osteoblasts
Fibroblast growth factor-2 (FGF)	FGF-2 increases osteoblast population, but not function; inhibits alkaline phosphatase activity, osteocalcin, type 1 collagen, and osteopontin
Insulin-like growth factor (IGF)	
IGF-1	Increases peak bone mass during adolescence; decreases osteoblast apoptosis; maintains bone matrix
IGF-2	Increases BMP-9–induced endochondral ossification
Smad proteins	Mediate the signaling cascade of transforming growth factor-beta (TGF-β), especially in embryonic bone development; play a role in crosstalk between BMP/TGF-β and Wnt signaling pathways
Bone morphogenic proteins (BMPs)	Members of transforming growth factor-beta (TGF-β) superfamily of polypeptides; have many functions outside skeletal system; stimulate endochondral bone and cartilage formation and function, promote osteoblast maturation; augment bone remodeling by affecting both osteoblasts and osteoclasts
Tumor necrosis factors (TNFs)	Superfamily of cytokines; play major role in regulating bone metabolism, especially osteoclast function
Osteoprotegerin (OPG)	Inhibits bone remodeling/resorption; produced by several cells, including osteoblasts; is a decoy receptor for RANKL (binds to RANKL, inhibiting RANK/RANKL interactions, suppressing osteoclast formation and bone resorption)
Receptor activator of nuclear factor κβ (RANK)	Stimulates differentiation of osteoclast precursors; activates mature osteoclasts
Bone morphogenic protein antagonists	Prevent BMP signaling
Noggin	Binds BMP-2 and BMP-4, reducing osteoblast function
Gremlin	Multiple effects in and out of skeletal system, but also binds BMP-2, -4, and -7; may play a role in development of osteoporosis
Twisted gastrulation	Acts as either a BMP agonist or an antagonist
Activin (a BMP-related protein)	Affects both osteoblasts and osteoclasts; may promote bone formation and fracture healing; expressed by both osteoblasts and chondrocytes; helps regulate bone mass
Inhibin	Dominant over activin and BMPs; helps regulate bone mass and strength by affecting formation of osteoblasts and osteoclasts
Leptin	Plays role in bone formation and resorption
Wnt (a signaling pathway)	Important in differentiating osteoblasts and bone formation; has overlapping effects with BMPs; helps regulate bone formation and remodeling
Wnt antagonists	
Dickkopf family (Dkk)	Disrupt Wnt signaling, leading to reduced bone mass
Sclerostin	Protein secreted by osteocytes, osteoblasts, and osteoclasts; binds to BMP-6 and BMP-7; interferes with Wnt signaling pathway, inhibiting bone formation by osteoblasts

Continued

TABLE 43-3 SELECTED FACTORS AFFECTING BONE FORMATION AND HOMEOSTASIS—cont'd

FACTOR	FUNCTION
Transcription Factors	
Nuclear factor of activated κβ cells (NF-κβ)	Affects embryonic osteoclastogenesis; plays a role in certain osteoclast, osteoblast, and chondroblast functions
Matrix metalloproteinases (MMPs)	
Family of endopeptidases (enzymes) that includes collagenases, gelatinases, stromelysins, matrilysins	Help maintain equilibrium of extracellular matrix (ECM); break down almost all components of ECM
A disintegrin and metalloproteinase (ADAM)	Proteolytic enzymes; also have cell-signaling functions, usually linked to cell membrane
A disintegrin and metalloproteinase with thrombospondin motifs (ADAMTS)	Similar to ADAMs but are secreted into circulation, are found around cells; various subgroups affect multiple tissues
Cysteine Protease	
Cathepsin	K-expressed by osteoclasts; assists in bone remodeling by cleaving proteins, such as collagen type I, collagen type II, and osteonectin
MMP Inhibitors	
Tetracyclines (especially doxycycline), bisphosphonates	Block enzymatic function of MMPs
Tissue inhibitors of metalloproteinases (TIMPs)	Balance effect of MMPs in maintaining ECM equilibrium

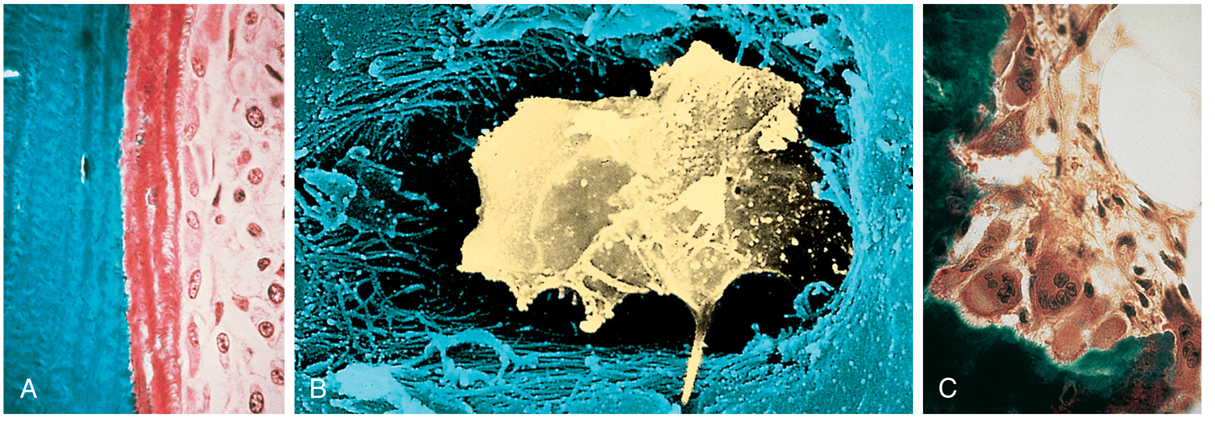

FIGURE 43-2 Bone Cells. **A,** Osteoblasts are responsible for the production of collagenous and noncollagenous proteins that compose osteoid. Active osteoblasts are lined up on the osteoid. Note the eccentrically located nuclei. **B,** Osteocyte. Scanning electron micrograph showing an osteocyte within a lacuna. The cell is surrounded by collagen fibers and mineralized bone. **C,** Osteoclasts actively resorb mineralized tissue. The scalloped surface in which the multinucleated osteoclasts rest is termed the *Howship lacuna.* (**A** and **C** from Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby. **B** from Erlandsen S, Magney J: *Color atlas of histology,* St Louis, 1992, Mosby.)

Osteoblasts. **Osteoblasts** are cells derived from mesenchymal stem cells. Osteoblasts produce several substances, including osteocalcin, TGF-β, macrophage colony-stimulating factor, **receptor activator of nuclear factor κβ ligand (RANKL), osteoprotegerin (OPG),** and bone matrix[6] and osteocalcin when stimulated by 1,25-dihydroxy-vitamin D. Osteoblasts are active on the outer surface of bones, where they form a single layer of cells. They initiate the formation of new bone by their synthesis of **osteoid** (nonmineralized bone matrix). The mechanism of osteoblast stimulation is reported to be the production of so-called coupling factors generated during the resorption process. Osteoblasts cause the formation of new bone and the orderly mineralization of bone matrix by concentrating some of the plasma proteins (growth factors) found in the bone matrix and by facilitating the deposit and exchange of calcium and other ions at the site. Osteoblasts alter levels of RANKL and OPG; the balance of these two cytokines determines overall osteoclast formation[7] (see Figure 44-11). As new bone is formed, it is shaped and remodeled through TGF-β, as well as other plasma proteins (growth factors) found in the bone marrow (Table 43-4).

Osteocytes. An **osteocyte** is a transformed osteoblast that is trapped or surrounded in osteoid as it hardens from minerals that enter during ossification (see Figure 43-2, *B*). It is the final differentiation stage for an osteoblast. The osteocyte is within a space in the hardened bone matrix called a **lacuna.** Each osteocyte has a high nucleus/cytoplasm ratio with a thin layer of nonmineralized osteoid around it, similar to the egg white surrounding an egg yolk.

TABLE 43-4 EFFECTS OF SELECTED CYTOKINES (GROWTH FACTORS) ON SKELETAL TISSUES

CYTOKINE (GROWTH FACTOR)	TARGET TISSUE	FORMATION	RESORPTION
Transforming growth factor-beta	Bone	+, –	+, –
	Cartilage	+, –	–
Transforming growth factor-alpha or epidermal growth factor	Bone	+, –	+

The cells of the osteoblastic lineage (osteoblasts and osteocytes) form a network of cells in bone that sense the shape and structure of bone (mechanoreceptors) and determine the appropriate locations for bone formation or resorption, according to Wolff's law (bone is shaped according to its function).

Osteocytes communicate with other bone cells and instruct both osteoblasts and osteoclasts about when and where to form and resorb bone; concentrate nutrients in the matrix; regulate bone mass and minerals (especially calcium and phosphorus); and secrete other proteins, such as sclerostin and fibroblast growth factor-23 (FGF-23), that influence mineral metabolism.[3,4,8,9] Sclerostin inhibits osteoblasts, thus reducing bone formation. Additionally, osteocytes seem to function as endocrine receptors in regulating bone metabolism and are prime target cells of parathyroid hormone (PTH).[9-11] Through exchanges between these cells, hormone catalysts, and minerals, optimal levels of calcium, phosphorus, and other minerals are maintained in blood plasma. The osteocyte also aids in modifying bone matrix through release of enzymes to dissolve the mineralized walls of the lacunae to prepare the bone for remodeling. (Remodeling is described on p. 1519.)

Osteoclasts. **Osteoclasts** are large, multinucleated bone cells derived from hematopoietic stem cells in the bone marrow stroma and are the major resorptive cells of bone. Considered to be the major remodelers of bone, osteoclasts contain lysosomes (digestive vacuoles) filled with hydrolytic enzymes. Fine projections, or microvilli, fan out from the osteoclast cell's surface and are known as **ruffled borders;** these projections result from extensive infoldings of the cell membrane adjacent to the resorptive surface.[12] Osteoclasts in regions of bone resorption lie in pits called *Howship lacunae,* where the infolded, ruffled borders of the osteoclasts greatly increase the surface area of the plasma membrane. The infolds end in numerous channels and vesicles in the cell cytoplasm, permitting them to resorb the bone under their ruffled, infolded borders.

Osteoclasts bind to the bone surface of cell attachment proteins called **integrins.**[12] In contact with bone mineral, osteoclasts use adhesive structures, called *podosomes,* to attach themselves to the bone surface. They then seal their cytoplasm with the underlying bone and dissolve the bone and matrix while protecting the surrounding tissue.[13] They effect resorption of bone by secretion of hydrochloric acid (HCl) and cathepsin K (a protease enzyme), which help dissolve bone minerals and collagenase, thereby aiding the digestion of collagen along with the action of cytokines (see Table 43-4). Matrix metalloproteinases (MMPs), a group of proteolytic enzymes, help control osteoclast-matrix interactions necessary for bone resorption. Once resorption is completed, the osteoclast disappears by degeneration, either by reverting to its parent cell or by leaving the site through the process of cell mobility, wherein the osteoclast then becomes an inactive, or "resting," osteoclast. Overall, bone homeostasis is the result of crosstalk between osteoclasts, osteoblasts, and osteocytes.[14] Recent evidence has indicated that osteoclasts also may play a role in the body's immune system.[15-17]

Bone Matrix

Bone matrix is made of the extracellular elements of bone tissue, composed of about 35% organic and 65% inorganic materials. The major organic components are collagen fibers, and the major inorganic components are the calcium and phosphate minerals. Other parts of the bone matrix are the proteins, carbohydrate-protein complexes, and ground substances. Water comprises 5% to 8% of the matrix. Within the matrix are small particles known as matrix vesicles that "bud" from chondrocytes, osteoblasts, and odontoblasts. These vesicles are the initial sites for calcification in skeletal tissues.[18] Calcification begins as extracellular calcium enters the matrix vesicles and forms hydroxyapatite crystals.

TABLE 43-5 TYPES OF COLLAGEN IN MUSCULOSKELETAL TISSUES

TYPE OF COLLAGEN	DISTRIBUTION IN MUSCULOSKELETAL TISSUES
I	Bone, tendon, ligament, intervertebral disk, muscle*
II	Cartilage, intervertebral disk
III	Skin, muscle, often with type I
IV	Basement cell membrane, muscle
V	Codistributed with type I muscle, most interstitial tissues
VI	Ubiquitous, muscle
IX	Codistributed with type II muscle

XI	Cartilage, muscle
XII	Codistributed with types I and III muscle
XIII	Molecule has not been isolated in connective tissues to date
XIV	Codistributed with type I muscle
XV	Muscle; contains heparin sulfate proteoglycans (HSPGs)
XVII	Muscle; contains HSPGs

*Refers specifically to skeletal muscle.

Collagen Fibers. **Collagen fibers** are the major organic component of bone matrix. The fibers are approximately 90% type I collagen, are essential for bone strength, and are synthesized and secreted by osteoblasts. Once secreted, collagen molecules assemble into thin chains called *α-chains,* which combine in groups of 3 to form **fibrils.** The fibrils form a staggered pattern, overlapping nearby fibrils by approximately one fourth their length. This staggered, overlapping pattern creates regular gaps, called *hole zones,* into which mineral crystals are deposited.[18] After mineral deposition, the fibrils link together and twist to form ropelike fibers. Collagen fibers then join to form a framework that gives bone its tensile strength and enables it to bear weight.

Collagen is the most abundant macromolecule in the body, accounting for approximately one third of all protein and providing the structural framework for nearly all tissues. Collagen is one of the extracellular components, along with proteoglycans and noncollagenous matrix proteins, of articular cartilage. To date, more than 20 types of collagen have been identified, though all their functions are not yet known. Cartilage-specific collagens include types II (the principal component), VI, IX, X, and XI. Type IX collagen is thought to be the "glue" that holds together the type II collagen scaffold of articular cartilage, helps maintain the structural integrity of cartilage, and resists tensile forces on the joint cartilage. Type XI regulates the fibril diameter of type II cartilage. Degradation of type IX collagen by proteolytic enzymes has been seen in the early stages of osteoarthritis and rheumatoid arthritis. Researchers have proposed that this degradation, or "unplugging," may be the mechanism for the degenerative changes seen in osteoarthritic and rheumatoid cartilage. Table 43-5 gives the musculoskeletal distribution of other types of collagen.

Proteoglycans. **Proteoglycans** are large complexes of numerous polysaccharides attached to a common protein core. Hyaline cartilage is primarily composed of the glycosaminoglycans chondroitin sulfate and keratin sulfate. They strengthen bone by forming compression-resistant networks between the collagen fibrils. Proteoglycans also control the transport and distribution of electrically charged particles (ions), particularly calcium, through the bone matrix, thereby playing a role in bone calcium deposition and calcification.

Glycoproteins. **Glycoproteins** are also carbohydrate-protein complexes of bone. Glycoproteins control the collagen interactions that lead to fibril formation. They also play a role in calcification.

Some of the glycoproteins in bone matrix include bone sialoprotein, osteocalcin, osteonectin, laminin, albumin, and α-glycoprotein. Other proteins found in bone matrix are the compounds currently called **bone morphogenic proteins (BMPs)** (see Table 43-2). **Sialoprotein (osteopontin)** comprises about 8% of the noncollagenous matrix of bone and easily binds with calcium.

Osteocalcin is also a calcium-binding protein that binds preferentially to calcium that has already crystallized. The roles of osteocalcin may be to inhibit calcium phosphate precipitation and to play a part in bone resorption by recruiting osteoclasts.

Osteonectin is a bone-specific protein that binds selectively to both hydroxyapatite and collagen in the bone matrix. **Laminin** is an abundant bone matrix protein in humans that stabilizes basement membranes in bones and is important in neurite and axon growth.

Bone albumin is identical to serum albumin. In calcified matrix, bone albumin is permanently fixed to bone mineral crystals and remains so until the bone is resorbed. Bone albumin transports essential elements such as hormones, ions, and other metabolites to and from the bone cells and maintains the osmotic pressure of **bone fluid** (fluid surrounding mineral crystals and osteoblasts).

Bone Minerals

Mineralization is the final step in bone formation, after collagen synthesis and fiber formation. Mineralization has two distinct phases: (1) formation of the initial mineral deposit (initiation), and (2) proliferation or accretion of additional mineral crystals on the initial mineral deposits (growth).[12] The majority of the mineral content in the body is an analog of the naturally occurring mineral *hydroxyapatite.*

Table 43-6 lists the sequence in which calcium and phosphate form amorphous (fluid) calcium phosphate compounds that are converted, in stages, to solid hexagonal crystals of **hydroxyapatite (HAP).** As the calcium and phosphorous concentrations increase in the bone matrix, the first precipitate to form is dicalcium phosphate dihydrate (DCPD). Once DCPD precipitation begins, the remaining phases of bone crystal formation proceed until insoluble HAP is produced, with approximately 80% to 90% of the HAP being incorporated into the collagen fibers. Amorphous calcium phosphate is distributed throughout the bone matrix.

TABLE 43-6 SEQUENCE OF CALCIUM AND PHOSPHATE COMPOUND FORMATION AND CRYSTALLIZATION

FORMULA	NAME	ABBREVIATION
$Ca(HPO_4) \times 2H_2O$	Dicalcium phosphate dehydrate	DCPD
$Ca_4H(PO_4)_3$	Octacalcium phosphate	OCP
$Ca_9(PO_4)_6$ (var.)	Amorphous calcium phosphate	ACP
$Ca_3(PO_4)_2$	Tricalcium phosphate	TCP
$Ca_5(PO_4)_3OH$	Hydroxyapatite	HAP

NOTE: Compounds are listed in order in which precipitation and crystal formation occur.

Types of Bone Tissue

Bone consists of two types of bony (osseous) tissue: **compact bone (cortical bone)** and **spongy bone (cancellous bone)** (Figure 43-3). Compact bone constitutes approximately 85% of the skeleton; spongy bone comprises the remaining 15%. Both types of bone tissue contain the same structural elements, and, with a few exceptions, both compact tissue and spongy tissue are present in every bone. The major difference between the two types of tissue is the organization of the elements.

Compact bone is highly organized, solid, and extremely strong. The basic structural unit in compact bone is the haversian system (Figure 43-4). Each **haversian system** is made up of the following:

1. A central canal called the **haversian canal**
2. Concentric layers of bone matrix called **lamellae**
3. Tiny spaces (lacunae) between the lamellae
4. Bone cells (osteocytes) within the lacunae
5. Small channels or canals called **canaliculi**

Each haversian system is a separate cylindrical entity that looks like a set of concentric rings. In the center of the haversian system is the haversian canal that runs through the long axis of bone and contains one or two blood vessels and nerve fibers. The blood vessels in the canal communicate with blood vessels in the periosteum (surface cover) and marrow cavity to transport nutrients and wastes to and from the osteocytes contained within the lacunae. Surrounding each haversian canal are the concentric lamellae. Between the lamellae are the lacunae, each of which contains one osteocyte. The lacunae are connected to each other and to the haversian canal by the canaliculi, which run parallel to the horizontal axis of the bone. Each canaliculus encloses a small extension (cytoplasmic process) from the osteocyte contained in the lacuna. The canaliculi transport both nourishment and molecular signals into the lacunae, a mechanism essential for osteocyte survival.

Spongy bone is less complex and lacks haversian systems. In spongy bone the lamellae are not arranged in concentric layers but in plates or bars termed **trabeculae** that branch and unite with one another to form an irregular meshwork. The pattern of the meshwork is determined by the direction of stress on the particular bone. The spaces between the trabeculae are filled with red bone marrow. The osteocyte-containing lacunae are distributed between the trabeculae and interconnected by canaliculi. Capillaries pass through the marrow to nourish the osteocytes.

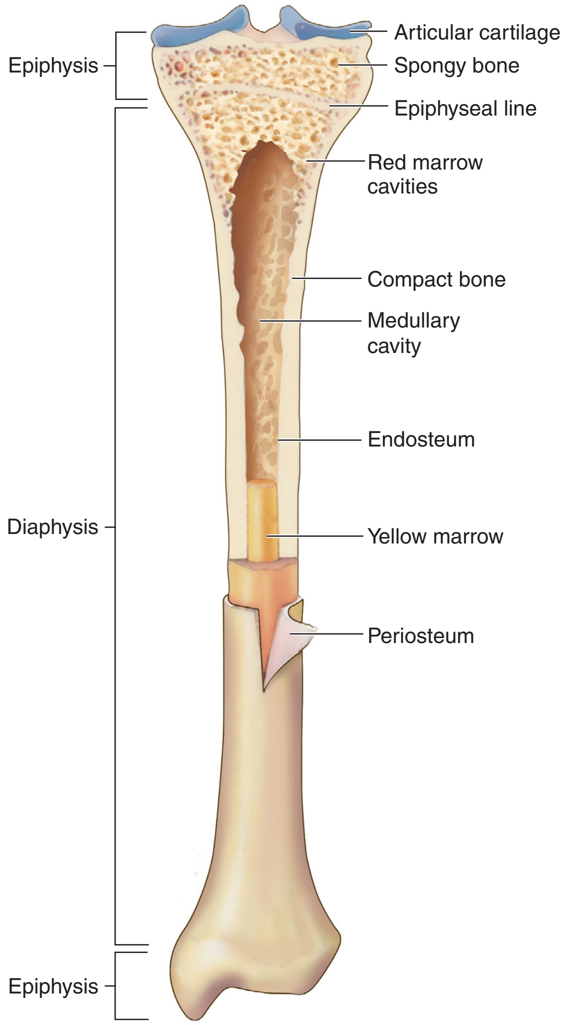

FIGURE 43-3 Cross Section of Bone. Longitudinal section of long bone (tibia) showing cancellous and compact bone. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

All bones are covered with a double-layered connective tissue called the **periosteum.** The outer layer of the periosteum contains blood vessels and nerves, some of which penetrate to the inner structures of the bone through channels called Volkmann canals (see Figure 43-4). The inner layer of the periosteum is anchored to the bone by collagenous fibers (Sharpey fibers) that penetrate the bone. Sharpey fibers also help hold or attach tendons and ligaments to the periosteum of bones.[12]

Characteristics of Bone

The human skeleton consists of 206 bones that constitute the axial skeleton and the appendicular skeleton (Figure 43-5). The **axial skeleton** consists of 80 bones that make up the skull, vertebral column, and thorax. The **appendicular skeleton** consists of 126 bones that make up the upper and lower extremities, the shoulder girdle (pectoral girdle), and the pelvic girdle. The skeleton contributes about 14% of the weight of the adult body.

Bones can be classified by shape as long, flat, short (cuboidal), or irregular. **Long bones** are longer than they are wide and consist of a narrow tubular midportion **(diaphysis)** that merges

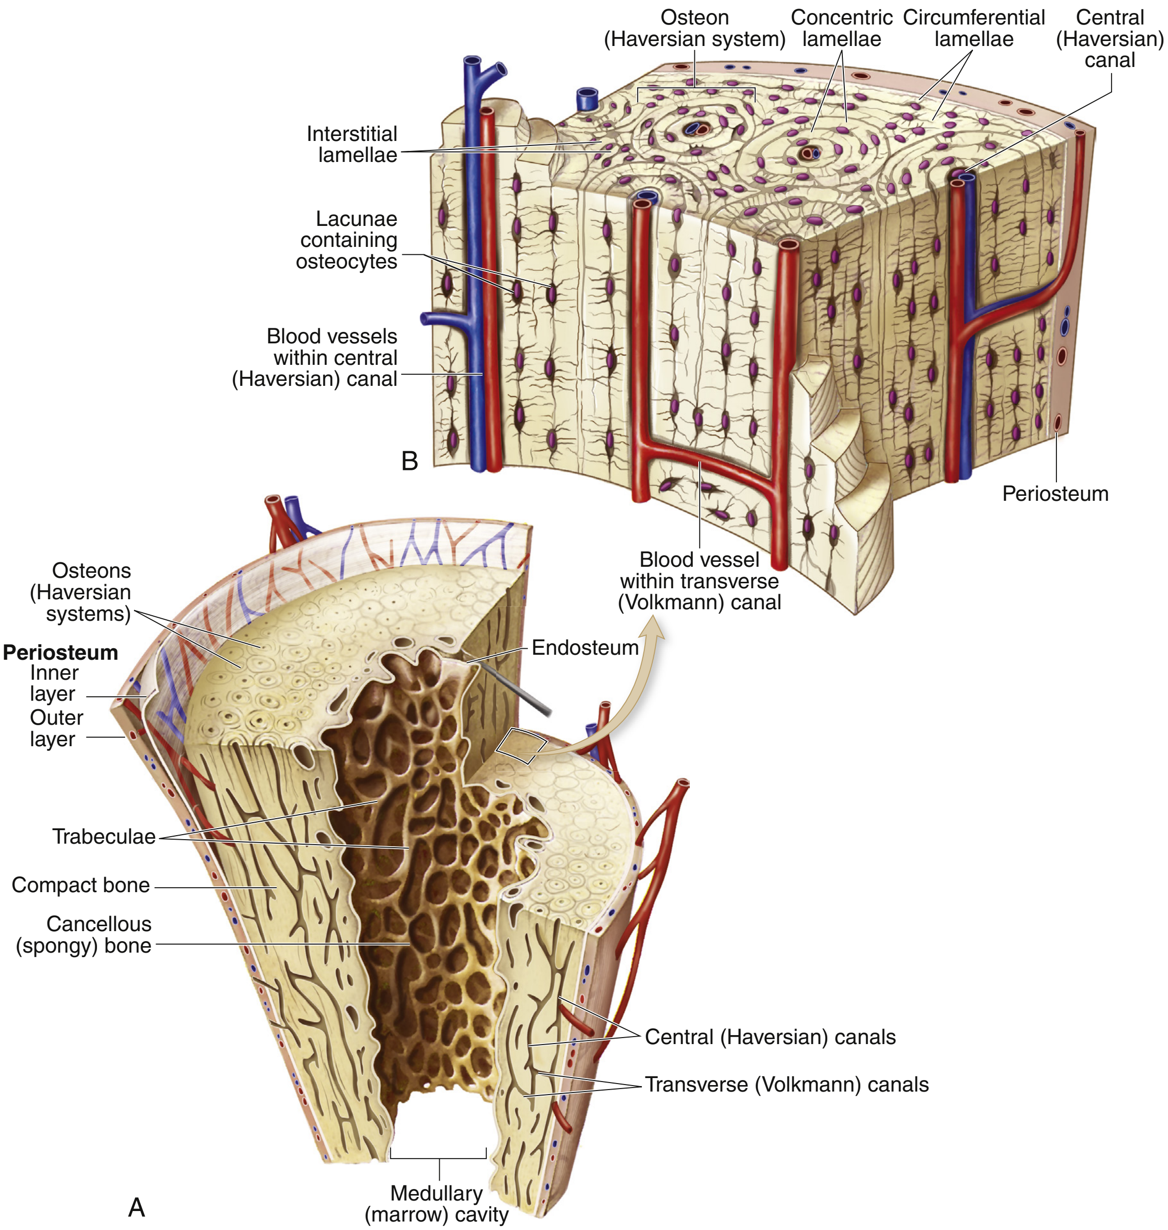

FIGURE 43-4 Structure of Compact and Cancellous Bone. **A,** Longitudinal section of a long bone showing cancellous and compact bone. **B,** A magnified view of compact bone. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

into a broader neck (**metaphysis**) and a broad end (**epiphysis**) (see Figure 43-3).

The diaphysis consists of a shaft of thick, rigid compact bone that can tolerate bending forces. Contained within the diaphysis is the elongated marrow (medullary) cavity. The marrow cavity of the diaphysis contains primarily fatty tissue, which is referred to as *yellow marrow.* The yellow marrow assists red bone marrow in hematopoiesis only during times of stress. The yellow marrow cavity of the diaphysis is continuous with marrow cavities in the spongy bone of the metaphysis and diaphysis. The marrow contained within the epiphysis is red because it contains primarily blood-forming tissue (see Chapter 27). A layer of connective tissue, the **endosteum,** lines the outer surfaces of both types of marrow cavity.

The broadness of the epiphysis allows weightbearing to be distributed over a wide area. The epiphysis is made up of spongy bone covered by a very thin layer of compact bone. In a child the epiphysis is separated from the metaphysis by a cartilaginous **growth plate,** the **epiphyseal plate.** After puberty the epiphyseal plate calcifies and the epiphysis and metaphysis merge. By adulthood the line of demarcation between the epiphysis and metaphysis is undetectable.

In **flat bones,** such as the ribs or scapulae, two plates of compact bone are roughly parallel to each other. Between the compact bone plates is a layer of spongy bone. **Short bones (cuboidal bones),** such as the bones of the wrist or ankle, are often cuboidal in shape. They consist of spongy bone covered by a thin layer of compact bone.

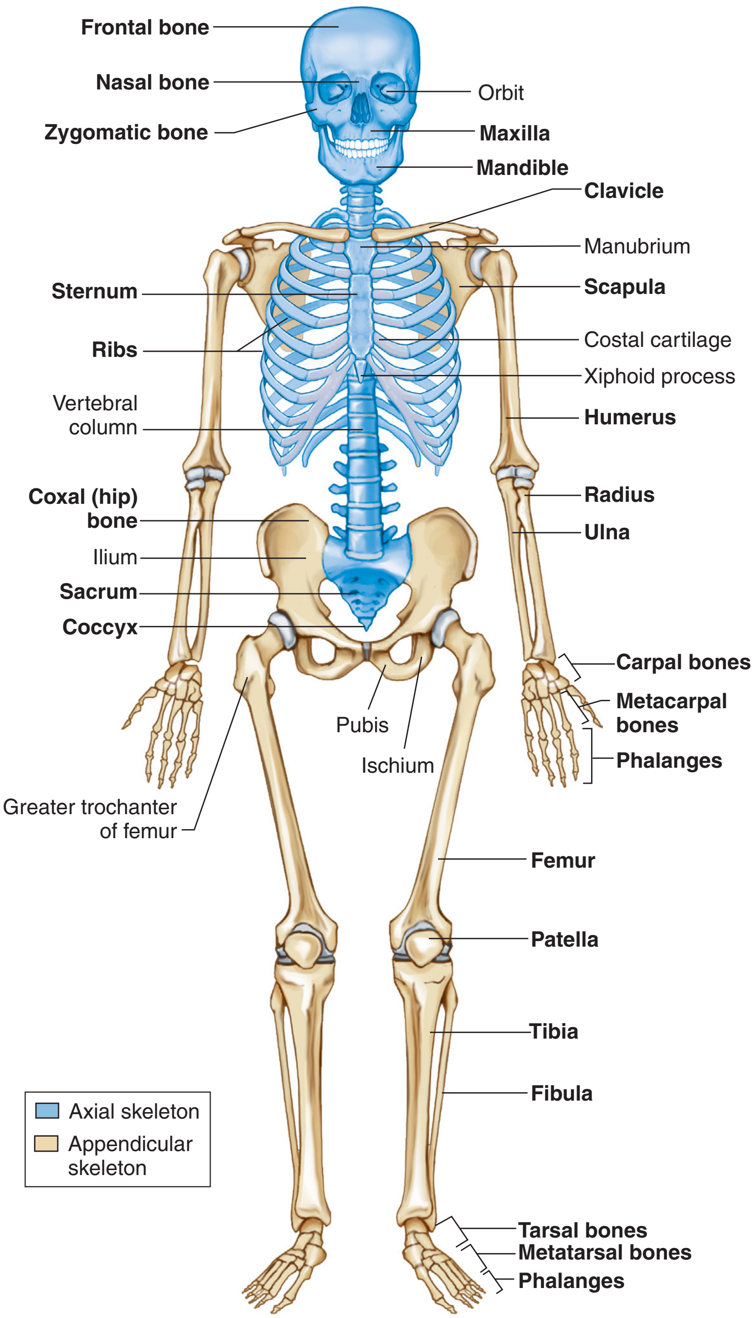

FIGURE 43-5 Anterior View of Skeleton. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby.)

Irregular bones, such as the vertebrae, mandibles, or other facial bones, have various shapes that include thin and thick segments. The thin part of an irregular bone consists of two plates of compact bone with spongy bone between the plates. The thick part consists of spongy bone surrounded by a layer of compact bone.

Maintenance of Bone Integrity

Remodeling

Clusters of bone cells, termed bone-remodeling units, are responsible for maintaining the structure of bone by **remodeling,** a three-phase process in which existing bone is resorbed and new bone is laid down to replace it. The **bone-remodeling units** are made up of bone precursor cells that differentiate into osteoclasts and osteoblasts. Precursor cells are located on the free surfaces of bones and along the vascular channels (especially the marrow cavities).

In phase 1 (activation) of the remodeling cycle, a stimulus (e.g., hormone, drug, vitamin, physical stressor) activates programmed osteocyte cell death (apoptosis). The distribution of these apoptotic osteocytes provides osteoclasts with information about where to begin resorbing damaged bone. In phase 2 (resorption), the osteoclasts form a "cutting cone," which gradually resorbs bone, leaving behind an elongated cavity termed

a *resorption cavity*. The resorption cavity in compact bone follows the longitudinal axis of the haversian system, and the resorption cavity in spongy bone parallels the surface of the trabeculae.

Phase 3 (formation) is the laying down of new bone, termed *secondary bone,* by osteoblasts lining the walls of the resorption cavity. Successive layers (lamellae) in compact bone are laid down until the resorption cavity is reduced to a narrow haversian canal around a blood vessel. In this way, old haversian systems are destroyed and new haversian systems are formed. New trabeculae are formed in spongy bone. The entire process of remodeling takes about 3 to 4 months.

Repair

The remodeling process can repair microscopic bone injuries, but gross injuries, such as fractures and surgical wounds (osteotomies), heal by the same stages as soft tissue injuries, except that new bone, instead of scar tissue, is the final result (see Chapter 7). In bone the stages of wound healing are as follows:

1. *Hematoma formation:* This process occurs if vessels have been damaged, causing hemorrhage. Fibrin and platelets within the hematoma form a meshwork that is the initial framework for healing with the help of hematopoietic growth factors such as platelet-derived growth factor and TGF-β (see Table 43-3).
2. *Procallus formation:* Fibroblasts, capillary buds, and osteoblasts move into the wound to produce granulation tissue called **procallus.** Cartilage is formed as a precursor of bone, and types I, II, and III collagen are formed. Enzymes and growth factors, such as insulin and insulin-like growth factors, plus bone morphogenic protein and osteogenin, aid in this stage of healing.
3. *Callus formation:* Osteoblasts in the procallus form membranous or **woven bone (callus).** Enzymes increase the phosphate content and permit the phosphate to join with calcium to be deposited as mineral to harden the callus.
4. *Callus replacement:* Osteoblasts continue to replace the callus with lamellar bone or trabecular bone (Figure 43-6).
5. *Remodeling:* The periosteal and endosteal surfaces of the bone are remodeled to the size and shape of the bone before injury. Synthesis of other types of collagen recedes in favor of type I, which is the collagen found in bone. This final stage of healing, or remodeling, is vital because bone that has not been remodeled does not have good mechanical properties for weightbearing and mobility.

The speed with which bone heals depends on the severity of the bone disruption; the type and amount of bone tissue that must be replaced (spongy bone heals faster); the blood supply and oxygen content at the site; the presence of growth and thyroid hormones, insulin, vitamins, and other nutrients; the presence of systemic disease; the effects of aging; and the effectiveness of treatment, including immobilization and the prevention of complications such as infection. In general, however, hematoma formation occurs within hours of fracture or surgery; formation of procallus by osteoblasts occurs within days; callus formation occurs within weeks; and replacement and contour modeling occur within years—up to 4 years in some cases.

STRUCTURE AND FUNCTION OF JOINTS

The site where two or more bones meet is called a **joint (articulation)** (Figure 43-7). The primary function of joints is to provide stability and mobility to the skeleton. Whether a joint provides stability or mobility depends on its location and its structure. Generally, joints that stabilize the skeleton have a simpler structure than those that enable movement of the skeleton. Most joints provide stability and mobility to some degree (Figure 43-8).

Joints are classified based on the degree of movement they permit or on the connecting tissues that hold them together. Based on movement, a joint is classified as a **synarthrosis (immovable joint),** an **amphiarthrosis (slightly movable joint),** or a **diarthrosis (freely movable joint).** On the basis of connective structures, joints are classified broadly as fibrous, cartilaginous, and synovial. Each of these three structural classifications can be subdivided according to the shape and contour of the articulating surfaces (ends) of the bones and the type of motion the joint permits.

Fibrous Joints

A joint in which bone is united directly to bone by fibrous connective tissue is called a **fibrous joint.** Generally, fibrous joints are synarthroses (immovable), but many fibrous joints allow some movement. The degree of movement depends on the distance between the bones and the flexibility of the fibrous connective tissue.

Fibrous joints are further subdivided into three types: sutures, syndesmoses, and gomphoses. A **suture** has a thin layer of dense fibrous tissue that binds together interlocking flat bones in the skulls of young children. Sutures form an extremely tight union that permits no motion. By adulthood the fibrous tissue has been replaced by bone. A **syndesmosis** is a joint in which the two bony surfaces are united by a ligament or membrane. The fibers of ligaments are flexible and stretch, permitting a limited amount of movement. The paired bones of the lower arm (radius and ulna) and the lower leg (tibia and fibula) and their ligaments are syndesmotic joints. A **gomphosis** is a special type of fibrous joint in which a conical projection fits into a complementary socket and is held there by a ligament. The teeth held in the maxilla or mandible are gomphosis joints.

Cartilaginous Joints

The two types of cartilaginous joints are symphyses and synchondroses. A **symphysis** is a cartilaginous joint in which bones are united by a pad or disk of fibrocartilage. A thin layer of hyaline cartilage usually covers the articulating surfaces of the two bones, and the thick pad of fibrocartilage acts as a shock absorber and stabilizer. Examples of symphyses are the symphysis pubis, which joins the two pubic bones, and the intervertebral disks, which join the bodies of the vertebrae. A **synchondrosis** is a joint in which hyaline cartilage, rather than fibrocartilage, connects the two bones. The joints between the ribs and the sternum are synchondroses. The hyaline cartilage of these joints is called *costal cartilage.* Slight movement at the synchondroses between the ribs and the sternum allows the chest to move outward and upward during breathing.

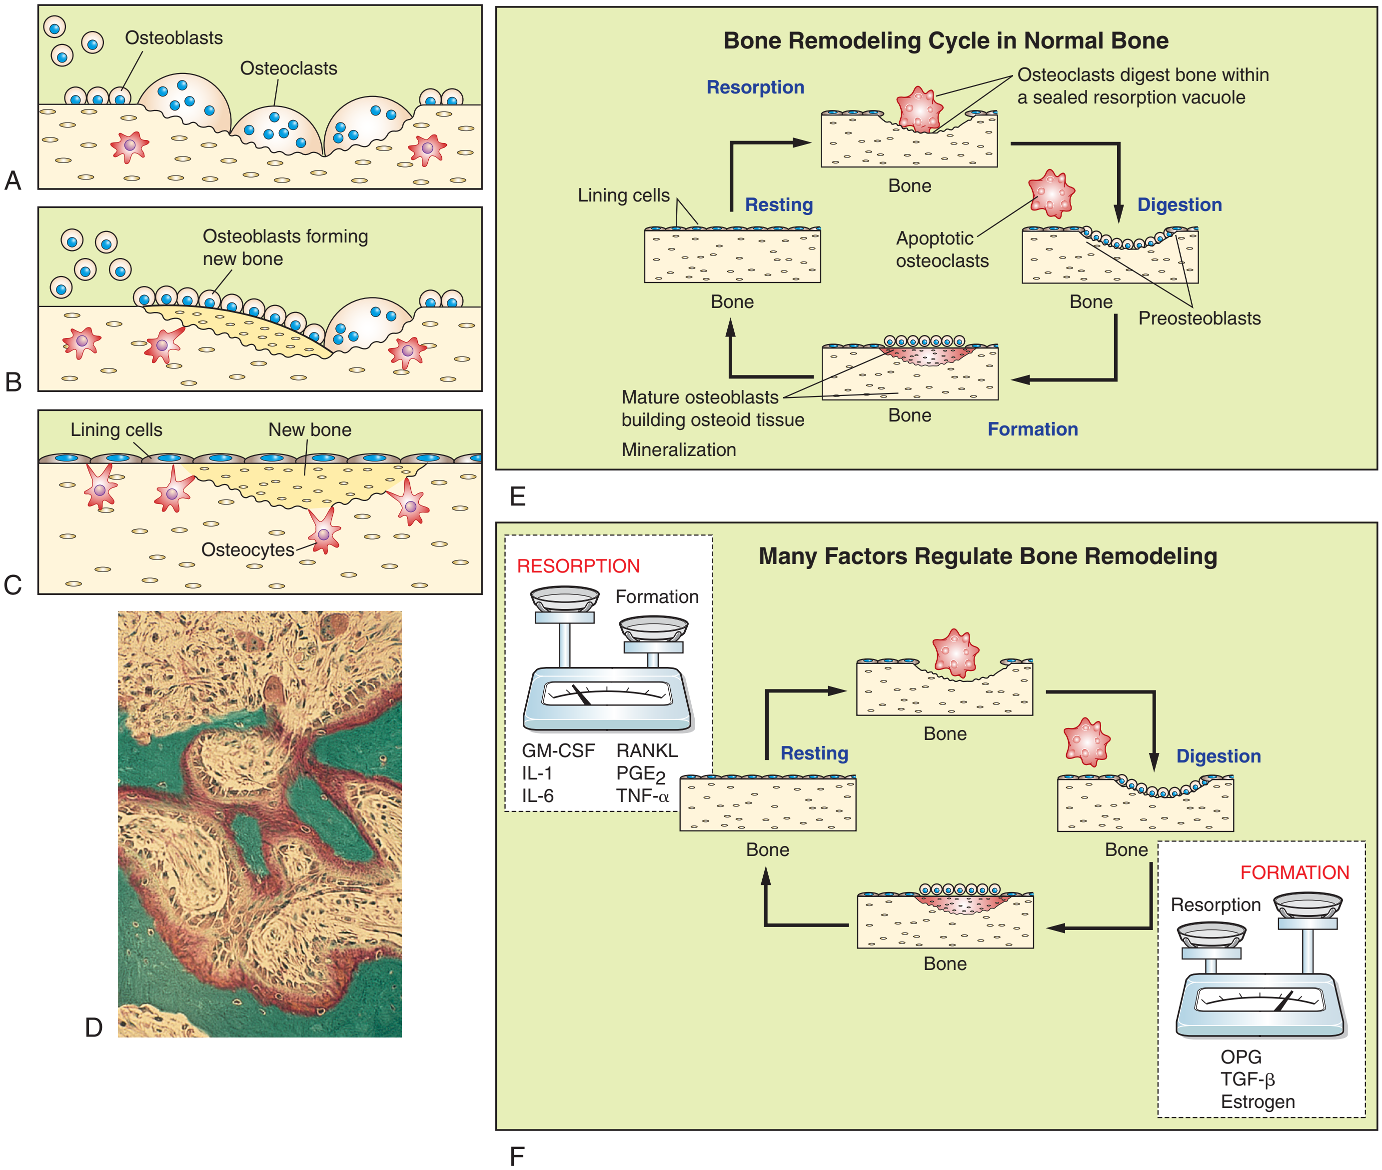

FIGURE 43-6 **Bone Remodeling.** All bone cells participate in bone remodeling. In the remodeling sequence bone sections are removed by bone-resorbing cells (osteoclasts) and replaced with a new section laid down by bone-forming cells (osteoblasts). Bone remodeling is necessary because it allows the skeleton to respond to mechanical loading, maintains quality control (repair and prevent microdamage), and allows the skeleton to release growth factors and minerals (calcium and phosphate) stored in bone matrix to the circulation. The cells work in response to signals generated in the environment (see **F**). Only the osteoclastic cells mediate the first phase of remodeling. They are activated, scoop out bone **(A),** and resorb it; then the work of the osteoblasts begins **(B).** They form new bone that replaces bone removed by the resorption process **(C).** The sequence takes 4 to 6 months. **D,** Micrograph of active bone remodeling seen in the settings of primary or secondary hyperparathyroidism. Note the active osteoblasts surmounted on red-stained osteoid. Marrow fibrosis is present. **E,** Bone remodeling cycle in normal bone **(F).** Numerous signaling factors are necessary for remodeling. Factors most important for resorption include granulocyte macrophage-colony-stimulating factor *(GM-CSF),* interleukins-1 and -6 *(IL-1* and *IL-6),* receptor activator for nuclear factor κβ ligand *(RANKL),* prostaglandin E_2 *(PGE₂),* and tumor necrosis factor-alpha *(TNF-α).* Important factors for bone formation include osteoprotegerin *(OPG),* transforming growth factor-beta *(TGF-β),* and estrogen. (Adapted from Nucleus Medical Art. **D** from Damjananov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

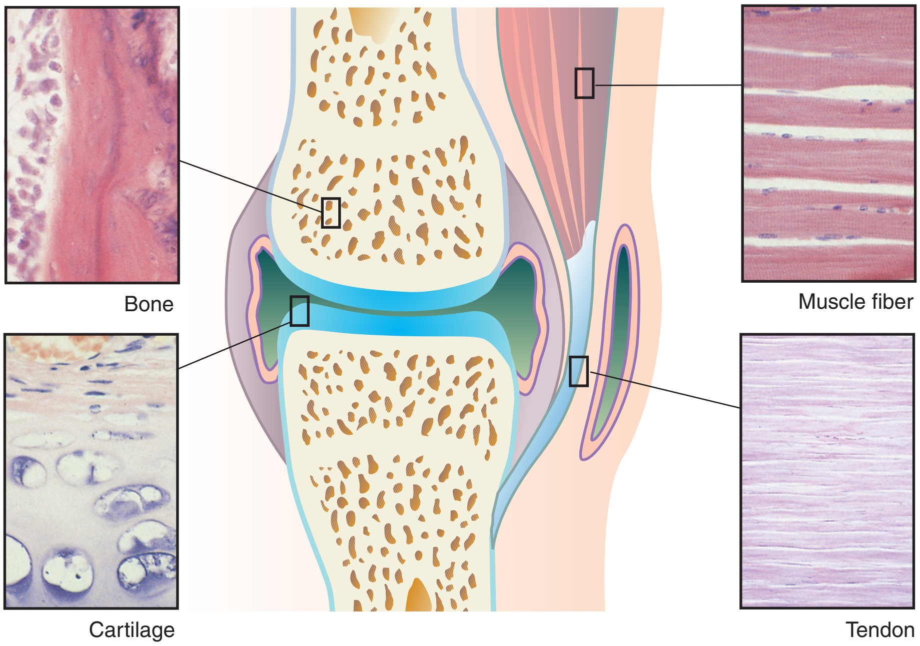

FIGURE 43-7 Main Tissues of a Joint. (Micrographs from Erlandsen SL, Magney JE: *Color atlas of histology,* St Louis, 1992, Mosby.)

Synovial Joints

Structure

Synovial joints (diarthroses) are the most movable and the most complex joints in the body (Figure 43-9). A synovial joint consists of the following parts:

1. A fibrous joint capsule (articular capsule)
2. A synovial membrane that lines the inner surface of the joint capsule
3. A joint cavity (synovial cavity), a space formed by the capsule
4. Synovial fluid, which fills the joint cavity and lubricates the joint surface
5. Articular cartilage, which covers and pads the articulating bony surfaces

Joint Capsule. The fibrous **joint capsule (articular capsule)** is connective tissue that covers the ends of the bones where they meet in the joint. Sharpey fibers firmly attach the proximal and distal capsules to the periosteum and ligaments and tendons, which also reinforce the capsule. The joint capsule consists of parallel, interlacing bundles of dense, white fibrous tissue. It is richly supplied with nerves, blood vessels, and lymphatic vessels. The nerves in and around the joint capsule are sensitive to the rate and direction of motion, compression, tension, vibration, and pain.

Synovial Membrane. The **synovial membrane (synovium)** is the smooth, delicate inner lining of the joint capsule (Figure 43-10). It lines the nonarticular portion of the synovial joint and any ligaments or tendons that traverse the joint cavity. It is made up of two layers—a vascular layer (**subintima**) and a thin cellular layer (**intima).** The vascular subintima merges with the fibrous joint capsule and is composed of loose fibrous connective tissue, elastin fibers, fat cells, fibroblasts, macrophages, and mast cells. The intima consists of rows of synovial cells embedded in a fiber-free intercellular matrix. The intima contains two types of synovial cells: type A and type B. **Type A synovial cells** ingest and remove bacteria and particles of debris by phagocytosis in the joint cavity. (Phagocytosis is described in Chapter 7.) **Type B synovial cells** secrete **hyaluronate,** a binding agent that gives synovial fluid its viscous quality. The synovial membrane is richly supplied with blood and lymphatic vessels; therefore, it is capable of rapid repair and regeneration.

Joint Cavity. The **joint cavity (synovial cavity)** is an enclosed fluid-filled space between the articulating surfaces of the two bones. This small cavity, often called the *joint space,* enables the two bones to move "against" one another. The synovial cavity is surrounded by the synovial membrane and filled with a clear, viscous, slick fluid called the *synovial fluid.*

Synovial Fluid. **Synovial fluid** is superfiltrated plasma from blood vessels in the synovial membrane. Synovial fluid lubricates the joint surfaces, nourishes the pad of the articular cartilage that covers the ends of the bones, and contains free-floating synovial cells and various leukocytes that phagocytize joint debris and microorganisms. Loss of synovial fluid leads to rapid deterioration of articular cartilage.

Articular Cartilage. **Articular cartilage** is a layer of hyaline cartilage that covers the end of each bone (Figure 43-11). It ranges from 2 to 5 mm thick, depending on the size of the joint, the fit of the two bone ends, and the amount of weight and shearing force the joint normally withstands. Cartilage strength and its biologic properties are due to an extensive network of cross-linked collagen fibers. Figure 43-12 illustrates how collagen cross-links from cartilage. The function of articular cartilage is to reduce friction in the joint and to distribute the forces of weightbearing. Articular cartilage is composed of **chondrocytes** (cartilage cells) (making up about 2% of the tissue) and an intercellular matrix made up of collagen (making

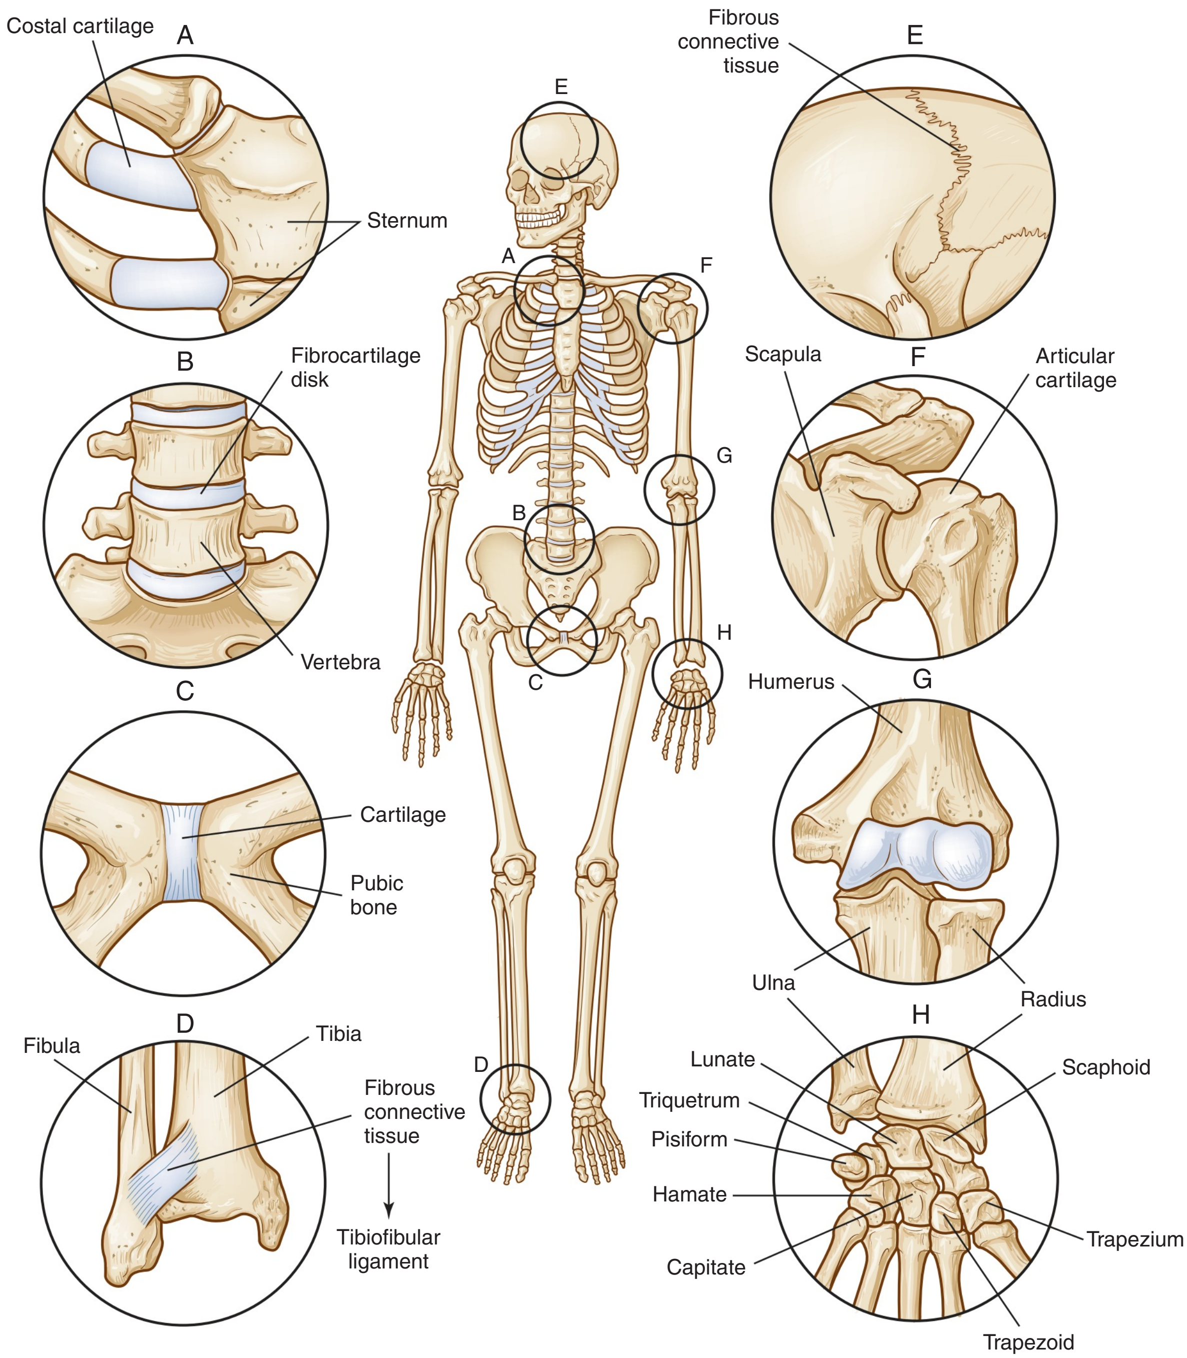

FIGURE 43-8 Types of Joints. Cartilaginous (amphiarthrodial) joints, which are slightly movable, include **(A)** a synchondrosis that attaches ribs to costal cartilage; **(B)** a symphysis that connects vertebrae; and **(C)** the symphysis that connects the two pubic bones. Fibrous (synarthrodial) joints, which are immovable, include **(D)** the syndesmosis between the tibia and fibula; **(E)** sutures that connect the skull bones; and the gomphosis (not shown), which holds teeth in their sockets. The synovial joints include **(F)** the spheroid type at the shoulder; **(G)** the hinge type at the elbow; and **(H)** the gliding joints of the hand.

up about 10% to 30% of weight), protein polysaccharides (making up 5% to 10% of weight), and water. The water content ranges from 60% to almost 80% of the net weight of the cartilage, and individual molecules rapidly enter or exit the articular cartilage to contribute to the resiliency of the tissue.

The intercellular matrix is produced by the chondrocytes, which synthesize and extrude collagen that, like the collagen produced by bone cells, is distributed throughout the cartilage in a highly organized system of fibers. Collagen fibers in cartilage are made up of many fine fibrils that, like bone fibrils, are assembled in an orderly fashion that makes them resistant to physical, metabolic, or chemical breakdown. The main differences between bone collagen and cartilage collagen are the amino acid content of the α-chains and the composition of the fibrils. Bone collagen fibrils are made up of two type I chains and one type II chain. Approximately 90% of the cartilage collagen fibrils is made up of three identical type II chains, with the remaining 10% consisting of types V, VI, IX, X, and XI.

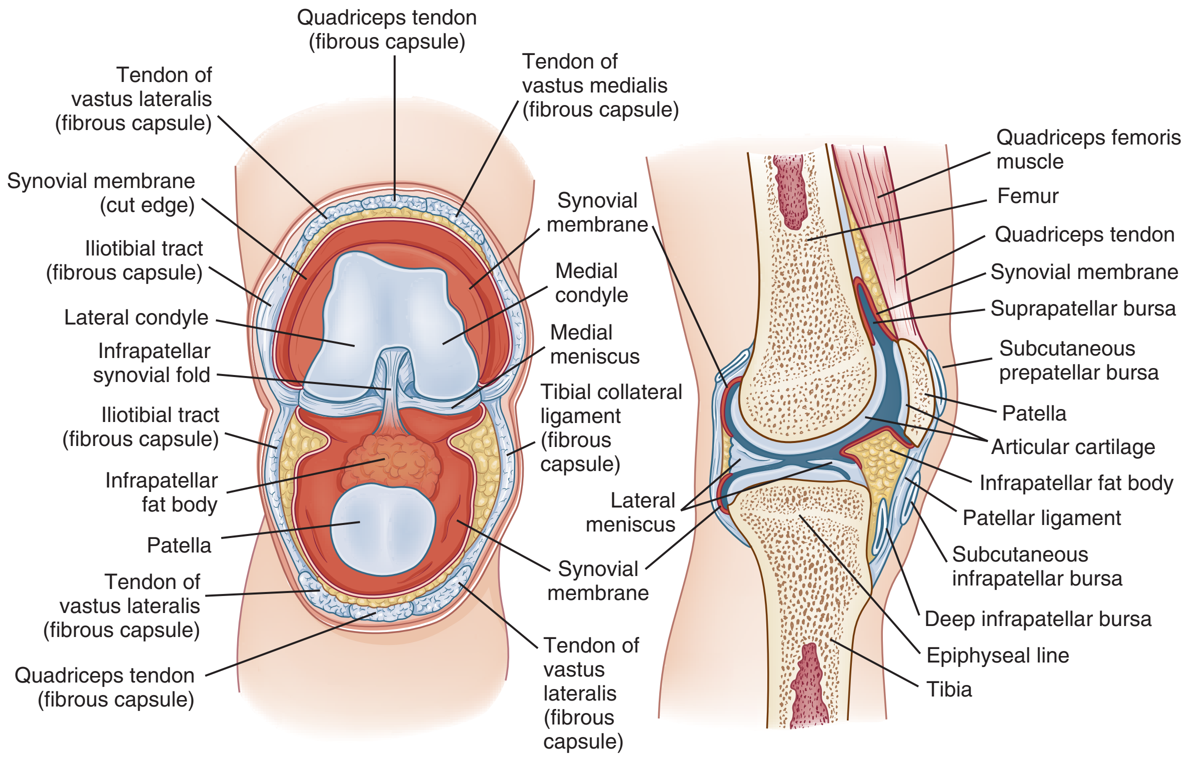

FIGURE 43-9 Knee Joint (Synovial Joint).

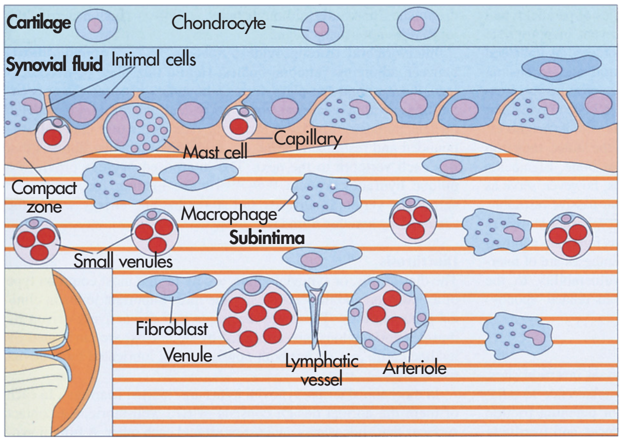

FIGURE 43-10 Synovium. Note the delicate synovial lining resting on a fibroadipose subintimal lining rich in capillaries, lymphatics, and nerve endings. (Modified from Hochberg MC et al: *Rheumatology,* ed 4, Philadelphia, 2008, Mosby.)

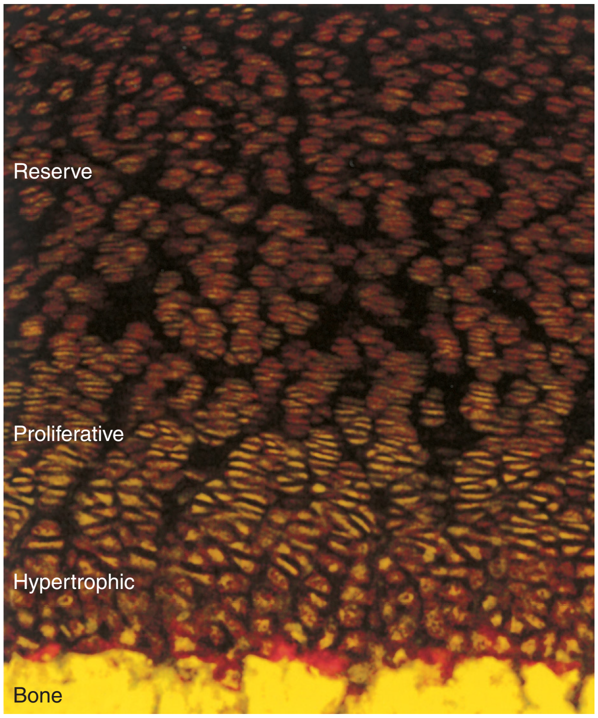

FIGURE 43-11 Collagen Zones. The three collagen zones (reserve, proliferative, and hypertrophic) are distinctly shown in a growth plate. (From Hjorten R et al: *Bone* 41[4]:535, 2007.)

At the surface of articular cartilage, the collagen fibers run parallel to the joint surface and are closely compacted into a dense, protective mat. (Loss of this dense, compacted configuration at the surface subjects the underlying fibers to splitting and thinning, in which case the cartilage is unable to tolerate weightbearing.) In the middle layer (the proliferative zone) of the cartilage, the fibers are arranged tangential to the surface, which allows them to deform and absorb some of the force of weightbearing (see Figure 43-11). In the bottom layer (the hypertrophic zone) of the cartilage, the fibers are perpendicular to the joint surface, allowing them to resist shear forces, and are embedded in a calcified layer of cartilage called the **tidemark.** The tidemark anchors the collagen fibers to the underlying (subchondral) bone and represents the zone between calcified and uncalcified cartilage. Collagen fibers are important components of the cartilage matrix because they account for approximately 60% of the dry weight and because they (1) anchor the cartilage securely to underlying bone, (2) provide a taut framework for the cartilage, (3) control

the loss of fluid from the cartilage, and (4) prevent the escape of protein polysaccharides (proteoglycans) from the cartilage.

The proteoglycans are macromolecules consisting of proteins, carbohydrates (**glycosaminoglycans**), and hyaluronic acid. One subgroup of proteoglycans, known as heparin sulfate proteoglycans (HSPGs), binds to many proteins involved in musculoskeletal development and homeostasis, including FGF, BMPs, Wnts, chemokines, interleukins, and extracellular matrix (ECM) proteins.[19] The glycosaminoglycans (keratin sulfate and chondroitin sulfate) are attached to the **protein core,** and several protein cores (with their attached glycosaminoglycans) are bound to a hyaluronic acid chain by a special protein called **link protein.** The proteoglycans give articular cartilage its stiff quality and regulate the movement of synovial fluid through the cartilage. Without proteoglycans, normal weightbearing would rapidly and completely press all the synovial fluid out of the cartilage. Proteoglycans act as a pump, permitting enough fluid to be pressed out to ensure that a fluid film is always present on the surface of the cartilage, even after hours of weightbearing. The pumping action of proteoglycans also draws synovial fluid back into the cartilage after a weightbearing load is released. Mobility and weightbearing are necessary for the pumping action of proteoglycans to occur. Nonuse of a joint quickly reduces the pumping action, which changes the composition of the matrix and interferes with the nutrition of the chondrocytes.

Normal articular cartilage has no blood vessels, lymph vessels, or nerves. Therefore, it is insensitive to pain and regenerates slowly and minimally after injury.[20,21] Regeneration occurs primarily at sites where the articular cartilage meets the synovial membrane, where blood vessels and nutrients are available. In general, it has been difficult to enhance cartilage repair, but that may be changing (see What's New? Progress in Rebuilding Cartilage).

WHAT'S NEW?

Progress in Rebuilding Cartilage

Efforts to repair damaged cartilage have been difficult because of the poor vascularity of cartilage. Currently available techniques, such as autologous chondrocyte transplantation, have not consistently produced good results. Developments in tissue engineering have been aided by maintaining improved biologic control of cell growth, differentiation, and metabolic activity. One persistent challenge is developing material with increased amounts of collagen to allow proper mechanical function of engineered cartilage.

Techniques known as "functional tissue engineering" not only should provide a network of chondrocyte cell growth but also should greatly improve the biomechanical properties of engineered cartilage. By more closely resembling native cartilage, these technologies show great promise for clinically improved outcomes in cartilage repair and replacement.

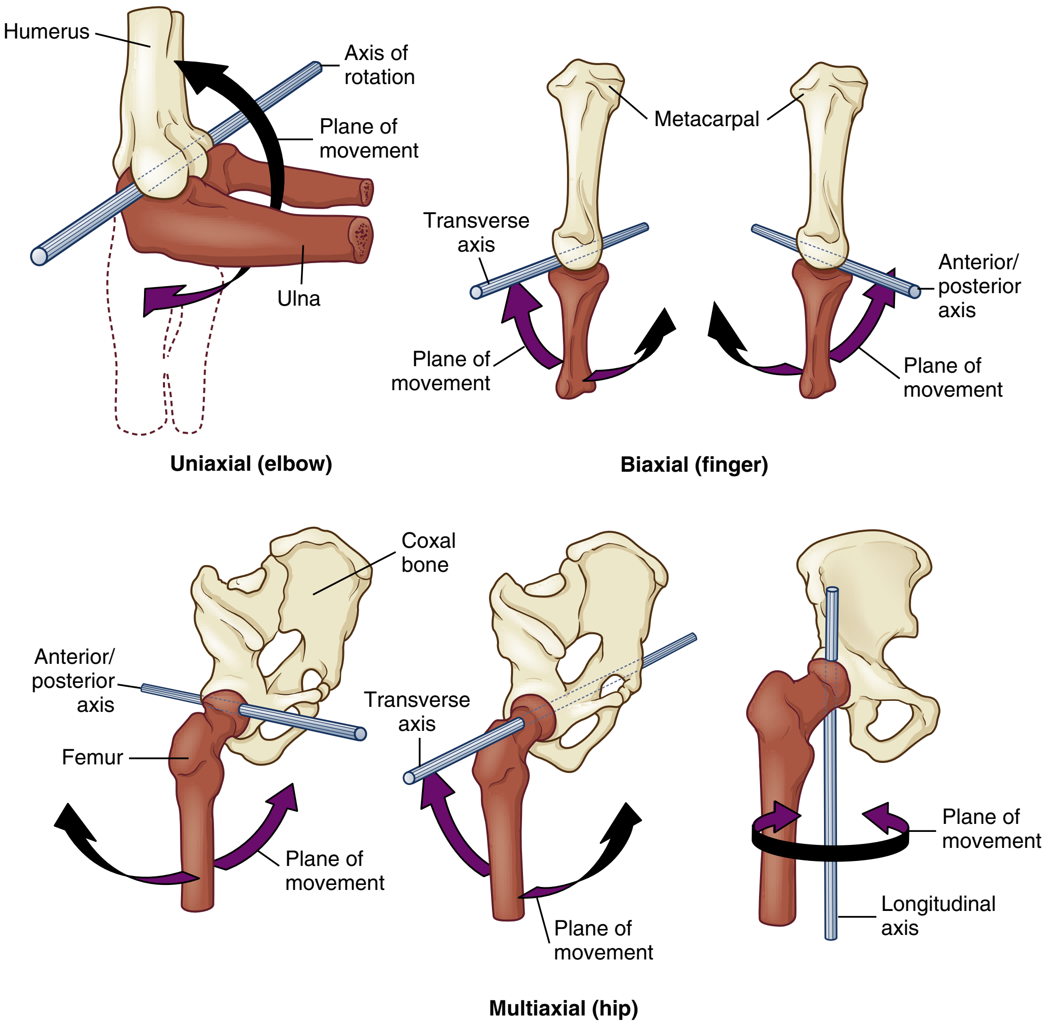

FIGURE 43-13 Movements of Synovial (Diarthrodial) Joints.

Movement

Synovial joints are described as uniaxial, biaxial, or multiaxial according to the shapes of the bone ends and the type of movement occurring at the joint (Figure 43-13). Usually one of the bones is stable and serves as an axis for the motion of the other bone. The body movements made possible by various synovial joints are either circular or angular (Figure 43-14).

STRUCTURE AND FUNCTION OF SKELETAL MUSCLES

Skeletal muscles arise from mesodermal progenitor cells; the most numerous are the somites. Actual formation of skeletal muscle is a complex process controlled by multiple signaling factors. A critical component of successful embryonic muscle formation (myogenesis) is protein kinase, an enzyme that adds phosphate groups to substrate proteins, thereby directing cell processes.[22] In muscle, these factors direct formation of myoblasts. Once myoblasts are formed, they fuse with other myoblasts and form myotubes, eventually developing into muscle fibers. At birth, the muscle fibers have completed development from myoblasts. Final muscle type is determined by transcription factors that regulate both pre- and postnatal muscle development.[23]

All **voluntary muscles** are derived from the mesodermal layer of the embryo. Genetic transcription factors, most notably myoblast determination protein (MyoD), induce skeletal muscle differentiation. Myoblasts are the main cells responsible for muscle growth and regeneration. Myoblasts are termed *satellite cells* when in a dormant state and are crucial in muscle growth, maintenance, repair, and regeneration. Once muscle is injured, satellite cells become activated and increase the number of transcriptional factors necessary to form myoblasts and assist in repair.

Skeletal muscles are made up of millions of individual fibers that by the process of contraction and relaxation do the work necessary to complete movements as varied as a ballerina's pirouette or an artist's deft stroke (Figure 43-15). Muscle constitutes 40% of adults' body weight and 50% of children's body weight. Muscle is 75% water, 20% protein, and 5% organic and inorganic compounds; 32% of all protein stores for energy and metabolism is contained in muscle.

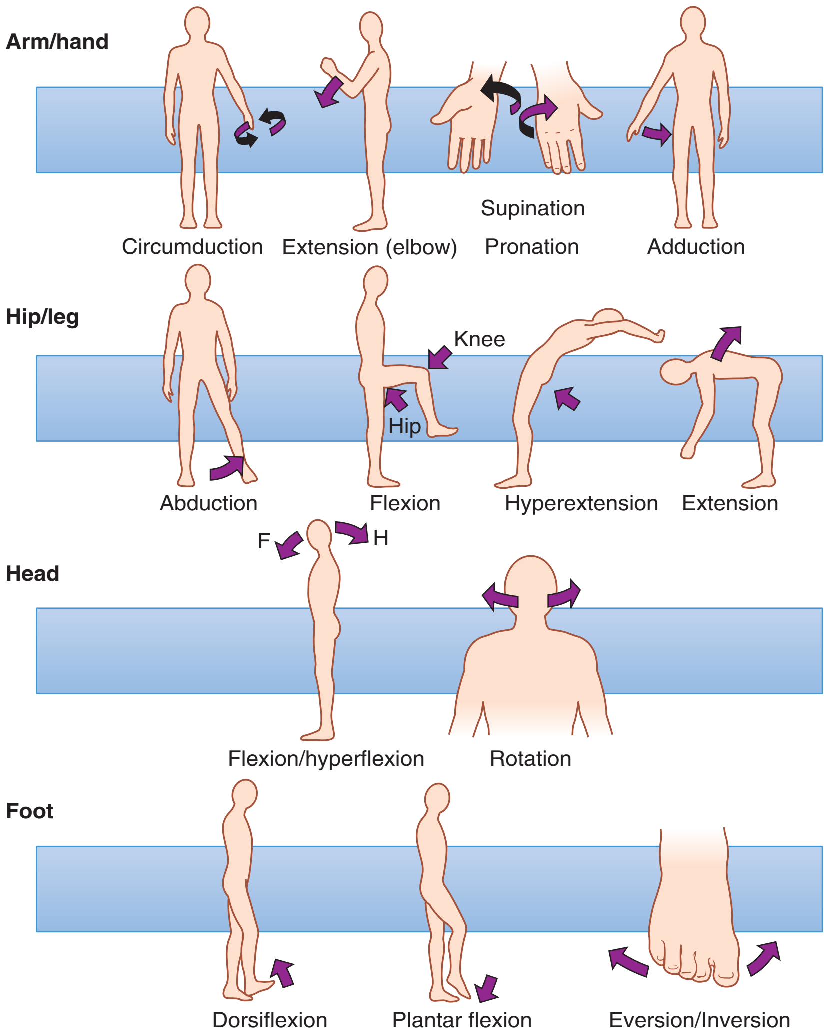

FIGURE 43-14 Body Movements Provided by Synovial (Diarthrodial) Joints.

Whole Muscle

There are more than 350 named muscles; almost all are paired. The body's muscles vary dramatically; they range from 2 to 60 cm in length and are shaped according to function.[24] **Fusiform muscles** are elongated muscles shaped like straps and can run from one joint to another. **Pennate muscles** are broad, flat, and slightly fan shaped, with fibers running obliquely to the muscle's long axis. The multipennate deltoid muscle, which flexes and extends the arm, is a good example of a muscle shaped according to its function.

Each skeletal muscle is a separate organ encased in a three-part connective tissue framework called **fascia.** The layers of connective tissue protect the muscle fibers, attach the muscle to bony prominences, and provide a structure for a network of nerve fibers, blood vessels, and lymphatic channels.

The outermost layer, the **epimysium,** is located on the surface of the muscle and tapers at each end to form the **tendon** (Figure 43-16). Tendons allow a short muscle to exert power on a distant joint, whereas a thick muscle interferes with joint mobility. The next layer, the **perimysium,** further subdivides the muscle fibers into bundles of connective tissue, or **fascicles.** The **endomysium** surrounds the muscle fascicles, the smallest unit of muscle fibers visible without a microscope. The ligaments, tendons, and fascia are made up of connective tissue that also serves to buffer the limbs from the effects of sudden strains or changes in speed. The rapid recovery necessary for strenuous exercise is supported by the elastic property of muscle and its connective tissue.

Skeletal muscle is described, almost interchangeably, as **voluntary, striated,** or **extrafusal.** "Voluntary" indicates that the muscle is controlled directly by the central nervous system. "Striated" describes the striated, or striped, pattern of skeletal muscle viewed under a light microscope. The striations result from the organization of the muscle fibers into the contractile units called *sarcomeres.* "Extrafusal" distinguishes the skeletal muscle fibers from other contractile fibers located within the sensory organs of the muscle.

Other components that are visible on gross inspection of the whole muscle include the motor and sensory nerve fibers. These function together with the muscle, innervating portions of it and providing the electrical impulses needed for motor function.

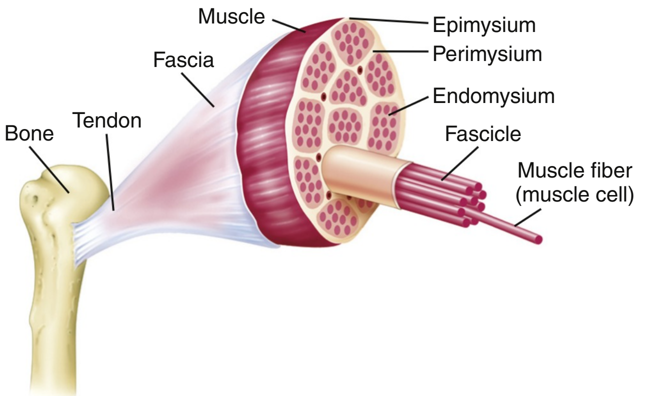

FIGURE 43-16 Cross Section of Skeletal Muscle Showing Muscle Fibers and Their Coverings. (From Thibodeau GA, Patton KT: *Anatomy & physiology,* ed 5, St Louis, 2003, Mosby.)

Motor Unit

From the anterior horn cell of the spinal cord, the axons of motor nerves branch out to innervate a specific group of muscle fibers. Each anterior horn cell, its axon (part of a lower motor neuron; see Chapter 15), and the muscle fibers innervated by it are called a **motor unit** (Figure 43-17). The motor units are composed of lower motor neurons, which extend to skeletal muscles. Often termed the *functional unit* of the neuromuscular system, the motor unit behaves as a single entity and contracts as a whole when it receives an electrical impulse.

The whole muscle may be controlled by several motor nerve axons. These branch to innervate many motor units within the muscle. The whole muscle then may consist of many motor units. The number of motor units per individual muscle varies greatly. In the calf, for example, 1 motor axon will innervate approximately 2000 muscle fibers, out of a total of 1,200,000 muscle fibers. This is a high innervation ratio of muscle fibers to axons, and it contrasts markedly with the low innervation ratio in the laryngeal muscles. There, two or three muscle fibers constitute each motor unit, and the innervation ratio can be of great functional significance. The greater the innervation ratio of a particular organ, the greater its endurance. Higher innervation ratios prevent fatigue, and lower innervation ratios allow for precision of movement.

Sensory Receptors. Although muscles function as effector organs, they also contain sensory receptors and are involved in sending different signals to the central nervous system. Among these are the muscle spindles and Golgi tendon organs. **Spindles** are mechanoreceptors that lie parallel to muscle fibers and respond to muscle stretching. **Golgi tendon organs** are dendrites that terminate and branch to tendons near the neuromuscular junction. Motor and sensory neurons secrete a proteoglycan called *neuroregulin (NRG)* that increases the

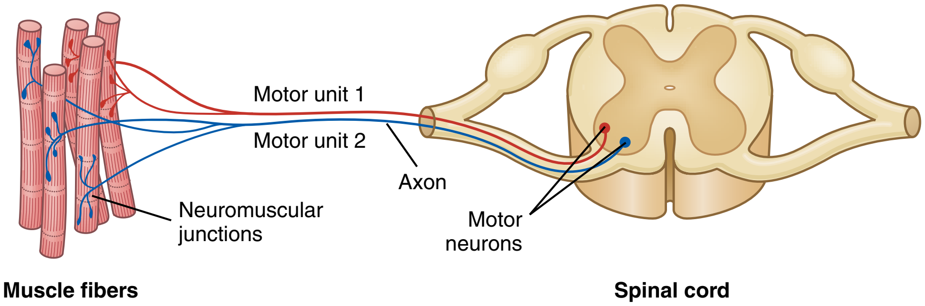

FIGURE 43-17 **Motor Units of a Muscle.** Each motor unit consists of a somatic motor neuron and all the muscle fibers (cells) supplied by the neuron and its axon branches.

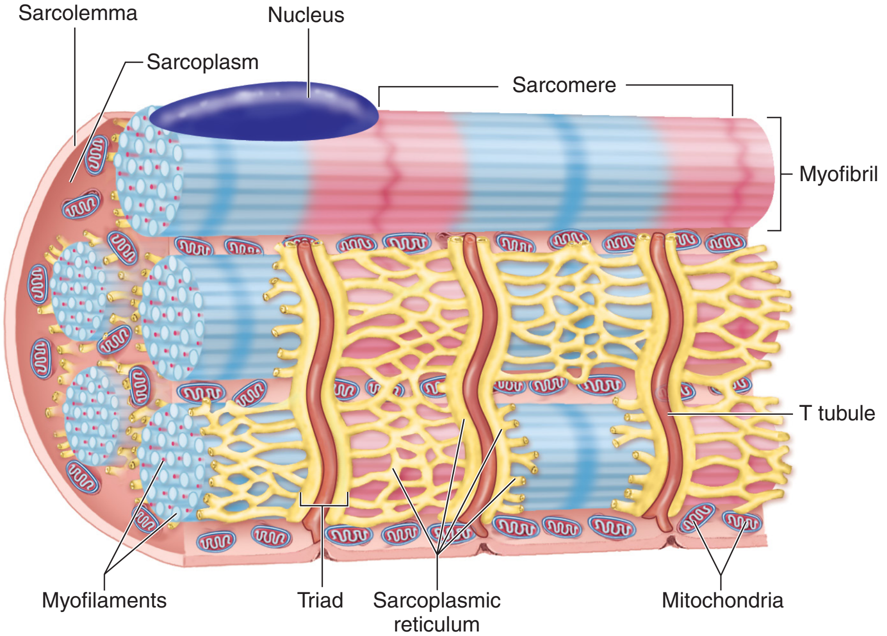

FIGURE 43-18 **Myofibrils of a Skeletal Muscle Fiber (Cell) and Overall Organization of Skeletal Muscle.** (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

number of acetylcholine receptors and helps in the formation of muscle spindle fibers. Muscle spindles, Golgi tendon organs, and free nerve endings provide a means of reporting changes in length, tension, velocity, and tone in the muscle. This system of afferent signals is responsible for the muscle stretch response and maintenance of normal muscle tone.

Muscle Fibers. Each **muscle fiber** is a single **muscle cell.** This long cell is cylindrical and surrounded by a membrane capable of excitation and impulse propagation. The muscle fiber contains bundles of **myofibrils,** the fiber's functional subunits, in a parallel arrangement along the longitudinal axis of the muscle (Figure 43-18). At birth the muscle fibers have completed development from precursor cells called **myoblasts.** All voluntary muscles are derived from the mesodermal layer of the embryo.

The type of peripheral nerve influences the muscle fiber and motor unit considerably. Whether motor nerves are fast or slow determines the type of muscle fibers in the motor unit. Type II fibers, also called *white fast-motor fibers,* are innervated by relatively large type II alpha motor neurons with fast conduction velocities. These fibers rely on a short-term anaerobic glycolytic system for rapid energy transfer, whereas type I fibers depend on aerobic oxidative metabolism. Histochemical stains are now routinely used to describe the structure of muscle fibers and contractile elements of muscle biopsy specimens. White muscle **(type II fibers)** stains dark in the enzyme stain adenosinetriphosphatase (ATPase) at a pH of 9.4. Red muscle **(type I fibers)** appears lightly stained.

The overlap of muscle fibers that appear with staining gives the checkerboard appearance of muscle biopsy specimens and provides an equal distribution of fiber types throughout the muscle. This overlap also helps compensate for muscle fiber loss and fatigue of individual motor units during activity. In spite of this, some muscles contain proportionally more of one fiber type than another. The postural muscles have more type I fibers, allowing them the high resistance to fatigue that is necessary to maintain the same position for extended periods. Ocular muscles have more type II muscle fibers, allowing them to respond rapidly to visual changes. (Table 43-7 describes the specific characteristics of type I and type II fibers.)

The number of muscle fibers varies according to location. Large muscles, such as the gastrocnemius, have more fibers (1,200,000) than smaller muscles, such as the lumbrical muscles in the hand (10,000). The diameter of muscle fibers also varies. The closely

TABLE 43-7 **CHARACTERISTICS OF MUSCLE FIBERS**

CHARACTERISTIC	TYPE I (RED)	TYPE II (WHITE)
Anatomic location	Deep axial portion of surface muscle	Surface portion of surface muscle
Contraction speed	Slow	Fast
Motor neuron type	Type I, small alpha	Type II, large alpha
Firing frequency	Low, long duration	Rapid, short duration
Resistance to fatigue	High	Low
Myoglobin	High	Low
Capillary supply	Profuse	Intermediate to sparse
Metabolism	Oxidative	Glycolysis
Mitochondria	Many	Few
Enzymes	Lactate dehydrogenase, types 1 to 3	Lactate dehydrogenase, types 4 and 5
Creatine kinase	Cardiac type	Fast, skeletal
Example (most muscles are mixed)	Greater proportion of slow-contracting fibers in soleus	Greater proportion of fast-contracting fibers in laryngeal and ocular muscles
Glycogen content	Low	High
Intensity of contraction	Low	High
Aerobic metabolic capacity	High	Low
Fiber diameter	Small	Large
Myosin-adenosinetriphosphatase (ATPase) activity	Low	High

packed polygons are small (10 to 20 μm) until puberty, when they attain the normal adult diameter of 40 to 80 μm. Women usually have smaller-diameter fibers than men. Small muscles, such as the ocular muscles, are 15 μm in diameter; larger, more proximal muscles are 40 μm in diameter. Both fiber size and muscle length have functional significance. Studies have shown that larger fiber diameter is associated with generation of greater forces. Fiber diameter can be increased by activities that cause hypertrophied muscle, such as exercise or occupational overuse.

The major components of the muscle fiber include the muscle membrane, myofibrils, sarcotubular system, sarcoplasm, and mitochondria (see Figure 43-18). The **muscle membrane** is a two-part membrane. It includes the **sarcolemma,** which contains the plasma membrane of the muscle cell, and the cell's **basement membrane.** The sarcolemma is 7.5 μm thick and is capable of propagating electrical impulses to initiate contraction. At the motor nerve end plate, where the nerve impulse is transmitted, the sarcolemma forms the highly convoluted synaptic cleft. The sarcolemma is comprised of lipid molecules and protein systems. The protein systems perform special functions, such as transport of nutrients and protein synthesis. They also provide the sodium-potassium pump and include the cell's cholinergic receptor. The basement membrane is 50 μm thick and is composed primarily of proteins and polysaccharides. It serves as the cell's microskeleton and maintains the shape of the muscle cell. The basement membrane also may function in some way to restrict further diffusion of electrolytes once they have crossed the sarcolemma.

The **sarcoplasm** is the cytoplasm of the muscle cell and contains the intracellular components that are common to all cells (see Chapter 1). The sarcoplasm is an aqueous substance that provides a matrix that surrounds the myofibrils. It contains numerous enzymes and proteins that are responsible for the cell's energy production, protein synthesis, and oxygen storage. The mitochondria house enzyme systems for energy production, particularly those that regulate such processes as the citric acid cycle and adenosine triphosphate (ATP) formation. Many other structures are present in the sarcoplasm. The ribosomes are composed primarily of ribonucleic acid (RNA) and participate in the process of protein synthesis. The cell nucleus, satellite cells, glycogen granules, and lipid droplets are suspended in the sarcoplasmic matrix. Blood vessels, nerve endings, muscle spindles, and Golgi tendon organs are also directly located within this structure.

Unique to the muscle is the **sarcotubular system,** a network that includes the transverse tubules and the sarcoplasmic reticulum, which crosses the interior of the cell. The **sarcoplasmic reticulum** is made in the same manner as the endoplasmic reticulum in other cells. In the muscle cells the sarcoplasmic reticulum is involved in calcium transport, which initiates muscle contraction at the **sarcomere,** a portion of the myofibril. The sarcoplasmic reticulum is composed of tubules that run parallel to the myofibrils. The longitudinal tubules are termed **sarcotubules.** The **transverse tubules,** which are closely associated with the sarcotubules, run across the sarcoplasm and communicate with the extracellular space. Together, the tubules of this membrane system allow for intracellular calcium uptake, regulation, and release during muscle contraction, and for the storage of calcium during muscle relaxation.

Myofibrils. Myofibrils, the most abundant subcellular muscle components, are the functional units of muscle contraction. Each myofibril contains sarcomeres, which, in turn, consist of repeating protein filaments[25] (see Figure 43-18). Sarcomeres are chiefly composed of the proteins **actin, myosin, titin,** and **nebulin.** The sarcomere is responsible for converting chemical energy into movement.

On cross section they are irregular polygons with a mean diameter of less than 1 μm. Each myofibril is composed of serially repeating sarcomeres, separated by Z lines that give the muscle its striped, cross-striated appearance. Each sarcomere has a dark A band and is flanked by two light I bands (Figure 43-19). Titin functions as a molecular spring that plays a

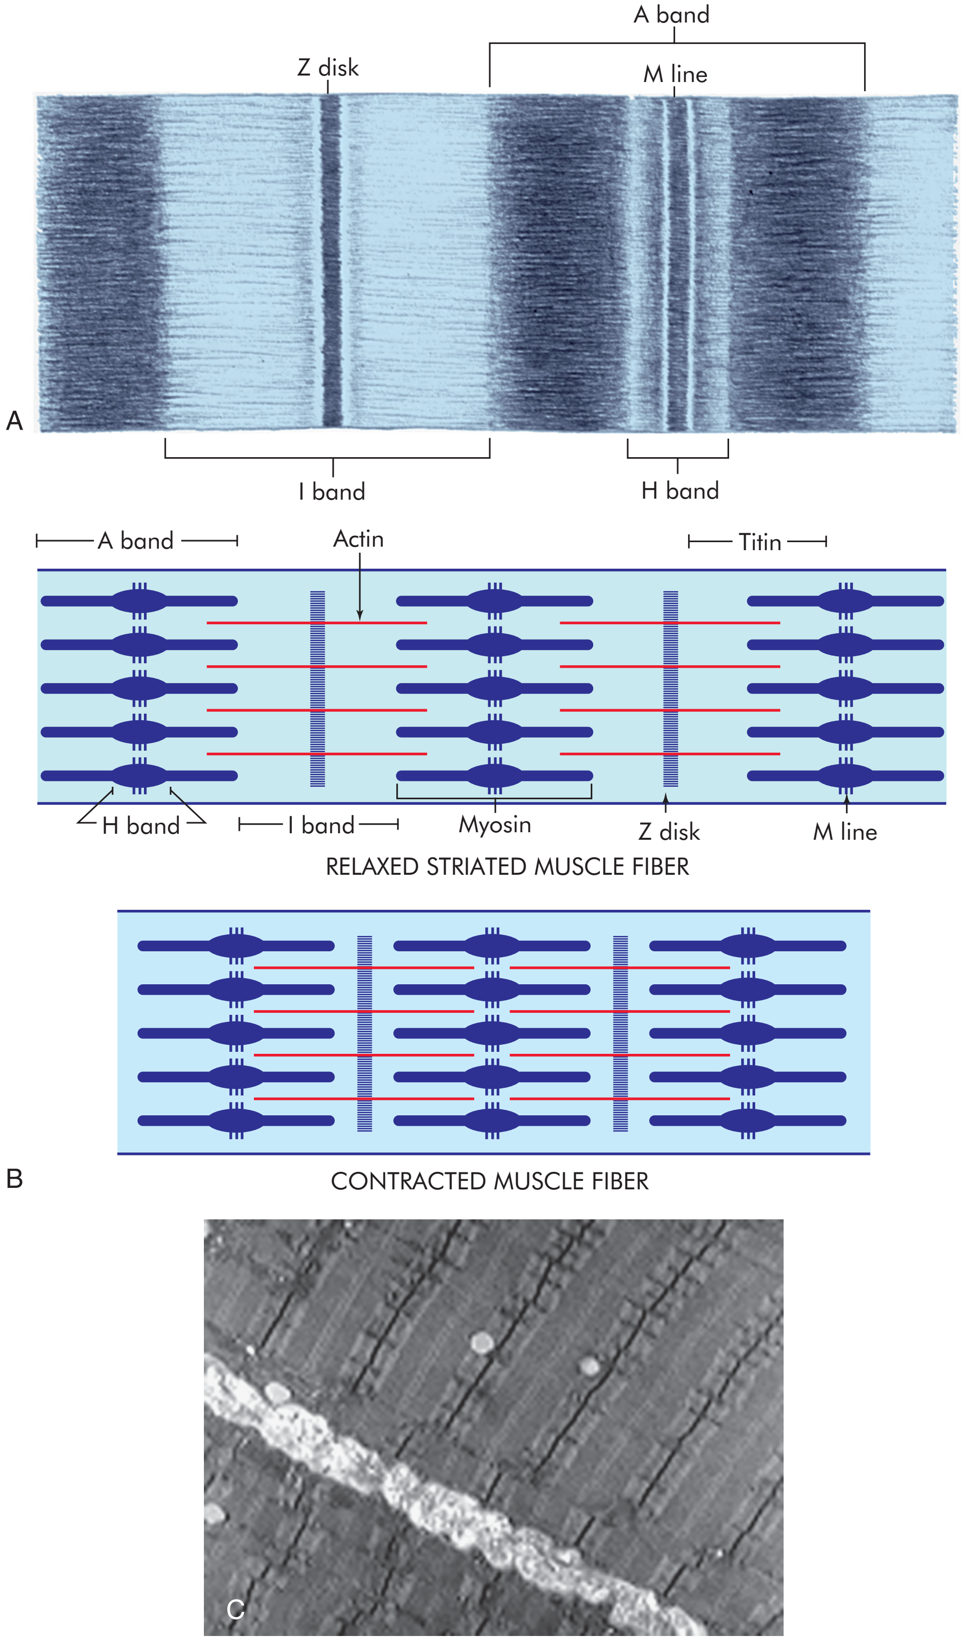

FIGURE 43-19 **Muscle Fibers. A,** The Z disks define the end of an individual sarcomere. The M line (which lies within the H band) is made of cross-connecting elements of the cytoskeleton. **B,** Actin is the primary protein of the I band (thin filament). Nebulin (not shown) also extends along the I band and contains binding sites for actin and myosin. Myosin (thick filament) extends through the A band. Titin extends from the Z disk to the M line, binding with myosin; strong titin anchoring within the I band is necessary for proper muscle function. During contraction, the I bands and H bands shorten, moving the Z disks closer together. **C,** Electron photomicrograph of human muscle tissue corresponding to schematics in **A** and **B.** (**A** modified from Thompson JM et al: *Mosby's clinical nursing,* ed 5, St Louis, 2002, Mosby; **C** courtesy Louisa Howard.)

TABLE 43-8 CONTRACTILE PROTEINS OF SKELETAL MUSCLE FIBRILS

NAME	APPROXIMATE PERCENTAGE OF MYOFIBRILLAR PROTEIN	LOCATION	FUNCTION
Myosin	55	A band (thick filament)	Contraction; hydrolyzes ATP and develops tension
Actin	20	I band (thin filament)	Contraction; activates myosin ATPase and interacts with myosin
Troponin	7	Thin filament	Regulatory protein; in presence of Ca^{++}, promotes actin-myosin activation
Tropomyosin	5-7	Thin filament	Regulatory and structural function; links filaments, controls filament length
Alpha (α) actin	10	Z band	Regulatory and structural function; links filaments, controls filament length
Beta (β) actin	2	Z band	Regulatory and structural function; links filaments, controls filament length
M protein	2	M line (center of thick filaments)	Regulatory and structural function; provides enzyme creatine kinase
C protein	2	A band (thick filaments)	Possible structural role
Titin	Unknown	Z line (thick filament)	Interconnects thin filaments in Z line
Creatine kinase	Unknown	M line	Catalyzes the phosphorylation of ADP to form ATP
Desmin	Unknown	Z line	Interconnects thin filaments in Z line
Filamin*	Unknown	Z line	Interconnects thin filaments in Z line; stabilizes membrane
Nebulin*	Unknown	Z line	Determines filament length

significant role in determining muscle stiffness and elasticity.[26] The A band is 1.5 to 1.6 μm long and contains thick myosin filaments. Included in the A band is a lighter zone called the H band, and in the center of the H band is the dark M band, or M line. The I band, which contains actin, is divided at the midpoint of each sarcomere by the Z line. Its length varies with the start of muscle contraction.

Myofibrils are composed of myofilaments. Each myofilament is structured in a closely packed hexagonal arrangement, with two thin filaments for every thick filament. The thick filament, along with C protein and M line protein, is made up of myosin. Myosin has two subunits, heavy and light meromyosin, which resemble twisted golf club shafts. The thin filaments are twisted double strands made up of actin, troponin, and tropomyosin (see Chapter 31 and Figure 31-15).

Muscle Proteins. Table 43-8 summarizes muscle protein distribution, location, and possible functional significance. The contractile and regulatory functions of actin, myosin, and the troponin-tropomyosin complex (associated with actin) are the most commonly known. They also account for most of the protein found in the myofibril. The structural and regulatory processes of muscle proteins are less well understood. Alpha actin and beta actin are known to link the filaments. M protein contains the enzyme creatine kinase (CK). Creatine is released when muscle cells are damaged, making serum creatine value an important measurement of pathologic conditions of muscles.

The most abundant proteins, actin and myosin, are also found in other cells, particularly motile cells such as platelets. The complete amino acid sequences of actin and myosin have been identified. Noteworthy is the presence of the amino acid 3-methylhistidine, found only in the thin filament, actin; 85% to 90% of 3-methylhistidine is found in skeletal muscle. The amino acids lysine and histidine, in addition to leucine, have been used to study protein synthesis by means of stable isotope infusion and muscle biopsy analysis.

Nonprotein Constituents of Muscle. Nitrogen, creatine, creatinine, phosphocreatine, purines, uric acid, and amino acids serve in the complex process of muscle metabolism. Phosphocreatine concentration is an extremely sensitive indicator of muscle fiber activity.[27] Glycogen and its derivatives are present as energy sources.

Creatine and creatinine metabolism have been used to measure muscle mass. Plasma creatine is taken up by muscle and converted into the high-energy phosphate compound *phosphocreatine* by the enzyme **creatine kinase.** Creatinine is formed in muscle from creatine at a constant rate of 2% per day. (Tests for plasma creatine are discussed in Chapter 37.) Creatine excretion is increased in muscle wasting. This change reflects the reduction in total body creatine stores and loss of muscle mass.

Inorganic compounds, anions (phosphate, chloride), and cations (calcium, magnesium, sodium, potassium) are important in regulating protein synthesis, muscle contraction, enzyme systems, and membrane stabilization. Intracellular calcium levels influence the force and duration of muscle contraction. Total body potassium (TBK), measured by the K_{40} method, has been used to measure muscle mass, also called *lean body mass.* TBK levels reflect changes in muscle mass seen during growth, malnutrition, and muscle wasting.

TABLE 43-9 **ENERGY SOURCES FOR MUSCULAR ACTIVITY**

SOURCES	REACTIONS
Short-term (anaerobic) sources	Adenosine triphosphate (ATP) → Adenosine diphosphate (ADP) + Inorganic phosphate (Pi) + Energy
	Phosphocreatine + ADP ⇌ Creatine + ATP
	Glycogen/glucose + Pi + ADP → Lactate + ATP
Long-term (aerobic) sources	Glycogen/glucose + ADP + Pi + O_2 → H_2O + CO_2 + ATP
	Free fatty acids + ADP + Pi + O_2 → H_2O + CO_2 + ATP
	Creatine kinase catalyzes the reversible reaction of ATP to ADP: Creatine phosphate + ADP $\xrightleftharpoons{\text{Creatine kinase}}$ Creatine + ATP

From Spence AP, Mason EE: *Human anatomy and physiology,* ed 4, St Paul, MN, 1992, West Publishing.

Components of Muscle Function

The ultimate function of muscle is to accomplish work. Although variously expressed in such measures as foot-pounds or kilogram-meters, work usually refers to the amount of energy liberated or force exerted over a distance (work = force × distance). Muscles usually contract or tense while doing work. Muscle contraction occurs on the molecular level and leads to the observable phenomenon of muscle movement.

Muscle Contraction at the Molecular Level

Muscle contraction is a four-step process: excitation, coupling, contraction, and relaxation. The initial contraction process is the excitation-contraction coupling (ECC) series, which involves the electrical properties of all cells and the movement of ions across the plasma membrane (see Chapter 1). At rest an electrical charge of −90 mV is continually maintained across the muscle sarcolemma. This resting potential, generated by the separation of positive and negative charges on either side of the membrane, creates an electrochemical equilibrium caused by the selective permeability of the sarcolemma to electrolytes in the intracellular and extracellular fluids, particularly potassium and sodium.

Specific intracellular receptors within skeletal muscle sarcoplasmic reticulum, called **ryanodine receptors (RyRs),** are the primary ion channels that control calcium release. RyRs are the largest known ion channels, allowing for rapid movement of calcium. Three RyRs have been identified: RyR1 is predominantly found in skeletal muscle; RyR2 is found mostly in cardiac muscle; and RyR3 is in the diaphragm, smooth muscle, and brain.[28-30]

Excitation, the first step of muscle contraction, begins with the spread of an action potential from the nerve terminal to the neuromuscular junction. The rapid depolarization of the membrane initiates an electrical impulse in the muscle fiber membrane called the **muscle fiber action potential.** As the action potential advances along the sarcolemmal membrane, it spreads to the transverse tubules (T-tubules). (The velocity of conduction is much slower in muscle fibers than in myelinated nerve fibers—only 3 to 5 m/second compared with 54 to 90 m/second in nerve fibers.)

The generated action potential then triggers voltage-sensitive receptors in the T-tubule wall; in turn, these receptors open the RyR channels, causing release of calcium from the sarcoplasmic reticulum.[28]

Following depolarization of the T-tubules, the second stage, **coupling,** occurs. This stage consists of the migration of calcium ions to the myofilaments. Calcium affects troponin and tropomyosin, muscle proteins that bind with actin when the muscle is at rest. In the presence of calcium, however, both of these proteins are attracted to calcium ions, leaving the actin free to bind with myosin.

Contraction begins as the calcium ions combine with troponin, a reaction that overcomes the inhibitory function of the troponin-tropomyosin system. The thin filament *actin* then slides toward the thick filament *myosin*. The two ends of the myofibril shorten after contraction when the myosin heads attach to the actin molecules, forming a cross-bridge that constitutes an actin-myosin complex. ATP, located on the actin-myosin complex, is released when the cross-bridges attach. This is the **sliding filament theory** and was first described by A.F. Huxley in the 1950s; however, it is now called the **cross-bridge theory** because of the formation of the actin-myosin cross-bridges. The process is so named because the actin actually slides onto the myosin, causing the sarcomere to shorten. The useful distance of contraction of a skeletal muscle is approximately 25% to 35% of the muscle's length. When actin and myosin filaments have maximum interactions, the muscle generates maximum force.[24]

The last step, **relaxation,** begins as the sarcoplasmic reticulum absorbs the calcium molecules, removing them from interaction with troponin. Calcium is pumped back into the sarcoplasmic reticulum by means of an active transport process. The cross-bridges detach, and the sarcomere lengthens. (The cross-bridge theory of muscle contraction is discussed in Chapter 31.)

Muscle Metabolism

Skeletal muscle requires a constant supply of ATP and phosphocreatine. These substances are necessary to fuel the complex processes of muscle contraction, driving the cross-bridges of actin and myosin together and transporting calcium from the sarcoplasmic reticulum to the myofibril. Other internal processes of the muscular system that require ATP include protein synthesis, which replenishes muscle constituents and accommodates growth and repair. The rate of protein synthesis is related to hormone levels (particularly insulin), amino acid substrates, and overall nutritional status. At rest the rate of ATP formation by oxidation of glucose or acetoacetate is sufficient to maintain internal processes, given normal nutritional status. During activity the need for ATP increases 100-fold. The metabolic pathways for muscle activity in Table 43-9 show reactions to the immediate need for increased ATP caused by contraction. Activity lasting longer than 5 seconds expends the available stored ATP and phosphocreatine.

Stored glycogen and blood glucose are converted anaerobically to sustain brief activity without increasing the demand for oxygen. Anaerobic glycolysis is much less efficient than aerobic glycolysis, using six to eight times more glycogen to produce the same amount of ATP. With increased activity, such as intense exercise, or ischemia, an increase in the level of lactic acid occurs because of the breakdown of glycogen, thus causing a shift in muscle pH (see Table 43-9). This short-term mechanism "buys time" by allowing ATP formation in spite of inadequate energy stores or oxygen supply. When the anaerobic threshold is reached and more oxygen is required, physiologic changes occur, including an increase in lactic acid concentration and increases in oxygen consumption, heart rate, respiratory rate, and muscle blood flow.

Strenuous exercise requires oxygen, which activates the aerobic glycogen pathway for ATP formation. During maximal exercise, free fatty acid mobilization and the aerobic glycogen pathways provide ATP over an extended time. These pathways require oxygen to maintain maximal activity and return the muscle to the resting state. Maximal exercise increases oxygen uptake 15 to 30 times over the resting state.[31] When this system becomes exhausted or unable to respond to the need for ATP, fatigue and weakness finally force the muscle to reduce activity, with a resultant buildup of lactic acid in muscle fibers.

The ability to sustain maximal muscular activity leads to the accumulation of oxygen debt. **Oxygen debt** is the amount of oxygen needed to convert the buildup of lactic acid to glucose and replenish ATP and phosphocreatine stores. For example, after running at maximal speed for 10 seconds, the average person has consumed 1 L of oxygen. At rest, oxygen consumption for the same period is approximately 40 ml. As the person recovers, the measured oxygen debt is 4 L greater than the amount used during activity.

Oxygen consumption is measured to calculate the metabolic cost of activity in normal and diseased muscle. It is an indirect measure of energy expenditure, along with timed tests of activity, heart rate, and respiratory quotient (ratio of carbon dioxide to expired oxygen consumed). Energy expenditure is measured directly by heat production because heat is released whenever work is accomplished.

Another factor that changes energy requirements is muscle fiber type. Type II fibers rely on anaerobic glycolytic metabolism and fatigue readily. Type I fibers can resist fatigue for longer periods because of their capacity for oxidative metabolism.

Muscle Mechanics

Muscle contraction cannot be viewed in isolation. Several factors determine how force is transmitted from the cross-bridges on individual muscle fibers to accomplish whole-muscle contraction. First, when a motor unit responds to a single nerve stimulus, it develops a phasic contraction, also called *twitch.* Because the motor unit contracts in an "all or nothing" manner, the contraction that is generated will be a maximal contraction. The central nervous system smoothly grades the force generated by "recruiting" additional motor units and varying the discharge frequency of each active motor unit. This adding of motor units within the muscle is called **repetitive discharge.**

Recruitment and repetitive discharge of motor units allow the muscle to activate the number of motor units needed to generate the desired force. The total force developed is the sum of the force generated by each motor unit. As the strength, speed, and duration of stimuli increase, the summation of contractions reaches a critical frequency called **tetanus.** When tetanus is reached, no further increase in force can be achieved.

Other variables, such as fiber type, innervation ratio, muscle temperature, and muscle shape, influence the efficiency of muscular contraction. The two muscle fiber types differ in their responses to electrical activity. Tetanus and duration of phasic contractions, which take microseconds to accomplish, are achieved more rapidly in type II than in type I muscle fibers. Low-innervation ratios promote control and coordination, whereas high ratios promote strength and endurance. Muscles work best at normal body temperature, 37° C (98.6° F). Finally, muscles with a large cross-sectional area, such as the fan-shaped pennate muscles, develop greater contractile forces than smaller-diameter muscles. The initial length of a muscle and the range of shortening that occur when the muscle contracts also determine the forces it can generate. The long fusiform muscles have a greater range of shortening and can contract up to 57% of their resting length. A certain amount of elongation is necessary to generate sufficient tension and muscular force. The elongation that occurs during the swing of a golf club or tennis racquet is an example of how stretch improves contractile force.

Types of Muscle Contraction

During **isometric contraction (static or holding contraction),** the muscle maintains constant length as tension is increased. Isometric contraction occurs, for example, when the arm or leg is pushed against an immovable object. The muscle contracts, but the limb does not move.

During **isotonic contraction (lengthening or shortening contraction),** the muscle maintains a constant tension as it moves. The terms "eccentric" for lengthening and "concentric" for shortening are technically inaccurate descriptions of muscle movement; the respective terms "lengthening" and "shortening" are more precise. Positive work is accomplished during shortening, and energy is released to exert force or lift a weight. In contrast, during lengthening the muscle lengthens and absorbs energy. Negative work is accomplished on the muscle by the load. Lengthening requires less energy to accomplish and may result in the development of pain and stiffness after unaccustomed exercise.

Movement of Muscle Groups

Muscles do not act alone but rather in groups, often under automatic control. When a muscle contracts it acts as a "prime mover," or **agonist,** and its reciprocal muscle, or **antagonist,** relaxes. This is easily tested by holding the right arm in the horizontal position in front of the body and then bending the elbow while feeling the upper arm, biceps in the front and the triceps in the back, with the other hand. The biceps is firm, and the triceps is soft. As the arm is extended, the muscles change. When the elbow is completely extended, the biceps is soft and the triceps firm. Completing this movement causes the agonist and antagonist to change

automatically; only the movement is commanded, not the alternate contraction and relaxation of the specific muscle groups.

Other associated actions may be seen during walking; as the foot leaves the ground, the paravertebral and gluteal muscles on the opposite sides of the body contract to maintain balance. One notices the loss of the associated muscle's action when paralysis offsets this process and decreases balance. If a person is paralyzed, difficulty in maintaining balance is noticeable.

TESTS OF MUSCULOSKELETAL FUNCTION

Tests of Bone Function

Diagnostic procedures to evaluate bone function include gait analysis, measurement of serum calcium and phosphorus levels, and imaging studies. Most imaging techniques provide morphologic rather than functional information about bone. Plain radiographs (x-rays) remain the standard initial imaging tool for bone evaluation because bone absorbs x-ray beams better than soft tissue. Computed tomography (CT) provides multiple images that are then processed into single (2-dimensional) or multiple images taken around a single axis to form (3-dimensional) pictures. Dual-energy computed tomography (DECT) utilizes x-ray beams at two different energy levels to determine different chemical composition of tissues, thereby expanding CT imaging to include soft tissues, bone marrow, and crystals.[32] Advances in CT technology allow for detailed visualization of bone microstructure.[33]

Magnetic resonance imaging (MRI) provides detailed anatomic information and is useful for evaluating primary or metastatic bone lesions, infection, marrow edema, bony erosions, osteonecrosis, fractures, and other pathologic changes of bone. Magnetic resonance arthrography (MRa) involves injection of a contrast agent into the area of interest but allows better visualization of small abnormalities. Detailed functional imaging of bone can be attained with positron emission tomography (PET) scanning. A relatively new technology, MRI-PET combines MRI with functional imaging of molecular events seen with PET.

Nuclear medicine studies also provide imaging about metabolic activity in bone and soft tissue. After a small amount of radioactive tracer is injected, a special camera is used to identify bone absorption of the tracer. Bone scanning is very sensitive, but not specific about the cause of increased metabolic activity.

Dual-photon absorptiometry (DXA) is often used to measure the density of bones in the extremities and the fracture risk of vertebral bodies, femoral neck, and distal radius (DXA). Dual-photon absorptiometry allows the soft tissue components to be subtracted. New technology promises more accurate evaluation of bone.

Serum bone-specific alkaline phosphatase (BAP) is a marker of bone formation. Bone resorption is evaluated with urinary and serum measurements of cross-linked N-terminal telopeptides (NTx), a product of osteoclast bone resorption. NTx is specific for bone because the cross-links assessed are characteristic of bone collagen alone. Urine NTx is a more sensitive and specific biochemical marker of bone resorption than serum NTx.[34,35]

Tests of Joint Function

Procedures used to diagnose joint function include arthrography, arthroscopy, magnetic resonance imaging, and synovial fluid analysis. **Arthrography** (the injection of dye into the joint) is particularly useful to diagnose tears in the fibrocartilage of the knee (meniscus) and the rotator cuff of the shoulder. **Arthroscopy** is the direct visualization of a joint through an arthroscope. **Magnetic resonance imaging (MRI)** produces images of body tissues through the use of electromagnetic (radio) waves that alter the atoms (hydrogen ions) in the nuclei of cells being examined. When the polarized radiowaves are stopped, the nuclear atoms return to their original positions, emitting energy as signals as they move back. The signals produce visible images for examination and diagnosis. MRI produces excellent contrast of soft tissues for evaluation of musculoskeletal conditions. Magnetic resonance arthroscopy (MRa) is injection of contrast into a joint, followed by MRI evaluation.

Analysis of synovial fluid may reveal inflammatory, septic, and noninflammatory joint diseases, which cause characteristic changes in the color, clarity, viscosity, and cellular elements of the fluid. The presence of blood in the joint fluid (hemarthrosis) usually indicates joint trauma. Normal synovial fluid is sterile, so the presence of bacteria in the fluid always indicates disease. Cell fragments and fibrous tissue in the fluid are the result of inflammation or wear-and-tear on the articular surfaces.

Tests of Muscular Function

When the individual's history and physical examination disclose abnormalities, such as weakness, atrophy, muscle tenderness, cramps, and stiffness, specific tests of muscle function are in order. One of the most useful tests is the serum creatine kinase (CK) concentration. CK is found in large quantities in the muscle fibers, and when these are diseased or damaged, CK leaks into the serum. Myoglobin is also detectable in the urine after acute muscle damage caused by crush injury, ischemic disorders, extreme exertion, and some inherited diseases.

Because the muscle membrane tissue is excitable and carries an electrical charge, its capacity to function can be assessed by electromyography. Using sensitive needle electrodes, the **electromyogram (EMG)** records the summation of action potentials of the muscle fibers in each motor unit. The EMG is often compared with the electrocardiogram (ECG), but the activity recorded on the EMG is on a much smaller scale. The amplitude of the ECG is measured in volts, the duration of impulse is recorded in seconds, and both are recorded as the heart rate (e.g., 80 V/60 seconds). EMG amplitude is recorded in millivolts and the duration is measured in milliseconds, with a frequency of about 5 to 50 action potentials per second. Motor unit potentials are measured to determine rate of firing, duration, and amplitude. Abnormalities in EMG and nerve conduction velocities help differentiate muscle diseases (myopathy) from peripheral nerve (neuropathy) and neuromuscular junction disorders. The muscle biopsy (using histologic, histochemical, and electron microscopic studies) is used to further define the presence of myopathic and neuropathic disorders, many of which can be diagnosed only by muscle biopsy. Complex myography, a relatively new technique, allows a noninvasive way to gather information on the mechanical characteristics of muscle.

A new area of evaluation is genetics. Recent advances in molecular genetics, deoxyribonucleic acid (DNA) libraries, genetic probes, and gene localization techniques have enhanced our knowledge of neuromuscular diseases, including types of muscular dystrophy, Charcot-Marie-Tooth disease, and familial amyotrophic lateral sclerosis.

AGING AND THE MUSCULOSKELETAL SYSTEM

Aging of Bones

Aging is accompanied by the loss of bone tissue. Bones become less stiff, less strong, and more brittle with aging. The bone remodeling cycle takes longer to complete, and the rate of mineralization also decelerates. Studies have shown that an individual's bone mass at the end of their growth period helps determine the significance of bone loss as they age. With aging, women experience loss of bone density, accelerated by rapid bone loss during early menopause from increased osteoclastic bone resorption.[36] By age 70, susceptible women have lost an average of 50% of their peripheral cortical bone mass. Extensive loss of bone mass leads to deformity, pain, stiffness, and a high risk for fractures. Asymptomatic vertebral fractures can cause loss of height. Men also experience bone loss but at later ages and much slower rates than women. Also, peak bone mass in men is higher than that in women.[37] In general, age-related bone loss is caused by genetics, hormonal factors (decreased estrogen and estradiol levels), decreased bone formation, vitamin and mineral deficiencies (vitamin D, magnesium, and calcium), underlying conditions (malignancy, autoimmune diseases, hyperthyroidism), and lifestyle choices (physical inactivity, smoking, certain medications, and alcohol intake). Men's peak bone mass is related to race, heredity, hormonal factors (testosterone and estradiol levels), physical activity, and calcium intake during childhood.[38]

Bone mass can be gained in healthy young women up to the third decade through physical activity and intake of dietary calcium and magnesium. In addition to the positive effects of exercise on bone mineral density (BMD), exercise has been shown to improve balance, coordination, muscle strength, lean body mass, and mobility, all of which may decrease the incidence of falls[39,40] (also see Figure 2-22, p. 85).

Aging of Joints

With aging, cartilage becomes more rigid, fragile, and susceptible to fibrillation because of increasing cross-linking of collagen and elastin, decreasing water content in the cartilage ground substance, and decreasing concentrations of glycosaminoglycans. Changes in collagen result in cartilage calcification and muscle stiffness. Decreased range of motion of the joint is related to the changes in ligaments and muscles. Bones in joints develop evidence of osteoporosis with fewer trabeculae and thinner, less dense bones, making them prone to fractures. Intervertebral disk spaces decrease in height.

Aging of Muscles

The function of skeletal muscle depends on many factors that are affected by aging, including the nervous, vascular, and endocrine systems. Mitochondrial dysfunction within cells contributes to oxidative stress and results in increased bone resorption and apoptosis of muscle cells.[41,42] In the young child, development of muscle tissue is highly dependent on continuing neurodevelopmental maturation. Muscle function remains trainable even into advanced age. Muscle diseases have a definite association with specific age groups. Muscular dystrophies occur in children, and muscle disabilities related to rheumatic diseases usually occur in advancing age.

Age-related loss in skeletal muscle is referred to as **sarcopenia** and is a direct cause of the age-related decrease in muscle strength. As the body ages, muscle bulk and strength decline slowly, beginning as early as age 50, with loss of about 1% per year thereafter. Muscle strength declines faster than muscle mass.[42] Type II fibers decrease to a greater extent than the slower acting type I fibers. Loss of satellite cells appears to play a major role in the development of sarcopenia. Although muscle's regenerative function remains largely intact, satellite cell numbers are decreased.[43] The reduced RNA synthesis, loss of mitochondrial volume, shortening of telomeres, and reduction in the size of motor units contribute to sarcopenia. As much as 30% to 40% of skeletal muscle mass and strength may be lost from the third to ninth decades.

Maximal oxygen intake decreases with age. Reduced basal metabolic rate and decreased lean body mass are also seen in the older adult population.

SUMMARY REVIEW

Structure and Function of Bones

1. Bones provide support and protection for the body's tissues and organs and are important sources of minerals and blood cells.
2. Bone formation begins in utero with the differentiation of mesenchymal cells into either chondrocytes or osteoblasts. Bone minerals then either crystallize on a cartilage framework or become bone-forming cells without cartilage.
3. Bone tissue is continuously being resorbed and synthesized by bone-remodeling units of osteoclasts and osteoblasts.
4. RANKL induces osteoclast activation and bone resorption. OPG, a protein, binds to a protein called OPG ligand. This attachment serves as a decoy receptor for RANKL and blocks osteoclast activity, thus decreasing bone resorption. The balance between RANKL and OPG determines the quality of bone.
5. Bones in the body are made up of compact bone tissue and spongy bone tissue. Compact bone is highly organized into haversian systems that consist of concentric layers of crystallized matrix surrounding a central canal that contains

SUMMARY REVIEW—cont'd

blood vessels and nerves. Dispersed throughout the concentric layers of crystallized matrix are small spaces containing osteocytes. Smaller canals, called *canaliculi,* interconnect the osteocyte-containing spaces. The crystallized matrix in spongy bone is arranged in bars or plates. Spaces containing osteocytes are dispersed between the bars or plates and interconnected by canaliculi.

6. BMPs are part of the TGF-β superfamily and involved in nearly all aspects of bone formation.
7. There are 206 bones in the body, divided into the axial skeleton and the appendicular skeleton. Bones are classified by shape as long, short, flat, or irregular. Long bones have a broad end (epiphysis), broad neck (metaphysis), and narrow midportion (diaphysis) that contains the medullary cavity.
8. Bone injuries are repaired in stages. Hematoma formation provides the fibrin framework for formation and organization of granulation tissue. Granulation tissue provides a cartilage model for the formation and crystallization of bone matrix. Remodeling restores the original shape and size to the injured bone.

Structure and Function of Joints

1. A joint is the site of attachment of two or more bones. Joints provide stability and mobility to the skeleton.
2. Joints are classified as synarthroses, amphiarthroses, or diarthroses, depending on the degree of movement they allow. Joints also can be classified by the type of connecting tissue holding them together. Fibrous joints are connected by dense fibrous tissue, ligaments, or membranes. Cartilaginous joints are connected by fibrocartilage or hyaline cartilage. Synovial joints are connected by a fibrous joint capsule. Within the capsule is a small fluid-filled space. The fluid in the space nourishes the articular cartilage that covers the ends of the bones meeting in the synovial joint.
3. Articular cartilage is a highly organized system of collagen fibers and proteoglycans. The fibers firmly anchor the cartilage to the bone, and the proteoglycans control the loss of fluid from the cartilage.
4. Joints help move bones and muscle.

Structure and Function of Skeletal Muscles

1. Skeletal muscle is the largest organ in the body and is made up of millions of individual fibers.
2. Whole muscles vary in size (2 to 60 cm) and shape (fusiform and pennate). They are encased in a three-part connective tissue framework. The fundamental concept of muscle function is the *motor unit,* defined as all muscle fibers innervated by a single motor nerve.
3. Muscle fibers contain bundles of myofibrils arranged in parallel along the longitudinal axis and include the muscle membrane, myofibrils, sarcotubular system, aqueous sarcoplasm, and mitochondria. There are two types of muscle fibers, type I and type II, determined by motor nerve innervation.
4. Myofibrils and myofilaments contain the major muscle proteins actin and myosin, which interact to form cross-bridges during muscle contraction. The nonprotein muscle constituents provide an energy source for contraction and regulate protein synthesis, enzyme systems, and membrane stabilization.
5. Muscle contraction includes excitation, coupling, contraction, and relaxation.
6. Muscle strength is graded by the "all or nothing" phenomenon and recruitment. Speed of contraction is affected by several factors: muscle fiber type, temperature, stretch, and weight of the load.
7. The two types of muscle contraction are isometric and isotonic. Muscle shortening occurs during contraction but can be seen also during pathologic and physiologic contracture.
8. Actin and myosin filaments form cross-bridges that cause the sarcomere to shorten, a process now known as the *cross-bridge theory of muscle contraction.*
9. Skeletal muscle requires a constant supply of ATP and phosphocreatine to fuel muscle contraction and for growth and repair. ATP and phosphocreatine can be generated aerobically or anaerobically. Phosphocreatine concentration is an extremely sensitive indicator of muscle fiber activity.
10. Several factors determine how force is transmitted from the actin-myosin cross-bridges on individual muscle fibers to accomplish whole-muscle contraction. When a motor unit responds to a single nerve stimulus, it develops a phasic contraction. The central nervous system smoothly grades the force generated by "recruiting" additional motor units and varying the discharge frequency of each active motor unit.

Tests of Musculoskeletal Function

1. Various diagnostic procedures are used to evaluate bone function, including urinary markers, serum calcium and phosphorus levels, x-ray films, angiography, bone scanning, and MRI.
2. Procedures used to evaluate joint function include arthrography, arthroscopy, MRI, and synovial fluid analysis.
3. Genetic evaluation is useful in detecting, diagnosing, and developing specific treatment for certain inheritable muscle diseases such as muscular dystrophy.

Aging and the Musculoskeletal System

1. Muscle bulk and strength slowly decline with aging, although not to a pathologic degree. The bone remodeling cycle takes longer to complete, and the rate of mineralization slows.
2. Exercise in older adults improves muscle strength, helps increase bone mineral density, and improves balance, coordination, lean body mass, and mobility.
3. Age-related loss in skeletal muscle is referred to as sarcopenia. Loss of satellite cells appears to play a major role in the development of sarcopenia.

CHAPTER OUTLINE

Musculoskeletal injuries include fractures, dislocations, sprains, and strains. Alterations in bones, joints, and muscles may be caused by trauma, metabolic disorders, infections, inflammatory or noninflammatory diseases, or tumors. Trauma is the leading cause of death of people ages 1 to 44 years of all races and socioeconomic levels.

MUSCULOSKELETAL INJURIES

Skeletal muscles can withstand many penetrating injuries without permanent loss of function. For example, studies of soldiers with severe combat injuries showed that muscle function was preserved after the removal of large portions of muscle tissue. Successful regeneration of skeletal muscle fibers depends primarily on the extent of injury, the preservation of vascular supply (and source of nutrition), and the availability of satellite cells and terminal axons for reinnervation.

Skeletal Trauma

Fractures

A **fracture** is a break in the continuity of a bone. A break occurs when force is applied that exceeds the tensile or compressive strength of the bone. The highest incidence of fractures occurs in young males (between ages 15 and 24 years) and in adults 65 years of age and older, and varies for individual bones according to age, gender, and possibly race. In a study of more than 158,000 people, fractures were most prevalent among black males younger than age 65, whereas fractures in whites were highest in those age 65 and older.[1] Fractures of healthy bones, particularly the tibia, clavicle, and lower humerus, tend to occur in young persons and are often the result of trauma. Fractures of the hands and feet are usually caused by accidents in the workplace. The incidence of fractures of the upper femur, upper humerus, vertebrae, and pelvis is highest in older or older adults and is often associated with osteoporosis (see p. 1550). In

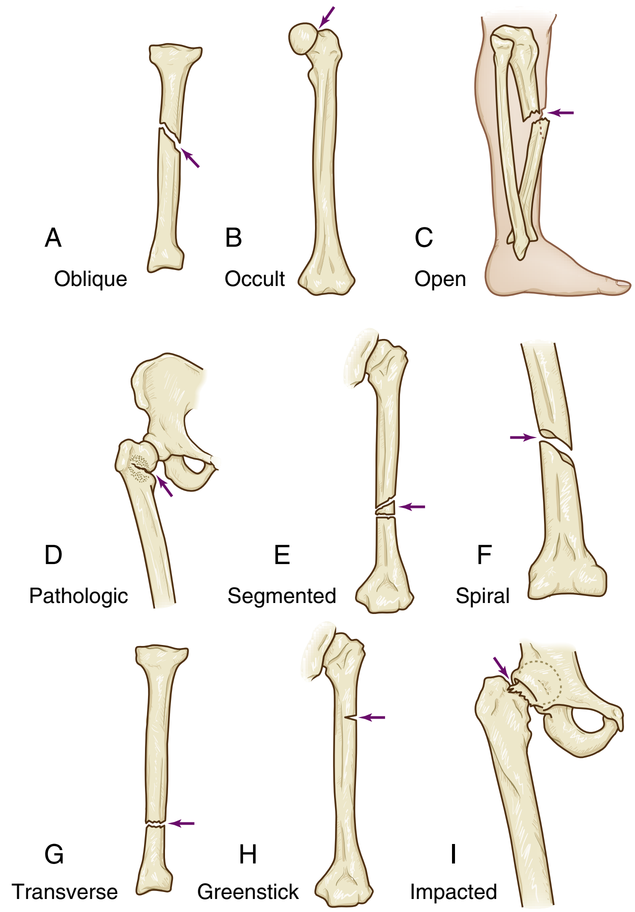

FIGURE 44-1 Examples of Types of Bone Fractures. **A,** *Oblique:* fracture at oblique angle across both cortices. *Cause:* direct or indirect energy, with angulation and some compression. **B,** *Occult:* fracture that is hidden or not readily discernible. *Cause:* minor force or energy. **C,** *Open:* skin broken over fracture; possible soft tissue trauma. *Cause:* moderate to severe energy that is continuous and exceeds tissue tolerances. **D,** *Pathologic:* transverse, oblique, or spiral fracture of bone weakened by tumor pressure or presence. *Cause:* minor energy or force, which may be direct or indirect. **E,** *Segmented:* fracture with two or more pieces or segments. *Cause:* direct or indirect moderate to severe force. **F,** *Spiral:* fracture that curves around cortices and may become displaced by twist. *Cause:* direct or indirect twisting energy or force with distal part held or unable to move. **G,** *Transverse:* horizontal break through bone. *Cause:* direct or indirect energy toward bone. **H,** *Greenstick:* break in only one cortex of bone. *Cause:* minor direct or indirect energy. **I,** *Impacted:* fracture with one end wedged into opposite end of inside fractured fragment. *Cause:* compressive axial energy or force directly to distal fragment. (Redrawn from Mourad L: Musculoskeletal system. In Thompson JM et al, editors: *Mosby's clinical nursing,* ed 7, St Louis, 2002, Mosby.)

1990, an estimated 1.66 million hip fractures occurred worldwide; that number is expected to increase to 6.3 million by the year 2050.[2]

Classification. Fractures can be classified as complete or incomplete and open or closed (Figure 44-1). In a **complete fracture** the bone is broken all the way through, whereas in an **incomplete fracture** the bone is damaged but still in one piece. Complete or incomplete fractures also can be classified as **open** (formerly referred to as *compound*) if the skin is broken or as **closed** (formerly called *simple*) if it is not. A fracture in which a bone breaks into more than two fragments is termed a **comminuted fracture.** Fractures are classified also according to the direction of the fracture line. A **linear fracture** runs parallel to the long axis of the bone. An **oblique fracture** is a slanted fracture of the shaft of the bone. A **spiral fracture** encircles the bone, and a **transverse fracture** occurs straight across the bone.

Incomplete fractures tend to occur in the more flexible, growing bones of children. The three main types of incomplete fractures are greenstick, buckle or torus, and bowing. A **greenstick fracture** perforates one cortex and splinters the spongy bone and is relatively unstable.[3] The name is derived from the damage sustained by a young tree branch (a green stick) when it is bent sharply. The outer surface is disrupted, but the inner surface remains intact. Greenstick fractures typically occur in the metaphysis or diaphysis of the tibia, radius, and ulna. In a buckle or **torus fracture,** the cortex buckles but does not break; this is a relatively stable fracture. **Bowing fractures** usually occur when longitudinal force is applied to bone. This type of fracture is common in children and usually involves the paired radius-ulna or fibula-tibia. A complete diaphyseal fracture occurs in one of the bones of the pair, which disperses the stress sufficiently to prevent a complete fracture of the second bone, which bows. A bowing fracture resists correction (reduction) because the force necessary to reduce it must be equal to the force that bowed it. Treatment of bowing fractures is difficult also because the bowed bone interferes with reduction of the fractured bone. A fracture that results from a low-level trauma (one that would not normally cause a fracture) is called a **fragility fracture,** which is often seen in osteoporosis. Types of fractures are summarized in Table 44-1.

Fractures may be further classified by cause as pathologic, stress, or transchondral. A **pathologic fracture** is a break at the site of a preexisting abnormality (such as a tumor), usually by force that would not fracture a normal bone. Any disease process that weakens a bone (especially the cortex) predisposes the bone to pathologic fracture, commonly associated with tumors, osteoporosis, infections, and metabolic bone disorders.

Stress fractures occur in normal or abnormal bone that is subjected to repeated forces, such as occurs during athletics. **Fatigue fractures** are caused by abnormal stress or torque applied to a bone with normal ability to deform and recover (e.g., joggers, dancers, military recruits) and are a type of stress fracture. **Insufficiency fractures** include fragility fractures of osteoporosis and osteomalacia, and occur in bones lacking normal ability to deform and recover (i.e., normal weightbearing or activity fractures the bone).

A **transchondral fracture** consists of fragmentation and separation of a portion of the articular cartilage that covers the end of a bone at a joint. (Joint structures are defined in Chapter 43.) The fragments may consist of cartilage alone or cartilage and bone. Typical sites of transchondral fracture are the distal femur, the ankle, the kneecap, the elbow, and the wrist. Transchondral fractures are most prevalent in adolescents.

PATHOPHYSIOLOGY. When a bone is broken the periosteum and blood vessels in the cortex, marrow, and surrounding soft tissues are disrupted. Bleeding occurs from the damaged ends of the bone and from the neighboring soft tissue. A clot (hematoma) forms within the medullary canal, between the

TABLE 44-1 TYPES OF FRACTURES

TYPE	DEFINITION
Typical Complete Fractures	
Closed fracture	The skin overlying the bone is intact
Open fracture	Communicating wound between bone and skin
Comminuted fracture	Multiple bone fragments
Linear fracture	Fracture line parallel to long axis of bone
Oblique fracture	Fracture line at an angle to long axis of bone
Spiral fracture	Fracture line encircling bone (as a spiral staircase)
Transverse fracture	Fracture line perpendicular to long axis of bone
Impacted	Fracture fragments are pushed into each other
Pathologic	Fracture occurs at a point in the bone weakened by disease (e.g., bones with tumors or osteoporosis)
Avulsion	A fragment of bone connected to a ligament or tendon breaks off from the main bone
Compression	Fracture is wedged or squeezed together on one side of bone
Displaced	Fracture with one, both, or all fragments out of normal alignment
Extracapsular	Fragment is close to the joint but remains outside the joint capsule
Intracapsular	Fragment extends into or is within the joint capsule
Fragility	Fracture caused by low-level trauma
Typical Incomplete Fractures	
Greenstick fracture	Break on one cortex of bone with splintering of inner bone surface (commonly occurs in children and older adults)
Torus fracture	Buckling of cortex
Bowing fracture	Bending of the bone
Stress fracture	Microfracture
Transchondral fracture	Separation of cartilaginous joint surface (articular cartilage) from main shaft of bone

fractured ends of the bone, and beneath the periosteum. Bone tissue immediately adjacent to the fracture dies. This necrotic tissue (along with any debris in the fracture area) stimulates an intense inflammatory response characterized by vasodilation, exudation of plasma and leukocytes, and infiltration by inflammatory leukocytes and mast cells. Cytokines, including transforming growth factor-beta (TGF-β), platelet-derived growth factor (PDGF), prostaglandins, and other factors that promote healing are released. Within 48 hours after the injury, vascular tissue invades the fracture area from surrounding soft tissue and the marrow cavity, and blood flow to the entire bone is increased. Bone-forming cells in the periosteum, endosteum, and marrow are activated to produce subperiosteal procallus along the outer surface of the shaft and over the broken ends of the bone (Figure 44-2). Healing generally occurs in three overlapping phases. The initial inflammatory phase of healing lasts 3 to 4 days. During the next few days, the repair phase begins and capillary ingrowth, together with mononuclear cells and fibroblasts, begins the transformation of a hematoma into granulation tissue. Osteoblasts within the procallus synthesize collagen and matrix, which becomes mineralized to form callus. As the repair process continues, remodeling occurs, during which unnecessary callus is resorbed and trabeculae are formed along lines of stress; at the end of this stage, bone can withstand normal stresses. The last phase, remodeling, lasts for months to years. Except for the liver, bone is unique among all body tissues in that after a fracture it will heal with normal, not scar, tissue.

CLINICAL MANIFESTATIONS. The clinical manifestations of a fracture vary according to the type of fracture, site of the fracture, and associated soft tissue injury. In general, the signs and symptoms of a fracture include impaired function, unnatural alignment (deformity), swelling, muscle spasm, tenderness, pain, and impaired sensation. The position of the bone segments is determined by the pull of attached muscles, gravity, and the direction and magnitude of the force that caused the fracture. One or both segments may be rotated inward or outward on the bone's long axis (rotation), be misaligned at an angle (angulation), slide over the other segment (overriding), or be out of normal position (displaced).

FIGURE 44-2 Exuberant Callus Formation Following Fracture. (From Rosai J: *Ackerman's surgical pathology*, ed 8, St Louis, 1996, Mosby.)

The immediate pain of a fracture is severe and usually caused by trauma. Subsequent pain may be produced by muscle spasm, overriding of the fracture segments, or damage to adjacent soft tissues. Numbness is common and is caused by swelling, pinching or severing of a nerve, trauma, or by bone fragments. Pathologic fractures can cause angular deformity, painless swelling, or generalized bone pain. Stress fractures are painful, not because of trauma, but because of accelerated remodeling. The pain occurs during activity and is usually relieved by rest. Stress fractures also cause local tenderness and soft tissue swelling. Transchondral fractures may be entirely asymptomatic or painful during movement. Range of motion in the joint is limited, and movement may evoke audible clicking sounds (crepitus).

EVALUATION AND TREATMENT. Treatment of a displaced fracture involves realigning the bone fragments (reduction) to their normal or anatomic position and holding the fragments in place (immobilization) so that bone union can occur. Several methods are available to reduce a fracture: closed manipulation, traction, and open reduction. Many fractures heal without manipulation—they require only adequate immobilization. A fracture that is malaligned, however, requires more aggressive treatment.

Many fractures can be reduced by closed manipulation: the skin is not opened, and the bone is moved or manipulated into place. Closed manipulation is used when the contour of the bone is in fair alignment and can be maintained well with immobilization.

Traction is used to accomplish or maintain reduction. When bone fragments are displaced (not in their anatomic position), weights are used to apply firm, steady traction (pull) and countertraction to the long axis of the bone. Traction stretches and fatigues muscles that pull the bone fragments out of place, allowing the distal fragment to align with the proximal fragment. Traction can be applied to the skin (skin traction), directly to the involved bone, or distal to the involved bone (skeletal traction). Skin traction is used when only a few pounds of pulling force are needed to realign the fragments or when the traction will be used for brief times only, such as before surgery or, for children with femoral fractures, for 3 to 7 days before applying a cast. In skeletal traction, a pin or wire is drilled through the bone below the fracture site, and a traction bow, rope, and weights are attached to the pin or wire to apply tension and to provide the pulling force needed to overcome the muscle spasm and help realign the fracture fragments.

External fixation can be used to reduce and immobilize significantly displaced open fractures. Pins are placed in the bone proximal and distal to the break and then stabilized by an external frame of clamps and rods (Figure 44-3).

Open reduction is a surgical procedure that exposes the fracture site; the fragments are brought into alignment under direct visualization. Some form of prosthesis, screw, plate, nail, or wire usually is used to maintain the reduction (internal fixation).

Splints and casts are used to immobilize and hold a reduction in place. Improper reduction or immobilization of a fractured bone may result in nonunion, delayed union, or malunion. **Nonunion** is failure of the bone ends to grow together (Figure 44-4). The gap between the broken ends of the bone fills with dense fibrous and fibrocartilaginous tissue instead of new bone. Occasionally the fibrous tissue contains a fluid-filled space that resembles a joint and is termed a *false joint,* or *pseudarthrosis.* **Delayed union** is union that does not occur until approximately 8 to 9 months after a fracture. **Malunion** is the healing of a bone in a nonanatomic position. Treatment of delayed union and nonunion includes use of various modalities designed to stimulate new bone formation. Physical modalities, such as implantable or external electric current devices, electromagnetic field generations, and low-density ultrasound, have been effective in stimulating bone formation.[4] Stem cells and gene therapy also show promise in promoting formation of new bone.[5,6] Large defects in bone can be filled with bone graft or synthetic materials, such as calcium phosphate cement.

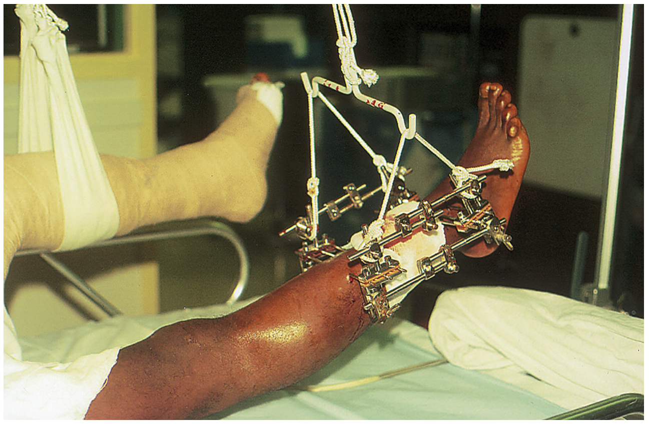

FIGURE 44-3 Example of an External Fixation Device on the Right Leg. The left leg is in a splint.

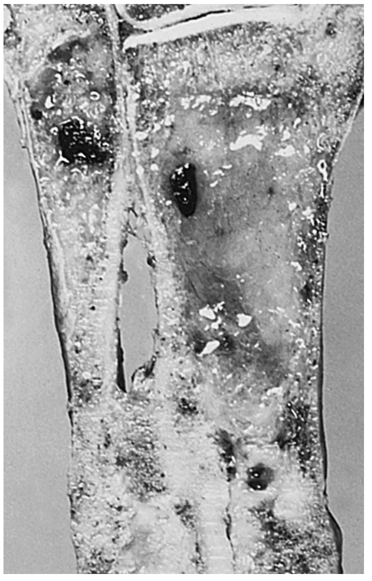

FIGURE 44-4 Nonunion of Old Fracture of Tibia and Fibula in a 53-Year-Old Man. Multiple fractures had occurred in 2 years previous and necessitated bone grafting. (From Rosai J: *Ackerman's surgical pathology,* ed 8, St Louis, 1996, Mosby.)

FIGURE 44-5 **Displaced Fracture.** An x-ray showing a displaced fracture of the base of the first metacarpal, also known as a Bennett fracture.

Dislocation and Subluxation

Dislocation and subluxation are usually caused by trauma but can also be due to ligamentous laxity, nerve injury, rheumatoid disease, or genetic problems. **Dislocation** is the temporary displacement of a bone from its normal position in a joint. If a dislocation does not involve a fracture, it is considered a simple dislocation; if there is an associated fracture, it becomes a complex dislocation. If the contact between the two joint surfaces is only partially lost, the injury is called a **subluxation.**

Dislocation and subluxation are most common in persons younger than 20 years and are generally associated with fractures. Dislocation and subluxation, however, may result from congenital or acquired disorders that cause (1) muscular imbalance, as occurs with congenital hip dislocation or neurologic disorders; (2) incongruities in the articulating surfaces of the bones, such as with rheumatoid arthritis (see p. 1568); or (3) joint instability.

Most often dislocated or subluxated are the joints of the shoulder, elbow, wrist, finger, hip, and knee (Figure 44-5). The shoulder's glenohumeral joint is a relatively unstable joint because the articular surface of the glenoid cavity is only one third as large as the surface of the humeral head. As a result, the glenohumeral joint is often injured. Physical trauma to the shoulder can cause anterior, posterior, superior, or inferior dislocation. Anterior dislocation is the most common and is usually the result of an indirect force that places the shoulder in extreme external rotation. Posterior dislocations usually occur as a result of trauma. A superior dislocation is rare and usually the result of an extreme forward and upward force on an adducted arm. Inferior displacement is often seen in persons with neurologic injuries of the brachial plexus and is believed to be caused by stretching of the supporting muscles or by joint effusion.

Traumatic dislocation of the elbow joint is common in the immature skeleton. In adults an elbow dislocation is usually associated with a fracture of the ulna or head of the radius. Posterior dislocations occur when the individual falls on an outstretched hand with the elbow extended. Anterior dislocations are usually the result of a direct blow to the flexed elbow.

Traumatic dislocation of the wrist usually involves the distal ulna and carpal bones. Any one of the eight carpal bones can be dislocated after an injury. The most common cause is a fall on the hyperextended hand.

Dislocation in the hand usually involves the metacarpophalangeal and interphalangeal joints. Dislocation of the metacarpophalangeal joint is often the result of a fall on the outstretched hand that forces the joint into hyperextension. Dislocation of the interphalangeal joint occurs as a result of injury to the fingers in a hyperextended position.

Considerable trauma is needed to dislocate the hip. Anterior hip dislocation is rather rare and is caused by forced abduction, for example, when an individual lands on the feet from a high fall. Posterior dislocation of the hip can occur in an automobile accident in which the flexed knee strikes the dashboard.

The knee is a relatively unstable joint that depends heavily on the soft tissue structures around it for support. Because the knee is an unstable weightbearing joint exposed to many different types of motion (flexion, extension, rotation), it is one of the most commonly injured joints. A knee dislocation can be anterior, posterior, lateral, medial, or rotary. It is often the result of a hyperextension injury that occurs during sports activities.

PATHOPHYSIOLOGY. Dislocations and subluxations are often accompanied by fracture because stress is placed on areas of bone not normally subjected to stress. In addition, as the bone separates from the joint, it may bruise or tear adjacent nerves, blood vessels, ligaments, supporting structures, and soft tissue. Dislocation of the shoulder may damage the shoulder capsule and the axillary nerve. Damage to the axillary nerve causes anesthesia in the sensory distribution of the nerve and paralysis of the deltoid muscle. Torn periosteum, ligaments, and muscle frequently accompany elbow dislocations. Bleeding from the damaged periosteum and muscle puts pressure on adjacent arteries that stop circulation to and from the forearm and hand. If the pressure is not promptly relieved, ischemic paralysis develops. Dislocations of the hand often result in permanent disability because of damage to the tendons and intricate mechanisms that allow smooth gliding in the joints. In the hip, avascular necrosis of the femoral head is a complication seen with dislocations. Knee dislocation usually tears both the collateral and cruciate ligaments.

CLINICAL MANIFESTATIONS. Signs and symptoms of dislocations or subluxations include pain, swelling, limitation of motion, and joint deformity. Pain may be caused by effusion of inflammatory exudate into the joint or associated tendon and ligament injury. Joint deformity is usually caused by muscle contractions that exert pull on the dislocated or subluxated joint or fluid within the joint. Limitation of motion may be a result of effusion into the joint or the displacement of bones.

Tenderness and deformity are prominent in dislocations of the fingers. Unusual muscle pull and pain often result in

abnormal posturing of the fingers; for example, the fingers or thumb may be abnormally flexed. A dislocated elbow is often held in a flexed position, and the joint resists active or passive movement. Pain is the key symptom of shoulder injuries. Attempts to lift the arm aggravate the pain. In most shoulder dislocations, the ability to elevate the arm is minimal and the individual supports the injured arm with the opposite hand. Pain and an abnormal gait or limp or inability to bear full weight usually accompanies traumatic dislocation of the hip. The pain is constant and severe and is often felt in the inguinal region or thigh. The thigh and leg may assume a position of inward rotation, adduction, or flexion and appear shortened. In a rare anterior dislocation, the limb is not shortened and the joint is fixed in abduction, outward rotation, and flexion.

EVALUATION AND TREATMENT. Evaluation of dislocations and subluxations is based on clinical manifestations and roentgenograms. Treatment consists of reduction and immobilization for 2 to 6 weeks and exercises to maintain normal range of motion in the joint. Depending on the joint, healing is usually complete within months to years.

Support Structure Trauma

Sprains and Strains of Tendons and Ligaments

Tendon and ligament injuries can accompany fractures and dislocations. A **tendon** is fibrous connective tissue that attaches skeletal muscle to bone. A **ligament** is a band of fibrous connective tissue that connects bones where they meet at a joint. Tendons and ligaments support the bones and joints and either facilitate or limit motion. Tendons and ligaments can be torn, ruptured, or completely separated from bone at their points of attachment.

A tear in a tendon is commonly known as a **strain.** Major trauma can tear or rupture a tendon at any site in the body. Most often injured are the tendons of the hands and feet, the knee (patellar), the upper arm (biceps and triceps), the thigh (quadriceps), the ankle, and the heel (Achilles). Lifting excessive weight with the arms can cause traumatic rupture of the biceps tendon. Rupture of the Achilles tendon occurs when forced dorsiflexion is applied to the foot when it is in plantar flexion. Spontaneous tendon ruptures can occur in individuals receiving local corticosteroid injections or fluoroquinolones and in persons with rheumatoid arthritis or systemic lupus erythematosus.

Ligament tears are commonly known as **sprains.** Ligament tears and ruptures can occur at any joint but are most common in the wrist, ankle, elbow, and knee joints. A complete separation of a tendon or ligament from its bony attachment site is known as an **avulsion.** An avulsion is the result of abnormal stress on the ligament or tendon and is commonly seen in young athletes, especially sprinters, hurdlers, and runners.

Strains and sprains are classified as first degree (least severe), second degree, and third degree (most severe).

PATHOPHYSIOLOGY. When a tendon or ligament is torn, an extensive cascade of inflammatory processes begins. An inflammatory exudate develops between the torn ends. Later, granulation tissue containing macrophages, fibroblasts, and capillary buds grows inward from the surrounding soft tissue and cartilage to begin the repair process. Within 3 to 4 days after the injury, collagen formation begins. At first, collagen formation is random and disorganized. As the collagen fibers interweave and connect with pre-existing tendon fibers, they become organized parallel to the lines of stress. Eventually vascular fibrous tissue fuses the new and surrounding tissues into a single mass. As reorganization takes place, the healing tendon or ligament separates from the surrounding soft tissue. Usually a healing tendon or ligament lacks sufficient strength to withstand strong pull for 4 to 5 weeks after the injury. If strong muscle pull does occur during this time, the tendon or ligament ends may separate again, which causes the tendon or ligament to heal in a lengthened shape with an excessive amount of scar tissue that renders the tendon or ligament functionless. Scar remodeling may take months to years before it is complete.[7]

CLINICAL MANIFESTATIONS. Tendon and ligament injuries are painful and are usually accompanied by soft tissue swelling, changes in tendon or ligament contour, and dislocation or subluxation of bones. The pain is generally sharp and localized, and tenderness persists over the distribution of the tendon or ligament. Painful joint swelling usually can be seen in finger and elbow sprains. Flexion deformities of the fingers and thumb occur in injuries to the extensor tendons. Crepitus may accompany tendon injury in the wrist. Pain in the elbow may be accentuated by flexion, supination, and extension of the elbow or by extension of the wrist. Lifting small objects requires extension of the wrist and therefore aggravates the pain. Tendon injuries in the upper arm cause weakness when the individual tries to flex the forearm. Pain is often the key symptom of shoulder injuries. It may be referred to the deltoid muscle or extend down the arm and is aggravated by attempts to actively raise the arms. Depending on the ligament or tendon involved, tendon and ligament injuries in the knee may produce pronounced immobility, absence of lateral movement, instability when walking down stairs, flexion deformity, crepitus, or an upward or downward shift of the patella.

EVALUATION AND TREATMENT. Evaluation is based on clinical manifestations, stress radiography, arthroscopy, or arthrography. When possible, treatment consists of protection of the involved structures (splinting), promotion of early motion, and rehabilitation. Suturing the tendon or ligament ends in close approximation may be necessary to treat complete rupture. If this is not possible because of the extent of damage, tendon or ligament grafting may be necessary. Prolonged rehabilitation exercises help ensure that the individual regains nearly normal functions.

Tendinopathy and Bursitis

Trauma and repetitive stress can cause painful degradation of collagen fibers (**tendinosis**), inflammation of tendons (**tendinitis**), or inflammation in bursal sacs (**bursitis**). The term *tendinopathy* includes tendinitis, tendinosis, and paratendinitis. Studies have shown that vascular ingrowth in tendinopathy (neovascularization) is accompanied with nerve ingrowth, facilitating pain transmission in Achilles and patellar tendinopathies.[8] Other causes of tendinopathy include crystal deposits, postural misalignment, and hypermobility in a joint. Table 44-2 summarizes classes of tendinopathies.

TABLE 44-2 HISTOPATHOLOGIC CLASSIFICATION OF TENDON DISORDERS

PATHOLOGIC DIAGNOSIS	MACROSCOPIC PATHOLOGY	HISTOPATHOLOGIC FINDINGS
Tendinosis	Intratendinous degeneration (commonly due to aging, microtrauma, muscular compromise)	Collagen disorientation, disorganization, and fiber separation by an increase in mucoid ground substance, increased preponderance of cells and vascular spaces with or without neovascularization and focal necrosis or calcification
Tendinitis	Symptomatic degeneration of the tendon with vascular disruption and inflammatory repair response	Degenerative changes as noted above with superimposed evidence of tear, including fibroblastic and myofibroblastic proliferation, hemorrhage, and organizing granulation tissue
Paratenonitis	"Inflammation" of the outer layer of the tendon (paratenon) alone, whether or not the paratenon is lined by synovium	Mucoid degeneration if the areolar tissue is seen; a scattered mild mononuclear infiltrate with or without focal fibrin deposition and fibrinous exudate
Paratenonitis with tendinosis	Paratenonitis associated with intratendinous degeneration	Degenerative changes as noted in tendinosis with mucoid degeneration with or without fibrous and scattered inflammatory cells in the paratenon alveolar tissue

From Maffulli N, Wong J, Almekinders LC: *Clin Sports Med* 22(4):675–692, 2003.

Epicondylitis is inflammation of a tendon where it attaches to a bone (at its origin). Most tendon pathology, however, is caused by tissue degeneration rather than inflammation.[9] Epicondylar areas of the humerus, radius, or ulna and the area around the knee are most often involved. **Lateral epicondylopathy,** commonly called **tennis elbow,** is the result of tissue degeneration or irritation of the extensor carpi radialis brevis tendon at its origin. **Medial epicondylopathy,** referred to as **golfer's elbow,** is a degenerative process of the pronator teres, flexor carpi radialis, and palmaris longus tendons at the medial humeral condyle (Figure 44-6). Epicondylopathy is also related to smoking, obesity, and work activities that involve forceful or repetitive cyclic flexion and extension of the elbow, or cyclic pronation, supination, extension, and flexion of the wrist that generates loads to the elbow and forearm region.

Bursae are small sacs lined with synovial membrane and filled with synovial fluid; they are located between tendons, muscles, and bony prominences. Their primary function is to separate, lubricate, and cushion these structures. When irritated or injured, these sacs become inflamed and swell. Because most bursae lie outside joints, joint movement is rarely compromised with bursitis. Acute bursitis occurs primarily in the middle years and is often caused by trauma; repetitive irritation can cause chronic bursitis. Septic bursitis is caused by wound infection or bacterial infection of the skin overlying the bursae. Bursitis commonly occurs in the shoulder, hip, knee, and elbow.

PATHOPHYSIOLOGY. In tendinitis, inflammatory fluid accumulates causing swelling of the tendon and its enclosing sheath. Inflammatory changes cause thickening of the sheath, which limits movements and causes pain. Microtears cause bleeding, edema, and pain in the involved tendons or surrounding structures. At times, after repeated inflammations, calcium may be deposited in the tendon origin area, causing a calcific tendinitis.

The typical bursitis is an inflammation that is reactive to overuse or excessive pressure. The inflamed bursal sac becomes engorged, and the inflammation can spread to adjacent tissues (Figure 44-7). The inflammation may decrease with rest, heat, and aspiration of the fluid. (Inflammation is discussed in Chapter 7.)

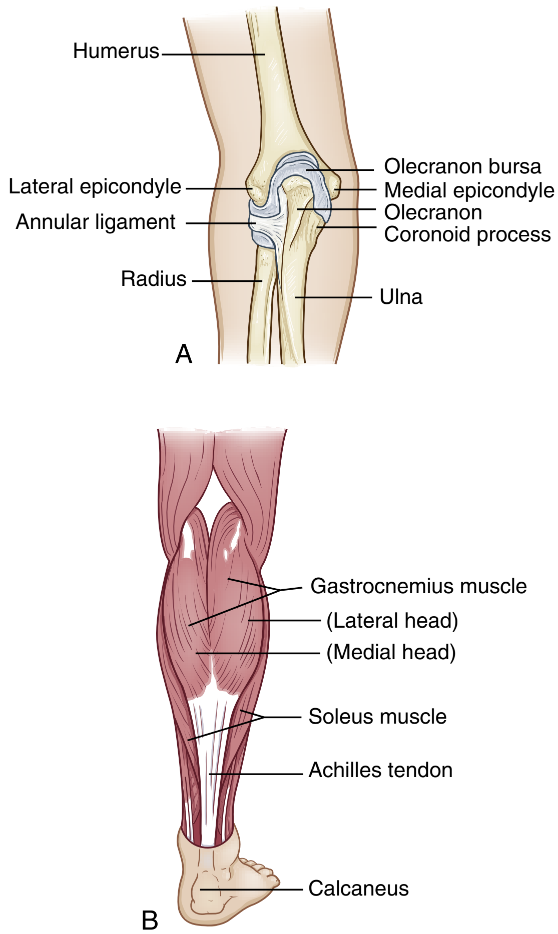

FIGURE 44-6 Tendinitis and Epicondylitis. **A,** Medial or lateral epicondyles of humerus, site of epicondylitis. **B,** Achilles tendon, site of commonly occurring tendinitis.

CLINICAL MANIFESTATIONS. Tendinopathy may be asymptomatic, but generally there is localized pain that worsens with active more than passive motion. With symptomatic tendinopathy, the pain is localized over the involved tendon and movement in the affected joint is limited. In bursitis, onset of pain may be

FIGURE 44-7 Olecranon Bursa. A case of olecranon bursitis in a patient with rheumatoid arthritis. A rheumatoid nodule is also shown. (From Hochberg MC et al: *Rheumatology,* ed 5, London, 2011, Mosby.)

gradual or sudden, but movement of the joint itself is normal. Shoulder bursitis impairs arm abduction because of pain and swelling of the bursa. Bursitis in the knee produces pain when climbing stairs, and crossing the legs is painful in bursitis of the hip. Lying on the side of an inflamed trochanteric bursa is also very painful. Table 44-3 summarizes common sites of bursitis. Signs of infectious bursitis may include the presence of a puncture site, prior corticosteroid injection, severe inflammation, or an adjacent source of infection.

EVALUATION AND TREATMENT. Evaluation of tendinopathy, epicondylopathy, and bursitis is based on clinical manifestations, physical examination, arthroscopy, arthrography, ultrasound, and possibly magnetic resonance imaging (MRI). Treatment includes administration of systemic analgesics, application of ice or heat, or local injection of an anesthetic and a corticosteroid to reduce inflammation. Bursitis may require aspiration to drain excess fluid. Physical therapy to prevent loss of function begins after acute symptoms subside.

Muscle Strains

Mild injury such as **muscle strain** is usually seen after traumatic or sports injuries. *Muscle strain* is a general term for local muscle damage. It is often the result of sudden, forced motion causing the muscle to become stretched beyond normal capacity. Strains often involve the tendon as well. Muscles are ruptured more often than tendons in young people; the opposite is true in older adults. Muscle strain may be chronic when the muscle is repeatedly stretched beyond its usual capacity. There is evidence of tissue disruption with subsequent signs of muscle regeneration and connective tissue repair when a biopsy is performed. Hemorrhage into the surrounding tissue and signs of inflammation also may be present. Knife and gunshot wounds also cause traumatic rupture. Regardless of the cause of trauma, muscle cells usually can regenerate. Regeneration may take up to 6 weeks, and the affected muscle should be protected during this time. Types of muscle strain, together with their manifestations and treatment, are summarized in Table 44-4.

A late complication of localized muscle injury is abnormal bone formation in soft tissue, often called **myositis ossificans** or **heterotopic ossification (HO).** Its exact pathophysiology

TABLE 44-3 COMMON SITES AND CAUSES OF BURSITIS

SITE	COMMON CAUSES
Shoulder (subacromial)	Repetitive overhead activities
Elbow (olecranon)	Rheumatoid arthritis (RA), gout, tuberculosis, leaning on elbow
Hip (greater trochanter)	Acute trauma, chronic stress
Ischial (weaver's bottom)	Overuse (runner, ballet dancers), lumbosacral disease, RA, osteoarthritis (OA)
Knee	
Prepatellar (housemaid's knee)	Trauma, frequent kneeling, infection
Pes anserine (medial knee)	Obesity, long-distance runner, OA, type 2 diabetes
Heel (calcaneal)	Poorly fitting footwear, Achilles tendinitis

remains unknown, but the basic problem seems to be the inability of mesenchymal cells to differentiate into osteoblastic stem cells and the improper development of fibroblasts into bone-forming cells. Though uncommon, HO is associated with burns, joint surgery, and trauma to the musculoskeletal system or central nervous system. HO may involve muscle or tendons, ligaments, or bones near a muscle.[10] Examples include "rider's bone," in which the adductor muscle of the thigh of equestrians becomes calcified, as well as in football players after muscle injury to thigh muscles; and "drill bone," in which the same complication is seen in the deltoid and pectoral muscles of fencers and infantry soldiers.

Rhabdomyolysis

Once used interchangeably with the term *myoglobinuria,* **rhabdomyolysis** is the rapid breakdown of muscle that causes the release of intracellular contents, including protein pigment myoglobin, into the extracellular space and bloodstream. Physical interruptions in the sarcolemmal membrane, called delta lesions, suggest that the sarcolemmal membrane is the route through which muscle constituents are released. Myoglobinuria, first described in victims of crush injuries in London during World War II, refers to the presence of the muscle protein myoglobin in the urine. More recently, myoglobinuria has been reported in individuals found unresponsive and immobile for long periods, such as drug and alcohol overdoses.

PATHOPHYSIOLOGY. Rhabdomyolysis is sometimes incorrectly used interchangeably with *crush injury* (a description of injuries resulting from crushing of a body part), *compartment syndrome* (the consequences of increased intracompartmental pressures of a muscle), or *crush syndrome* (the pathophysiologic events caused by rhabdomyolysis, primarily involving the kidneys and coagulation syndrome).[11] Although relatively rare, rhabdomyolysis has many causes (Box 44-1) and can result in serious complications, including hyperkalemia (because of the release of intracellular potassium into the circulation), metabolic acidosis (from liberation of intracellular phosphorus and sulfate), acute renal failure (myoglobin precipitates in the tubules, obstructing flow through the nephron and producing injury),

TABLE 44-4 MUSCLE STRAIN

TYPE	MANIFESTATIONS	TREATMENT
First degree (e.g., bench press in untrained athlete)	Muscle overstretched, painful	Ice should be applied 5 or 6 times in the first 24-48 hours; complete rest for up to 2 weeks, followed by weightbearing 3 times per week and range of motion daily
Second degree (e.g., any muscle strain with bruising and pain)	Muscle intact with some tearing pain, mild bruising; fascia is intact	Treatment similar to that for first-degree strains, with added mild analgesia; cryokinetics (a treatment system of alternating applications of cold with progressive exercise)
Third degree (e.g., traumatic injury)	Caused by tearing of fascia; muscle rupture palpable, bleeding present	Surgery to approximate ruptured edges; immobilization and rest for 6 weeks, followed by an individualized rehabilitation regimen of strengthening exercises

BOX 44-1 SELECTED CAUSES OF RHABDOMYOLYSIS

Medications and Toxic Substances That Increase the Risk of Rhabdomyolysis

Direct Myotoxicity

HMG-CoA reductase inhibitors (statins), especially in combination with fibrate-derived lipid-lowering agents such as niacin (nicotinic acid; Nicolar)
Cyclosporine (Sandimmune)
Itraconazole (Sporanox)
Erythromycin
Colchicine
Zidovudine (Retrovir)
Corticosteroids

Other Medications and Toxins

Amphetamines
Anesthetic and paralytic agents (halothane, propofol, succinylcholine—malignant hyperthermia syndrome)
Antihistamines (diphenhydramine, doxylamine)
Anti-hyperlipidemic agents (statins, clofibrate, bezafibrate)
Antipsychotics and antidepressants (amitriptyline, doxepine, fluoxetine, haloperidol, lithium, protriptyline, perphenazine, promethazine, chlorpromazine, trifluoperazine)
Caffeine
Cocaine
HIV integrase inhibitor (raltegravir)
Hypnotics and sedatives (benzodiazepines, barbiturates)
Heroin
LSD
Methamphetamine
Methadone
Methylenedioxymethamphetamine (MDMA; "ecstasy")
Miscellaneous medications (amphotericin B, azathioprine, epsilon-aminocaproic acid, quinidine, penicillamine, salicylates, theophylline, terbutaline, thiazides, vasopressin)
Phencyclidine
Protease inhibitors

Indirect Muscle Damage

Alcohol
Central nervous system depressants
Cocaine
Amphetamines
Ecstasy (MDMA)
LSD
Neuromuscular-blocking agents

Traumatic, Heat-Related, Ischemic, and Exertional Causes

Traumatic Causes

Direct trauma
Lightning strike
Immobilization
Extensive third-degree burn
Crush injury

Heat-Related Causes

Heat stroke
Malignant hyperthermia
Neuroleptic malignant syndrome

Ischemic Causes

Ischemic limb injury

Exertional Causes

Marathon running
Physical overexertion in untrained athletes
Pathologic muscle exertion
Severe dystonia
Tetanus
Status epilepticus
Delirium tremens
Heat dissipation impairment
Physical overexertion in persons with sickle cell disease

Genetic Causes

Lipid Metabolism

Carnitine palmitoyltransferase deficiency
Carnitine deficiency
Short-chain and long-chain acetyl-coenzyme A dehydrogenase deficiency

Carbohydrate Metabolism

Myophosphorylase deficiency (McArdle disease)
Phosphorylase kinase deficiency
Phosphofructokinase deficiency
Phosphoglycerate mutase deficiency
Lactate dehydrogenase deficiency (characteristic elevation of creatine kinase level with normal lactate dehydrogenase level)

Purine Metabolism

Myoadenylate deaminase deficiency
Duchenne muscular dystrophy

BOX 44-1 SELECTED CAUSES OF RHABDOMYOLYSIS—cont'd

Infectious, Inflammatory, Metabolic, and Endocrinologic Causes

Infectious Causes

Viruses: influenza virus B, parainfluenza virus, adenovirus, coxsackievirus, echovirus, herpes simplex virus, cytomegalovirus, Epstein-Barr virus, human immunodeficiency virus

Bacteria: *Streptococcus, Salmonella, Legionella, Staphylococcus,* and *Listeria* species

Inflammatory Causes

Polymyositis

Dermatomyositis

Capillary leak syndrome

Snake bites (mostly in South America, Asia, and Africa)

Metabolic and Endocrinologic Causes

Electrolyte imbalances: hyponatremia, hypernatremia, hypokalemia, hypophosphatemia, hypocalcemia

Hypothyroidism

Thyrotoxicosis

Diabetic ketoacidosis

Nonketotic hyperosmolar syndrome

Herbal Supplements

Red yeast rice (monascus, purpureus)

Compounds containing ma huang, guarana, and garcinia cambogia

Ephedra-based compounds, especially weight-loss supplements

and even disseminated intravascular coagulation (DIC) (likely caused by activation of the clotting cascade by sarcolemma damage and release of intracellular components from the damaged muscles). Even the weight of a limp extremity can generate enough pressure to produce muscle ischemia (Figure 44-8).

Malignant hyperthermia (MH) is a potentially life-threatening hereditary disorder of skeletal muscle ryanodine receptors (RyR1), allowing large quantities of calcium to be released from the sarcoplasmic reticulum (SR) after exposure to certain volatile anesthetics. The sustained elevation of calcium concentration allows excessive stimulation of aerobic and anaerobic glycolytic metabolism, causing a hypermetabolic state resulting in respiratory and metabolic acidosis, muscle rigidity, altered cell permeability, and hyperkalemia.[12] Dantrolene, a skeletal muscle relaxant, inhibits calcium release from the SR and is used to reverse the effects of MH.

Compartment syndromes occur when blood flow to the affected area is compromised because of increased venous pressure, leading to decreased arterial inflow, ischemia, and edema. Emergency treatment may be required to save an affected limb. Classic symptoms of compartment syndrome are: (1) pain out of proportion to the injury, (2) paresthesia, (3) pallor, (4) pulselessness (uncommon), and (5) paralysis (a late finding). Of these symptoms, pain is the most sensitive clinical sign.[13]

When clinical evaluation is inconclusive, the rising compartment pressure can be directly measured by inserting a wick catheter, needle, or slit catheter into the muscle. Immediate fasciotomy and débridement are advocated for reducing elevated intracompartmental pressures.[13] Compartments frequently affected are the compartments of the leg, the volar compartment of the hand, the abdomen, and the gluteal compartments.

CLINICAL MANIFESTATIONS. A *classic triad* of muscle pain, weakness, and dark urine is considered typical of rhabdomyolysis, but those affected may have no complaint of pain or muscle weakness.[11] Abnormally dark urine caused by myoglobinuria may be the first and only symptom. The renal threshold for myoglobin is low (approximately 0.5 mg/dl of urine), so only 200 g of muscle need to be damaged to cause visible changes in the urine. Myoglobin is rapidly cleared and levels may return to normal within 24 hours of injury. Along with the release of myoglobin, creatine kinase (CK) and other serum enzymes are released in massive quantities. The efflux of proteins and enzymes also includes loss of potassium, phosphate, nucleotides, creatinine, and creatine. Serum hypocalcemia is seen early in the course of myoglobinuria and is followed by late hypercalcemia.

EVALUATION AND TREATMENT. The most important and clinically useful measurement in rhabdomyolysis is serum creatine kinase (CK) level. With normal CK serum levels of 5 to 25 units/L for women and 5 to 35 units/L for men, a level five times the upper limit of normal (about 1000 units/L) is used to identify rhabdomyolysis. Once CK levels exceed 5000 units/L, acute renal failure is likely. A recent study evaluated the ultrasonographic appearance of rhabdomyolysis in damaged muscle from earthquake victims and found abnormalities in muscle texture and subcutaneous tissue, as well as areas of liquid in the damaged tissue.[14]

Maintaining adequate urinary flow and prevention of kidney failure are goals of treatment. Rapid intravenous hydration maintains adequate kidney flow. Other issues, such as hyperkalemia, may require temporary hemodialysis. Other treatments, such as using mannitol to cause an osmotic diuresis or bicarbonate to alkalinize the urine, have not been shown to consistently improve outcomes.

DISORDERS OF BONES

Metabolic Bone Diseases

Metabolic bone disease is characterized by abnormal bone structure that is caused by altered or inadequate biochemical reactions resulting in disorders of bone strength. Abnormalities include genetic, mineral, vitamin, and structural abnormalities.

Osteoporosis

Osteoporosis, or porous bone, is a disease in which bone tissue is normally mineralized but the mass—*density of bone*—is decreased and the structural integrity of trabecular bone is impaired. Two types of osteoporosis are generally considered. *Postmenopausal, or primary, osteoporosis* is most common. *Secondary osteoporosis* is osteoporosis caused by other conditions, including hormonal imbalances (endocrine disease, diabetes, hyperparathyroidism, hyperthyroidism), medications (such as heparin, corticosteroids, phenytoin, barbiturates, lithium), and other substances (including tobacco and ethanol). Other conditions, including rheumatoid disease, human immunodeficiency virus (HIV), malignancies, malabsorption syndromes, liver or kidney disease, also increase the risk for developing osteoporosis (Box 44-2). Cortical bone becomes more porous and thinner, making bone weaker and prone to fractures (Figure 44-9). The World Health Organization (WHO) has defined osteoporosis based on bone density:

1. Normal bone mass is greater than 833 mg/cm^2.
2. **Osteopenia,** or decreased bone mass, is 833 to 648 mg/cm^2.
3. Osteoporosis is bone mass less than 648 mg/cm^2.

Osteoporosis is a complex, multifactorial chronic disease that often progresses silently for decades until fractures occur. It is the most common disease that affects bone. It is not necessarily a consequence of the aging process because some older adults retain strong, relatively dense bones. In osteoporosis, old bone is being reabsorbed faster than new bone is being made, causing the bones to lose density, becoming thinner and more porous. A progressive loss of bone mass may continue until the skeleton is no longer strong enough to support itself. Eventually, bones can fracture spontaneously. As bone becomes more fragile, fractures occur from falls or bumps that would not previously have caused fracture.

Severe or established osteoporosis is identified when there has been a fragility fracture. The disease can be (1) generalized, involving major portions of the axial skeleton, or (2) regional, involving one segment of the appendicular skeleton.

Throughout a lifetime, old bone is removed (resorption) and new bone is added (formation) to the skeleton. During childhood and teenage years, new bone is added faster than old bone is removed. Consequently, bones become larger, heavier, and denser. Bone formation continues at a pace faster than resorption until **peak bone mass,** or maximum bone density and strength, is reached, around age 30, after which bone resorption slowly exceeds bone formation. In women, bone loss begins before menopause, and is most rapid in the first years after menopause but persists throughout the postmenopausal years. Though osteoporosis is most common in women, it is estimated that one in five men will experience an osteoporosis-related fracture at some point in his lifetime.[15] In adults over age 50, the prevalence of osteoporosis at either the spine or the femoral neck by age ranges from 3% to 10% in men and from 7% to 35% in women. One study showed that in men the prevalence of osteoporosis did not increase with age until age 80 years and older, but in women it increased for each decade after age 50 years.[16]

BOX 44-2 RISK FACTORS FOR OSTEOPOROSIS

Genetic
Family history of osteoporosis
White/Asian race
Increased age
Female gender

Anthropometric
Small stature
Fair or pale skinned
Thin build

Hormonal and Metabolic
Early menopause (natural or surgical)
Late menarche
Nulliparity
Obesity
Hypogonadism
Gaucher disease
Cushing syndrome
Weight below healthy range
Acidosis

Dietary
Low dietary calcium and vitamin D
Low endogenous magnesium
Excessive protein*
Excessive sodium intake
High caffeine intake
Anorexia
Malabsorption

Lifestyle
Sedentary
Smoker
Alcohol consumption (excessive)

Concurrent
Hyperparathyroidism

Illness and Trauma
Renal insufficiency, hypocalciuria
Rheumatoid arthritis
Spinal cord injury
Systemic lupus erythematosus

Liver Disease
Marrow disease (myeloma, mastocytosis, thalassemia)

Drugs
Corticosteroids
Dilantin
Gonadotropin-releasing hormone agonists
Loop diuretics
Methotrexate
Thyroid
Heparin
Cyclosporine
Depo-medroxyprogesterone acetate
Retinoids

*Low levels of protein intake also have been reported.

FIGURE 44-9 **Vertebral Body.** Osteoporotic vertebra *(right)* shortened by compression fractures compared with normal vertebral body *(left)*. Note that the osteoporotic vertebra has characteristic loss of horizontal trabeculae and thickened vertebral trabeculae. (From Kumar V et al: *Robbins & Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders.)

Approximately 52 million people in the United States are affected by osteoporosis or low bone density.[17] The major risks for persons with osteoporosis are fractures. Men lose bone density with aging but because they begin with a higher bone density, they reach osteoporotic levels at an older age than do women.[18] Osteoporotic fractures affect 1 in 2 women and 1 in 5 men older than the age of 50.[18] In 2011 the United States Preventive Services Task Force (USPSTF) issued a recommendation that women age 65 and older be routinely screened for osteoporosis.[19] Hip fractures, in particular, can have devastating effects on an individual's life. In addition to direct medical costs, studies have shown decreased quality of life as well as excess loss of life-years for those experiencing hip or osteoporotic fractures.[20,21]

Vertebral fractures are the most common osteoporotic fracture but may be asymptomatic. Even if the fracture does not cause pain, vertebral fractures can cause deformity, reduced pulmonary function, and loss of height. The degree of compression necessary to define a vertebral fracture has not been standardized.

Osteoporosis affects all races and both sexes. Recent data from the National Health and Nutrition Examination Survey (NHANES) showed that Mexican-Americans had higher risk for osteoporosis, whereas non-Hispanic black persons had lower risk of osteopenia or osteoporosis at the lumbar spine or femoral neck.[16] Multiple genetic factors also influence development of osteoporosis.[22]

Whites are more susceptible than other races to osteoporosis caused by loss of bone density with age. Blacks have only about half the fractures found in whites, probably related to their higher peak bone mass, but black women remain at a high risk because of factors such as decreased dietary calcium intake, a high percentage of lactose intolerance, and increased prevalence of diseases, such as sickle cell disease and lupus, that increases

the risk of developing osteoporosis.[23] Both black women and black men have generally been undertreated for osteoporosis.[24] Decreased bone strength with aging is partly due to lower bone mass, but other factors such as deterioration of type I collagen likely contribute to increased fracture risk.[25]

Measuring bone mineral density (BMD) by using dual x-ray absorptiometry (DXA) continues to be the most common method of estimating bone mass. Bone quality relates not just to bone mass (as measured by bone density) but also to the microarchitecture of the bone. Other variables include crystal size and shape, brittleness, vitality of the bone cells, structure of the bone proteins, water volume, integrity of the trabecular network, vascular supply, and the ability to repair tiny cracks.[26]

Because bone density relates to *quantity* of bone, bone *quality* is not accurately identified by bone density testing. Therefore, bone density testing may or may not accurately identify individuals with increased fracture risk. An online tool called FRAX incorporates clinical risk factors with BMD at the femoral neck to predict an individual's 10-year probability of fracture. This tool is available at www.shef.ac.uk/FRAX/. **Postmenopausal osteoporosis** occurs in middle-aged and older women. It can occur because of estrogen deficiency as well as estrogen-independent age-related mechanisms (e.g., secondary causes such as hyperparathyroidism and decreased mechanical stimulation). Recent studies indicate that increased oxidative stress (OS) and increased intracellular reactive oxygen species (ROS) play a significant role in the development of age-related bone loss, as well as other age-related changes in the body.[26] Hormonal deficiency also can increase with stress, excessive exercise, and low body weight. Postmenopausal changes include a substantial increase in bone turnover—that is, an imbalance between the remodeling activity of osteoclasts and osteoblasts. Increased formation and longevity of osteoclasts results in increased bone resorption and is associated with a cascade of proinflammatory cytokines. Increased cytokine activation, especially tumor necrosis factor (TNF), can occur with declining estrogen levels.[26] In addition, estrogen helps protect against the effects of OS and osteoclast apoptosis. Biologically, these processes involve the receptor activator nuclear factor κβ ligand (RANKL), transcription factors such as forkhead proteins, the Wnt and osteoprotegerin (OPG) signaling pathways (see the following Pathophysiology section), and insulin-like growth factor (IGF). Other causes may include a combination of inadequate dietary calcium intake and lack of vitamin D, possibly decreased magnesium level, lack of exercise, low body mass, and family history. IGF is known to help in fracture healing and collagen synthesis and improves conditions for bone mineralization. IGF levels significantly decline by age 60.

Sex hormones, especially estrogen and testosterone, are significant in premenopausal bone maintenance; however, when estrogen levels drop after menopause, it appears that circulating androgens become significant effectors on bone metabolism. In clinical studies of women, data have suggested that serum androgens influence bone density in pre-, peri-, and postmenopausal women. Androgens (i.e., testosterone and dihydrotestosterone) have long been recognized to stimulate bone formation. Other risk factors are identified in Box 44-2.

Poor nutrition and insufficient intake or malabsorption of dietary minerals, particularly calcium, are factors in the development of osteoporosis. Calcium absorption from the intestine decreases with age, and studies of individuals with osteoporosis show that their calcium intake is lower than that of age-matched controls. Deficiencies of vitamins, particularly vitamins C, D, E, and K, also contribute to bone loss.[27]

Skeletal homeostasis depends on a very narrow range of plasma calcium and phosphate concentrations, which are maintained by the endocrine system.[28] Therefore, endocrine dysfunction ultimately can cause metabolic bone disease. In addition to declining levels of sex steroids, the hormones most commonly associated with osteoporosis are parathyroid hormone, cortisol, thyroid hormone, and growth hormone. Excessive intakes of caffeine, alcohol, and nicotine along with low body fat have been considered risk factors. In addition, significant differences in the levels of trace elements (zinc, copper, manganese) were noted in the bones and hair of unaffected individuals compared with those with osteoporosis. Development of selective androgen receptor modulators (SARMs) promises novel treatment for osteoporosis through increasing bone formation and building more muscle mass. In theory, selectively affecting bone, muscle mass, and other desired sites while not affecting lipid or estrogen levels or blood pressure, side effects can be controlled but since the direct effects of SARMs on bone are not yet known, this remains a clinical challenge.[29,30]

Secondary osteoporosis sometimes develops temporarily in individuals receiving large doses of heparin, perhaps because heparin promotes bone resorption by decreasing collagen synthesis or by increasing collagen breakdown. Osteoporosis caused by heparin therapy usually resolves when therapy ceases. Treatment with other medications may lead to the development of osteoporosis, such as the use of glucocorticoid treatment for rheumatoid arthritis. Other medications increasing the risk of osteoporosis include lithium, methotrexate, anticonvulsants, cyclophosphamide, and cyclosporine.

One form, transient osteoporosis of the hip, is associated with the third trimester of pregnancy or the immediate postpartum period. However, most transient osteoporosis is a typically self-limiting syndrome affecting the lower extremity joints of middle-aged men. The etiology is unknown and although most cases spontaneously resolve, some occurrences of bone demineralization may be related to osteonecrosis.[31]

Regional osteoporosis—osteoporosis confined to a region or segment of the appendicular skeleton—usually has a known cause. Transient regional osteoporosis has no known etiology, is characterized by bone marrow edema, and can cause severe pain. The lower extremity is most often affected, but other areas also may be involved.[32] Fortunately, it is usually self-limited. It tends to occur in middle-aged men and women in their late second or third trimester of pregnancy.[33] It is characterized by bone marrow edema, seen on magnetic resonance imaging (MRI), and areas of localized bone demineralization are seen on plain radiographs. Treatment is primarily symptomatic and the condition usually resolves spontaneously over 3 to 6 months, with no long-term adverse effects.

Classic regional osteoporosis is associated with disuse or immobilization of a limb because of fractures, motor paralysis, or bone or joint inflammation (see Figure 44-13, p. 1555). A negative calcium balance develops early and continues throughout the period of immobilization. After 8 weeks of immobilization, significant osteoporosis is present, although it may develop earlier in persons younger than 20 years or older than 50 years. A uniform distribution of osteoporosis also has been observed in astronauts and in individuals treated with air suspension therapy as a result of weightlessness and lack of mechanical strain.

PATHOPHYSIOLOGY. Whatever the cause, osteoporosis develops when the remodeling cycle—the process of bone resorption and bone formation—is disrupted, leading to an imbalance in the coupling process. The explosion of new information in the field of bone biology has led to new understanding of the roles of hormones, growth, and signaling factors, and cellular biology in osteoporosis. Although hormonal influences remain important in maintaining bone health, genetic factors and the role of oxidative stress are receiving increased attention as critical determinants of bone homeostasis.[22,26] Reactive oxygen species are normal byproducts of aerobic metabolism, and although they can cause cell damage, at levels below which they cause OS, ROS serve as signaling molecules for many cell types, including osteocytes, osteoblasts, and osteoclasts. When excess ROS accumulate, OS occurs and can result in loss of bone mass and bone strength.[26]

The osteoclast differentiation pathway is directed by a series of processes that include proliferation, differentiation, fusion, and activation. These processes are controlled by hormones, cytokines, and paracrine stromal-cell microenvironment interactions. Thus the intercellular communication in bone and the key molecular regulators are necessary for bone homeostasis. Certain transcription factors, known as Forkhead box (FoxO), help protect against the effects of OS by preventing excess accumulation of ROS and regulating certain genes that affect DNA repair and cell life span. FoxOs help remove damaged and abnormal cells by inducing apoptosis.[26]

Interleukins (IL-1, IL-4, IL-6, IL-7, IL-11, IL-17), tumor necrosis factor-alpha (TNF-α), transforming growth factor-beta (TGF-β), prostaglandin E_2, and hormones interact to control osteoclasts[34] (Figure 44-10). Normal bone homeostasis is dependent on the balance between the cytokine **receptor activator of nuclear factor κβ ligand (RANKL),** its receptor **RANK,** and its decoy receptor **osteoprotegerin (OPG);** understanding this has led to a tremendously increased knowledge of osteoclast biology and pathogenesis of bone loss.[35]

RANKL, a member of the TNF family, is expressed by osteoblasts and their immature precursors and is necessary for osteoclast development. RANKL activates the receptor RANK, which is expressed on osteoclasts and their precursors and suppresses apoptosis, which leads to activation and prolongation of osteoclast survival.[36] The effects of RANKL are blocked by OPG, a glycoprotein that acts as a decoy receptor for RANKL that prevents it from binding and activating RANK (see Figure 44-10). Cytokines and hormones regulate the balance between RANKL and OPG. Alterations of the RANKL/RANK/OPG system can lead to dysregulation and pathologic conditions including osteoporosis, immune-mediated bone diseases, malignant bone disorders, and inherited skeletal diseases (see Figure 44-10).

Postmenopausal osteoporosis is characterized by increased bone resorption relative to the rate of bone formation, leading to sustained bone loss resulting from estrogen deficiency. Bone loss resulting from estrogen deficiency also contributes to osteoporosis in men.[37,38]

Increased bone resorption results from enhanced development of osteoclasts and decreased osteoclast apoptosis (see Figure 44-10). Estrogen stimulates OPG secretion and down-regulates RANKL; drugs known as selective estrogen response modifiers (SERMs) also stimulate OPG production. In estrogen deficiency, the exact role of OPG is less clear.[34] Postmenopausal women express higher levels of RANKL on bone marrow stromal cells, T cells, and B cells than premenopausal women. Importantly, RANKL expression is increased when estrogen levels are decreased, leading to increased formation of osteoclasts while reducing osteoclast apoptosis.[18] Other factors, such as sclerostin (SOST), a glycoprotein secreted by osteocytes, are powerful inhibitors of osteoblast formation by binding to low-density lipoprotein (LDL) receptor–related protein 5 (LRP5) and prevent binding with frizzled protein and Wnt signaling, important factors in osteoblast and bone formation.[34]

Sex steroids (e.g., estrogens) exert anti-apoptotic effects on osteoblasts but exert pro-apoptotic effects on osteoclasts; in both scenarios this is accomplished by activating the **extracellular signal regulated kinases (ERKs).** Estrogen activates ERKs outside the nucleus; ERKs then accumulate in the nucleus and activate downstream transcription factors.[39] This confusing and complicated data eventually revealed that the important determinant of whether pro-apoptosis or anti-apoptosis was exhibited was the *length of time* that the phosphorylated ERKs remained in the nucleus. Prolonged nuclear accumulation of activated ERKs converted the anti-apoptotic effect of estradiol to pro-apoptotic. In addition to ERKs, RANKL promotes the anti-apoptotic effects on osteoclasts, thus increasing their life span.[40] Wnt signaling induces a biochemical series of events that increases osteoblast and bone formation. Alterations in Wnt signaling account for critical pathophysiologic changes in most acquired metabolic bone diseases including postmenopausal osteoporosis, aging effects, and glucocorticoid (i.e., cortisone) excess. Agents such as parathyroid hormone and bisphosphonates, used for treatment of bone loss, exert their positive effects by altering the formation of osteoblasts or osteoclasts or by inducing osteoclast apoptosis.

Glucocorticoid (e.g., cortisone)-induced osteoporosis is characterized by increased bone resorption and decreased bone formation. Glucocorticoids increase RANKL expression and inhibit OPG production by osteoblasts (see Figure 44-10). The use of immunosuppressive drugs (e.g., cyclosporine A) to reduce rejection of transplanted organs also alters the OPG/RANKL/RANK system and can lead to posttransplantation osteoporosis. Other conditions affected by OPG/RANKL/RANK include rheumatoid arthritis, myeloma, vascular diseases, and skeletal metastases from neoplastic disorders.

Age-related bone loss begins in the third to fourth decade. The cause remains unclear, but it is known that decreased serum growth hormone (GH) and IGF levels along with increased

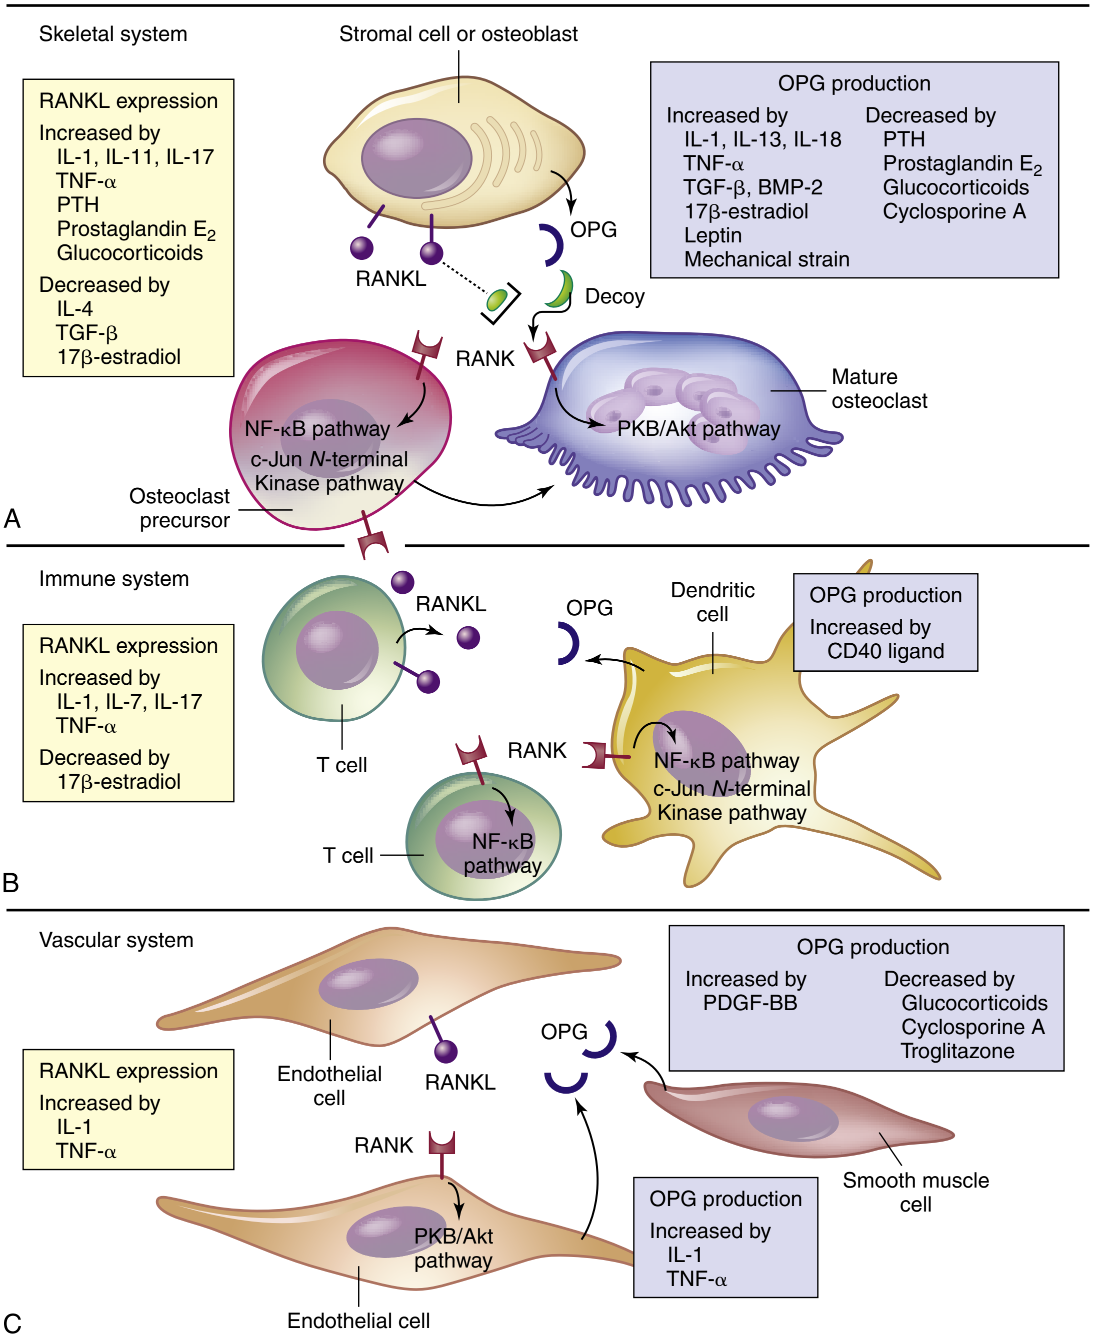

FIGURE 44-10 **OPG/RANKL/RANK System.** Receptor activator of nuclear factor κβ ligand *(RANKL),* a cytokine and part of the tumor necrosis factor *(TNF)* family, expression and osteoprotegerin *(OPG),* a glycoprotein receptor antagonist, are modulated by various cytokines, hormones, drugs, and mechanical strains (*see inserts*). **A,** In bone, RANKL is expressed by both stromal cells and osteoblasts. RANKL stimulates the receptor RANK on osteoclast precursor cells and mature osteoclasts, and activates intracellular signaling pathways to promote osteoclast differentiation and activation and cytoskeletal reorganization and survival *(PKB/Akt pathway)* that increases resorption and bone loss. OPG, secreted by stromal cells and osteoblasts, acts as a "decoy" receptor and blocks RANKL binding to and activation of RANK. **B,** In the immune system, RANKL is expressed and secreted by T cells. T-cell–derived RANKL also can activate RANK on osteoclasts, T cells, and dendritic cells (antigen-presenting cells), which enhances bone loss that occurs in inflammatory bone diseases such as rheumatoid arthritis. Dendritic cells may regulate these processes by secreting OPG. **C,** In the vascular system, endothelial cells express RANKL and the RANK receptor. RANKL/RANK interactions contribute to endothelial and smooth muscle cells and can block RANKL binding. The physiologic significance of the OPG/RANKL/RANK system in endothelial and smooth muscle cells is being studied. *BMP-2,* Bone morphogenic protein 2; *IL,* interleukin, *PDGF-BP,* platelet-derived growth factor-beta polypeptide; *PTH,* parathyroid hormone; *TGF-α,* tumor necrosis factor-alpha; *TGF-β,* transforming growth factor-beta. FIGURE 44-11 Osteoporosis in Cortical and Trabecular Bone.

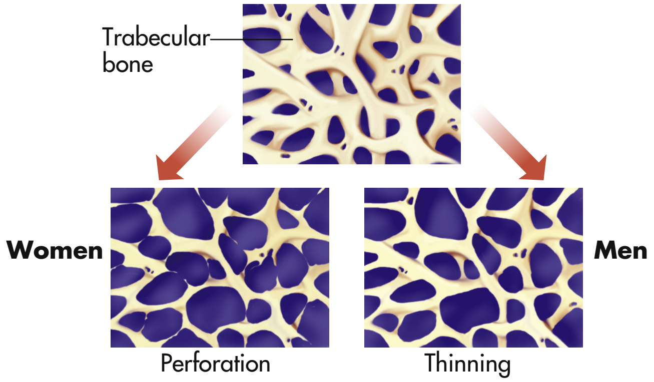

FIGURE 44-12 Mechanism of Loss of Trabecular Bone in Women and Trabecular Thinning in Men. Bone thinning predominates in men because of reduced bone formation. Loss of connectivity and complete trabecular loss predominates in women.

FIGURE 44-13 Kyphosis. This older adult woman's condition was caused by a combination of spinal osteoporotic vertebral collapse and chronic degenerative changes in the vertebral column. (From Kamal A, Brocklehurst JC: *Color atlas of geriatric medicine,* ed 2, St Louis, 1992, Mosby.)

binding of RANKL and decreased OPG affect osteoblast and osteoclast function. Loss of trabecular bone in men proceeds in a linear fashion, with thinning of trabecular bone rather than complete loss as is noted in women (Figure 44-11). Men have approximately 30% more bone mass than women, which may be a factor in their later involvement with osteoporosis (Figure 44-12). Androgens promote osteoprotegerin production, thus inhibiting the osteoclastic effect of RANKL.[41] Reduction in physical activity in older persons also may be a major factor in the degree of bone loss because preservation of bone mass depends on skeletal stress (mechanical) through muscle contraction and weightbearing.[34]

CLINICAL MANIFESTATIONS. The specific clinical manifestations of osteoporosis depend on the bones involved. The most common manifestation, however, is bone deformity. Pain tends to occur only when there is a fragility fracture. Fractures are likely to occur because the trabeculae of spongy bone become thin and sparse and compact bone becomes porous. As the bones lose volume, they become brittle and weak and may collapse or become misshapen. Vertebral collapse causes kyphosis (hunchback) and diminished height (Figure 44-13). Fractures of the long bones (particularly the femur and humerus), distal radius, ribs, and vertebrae are most common. The most serious fractures associated with osteoporosis are hip fractures because of their resultant chronic pain, disability, diminished quality of life, and premature death. Fracture of the neck of the femur (intertrochanteric fracture) tends to occur in older adult women with osteoporosis.[42] Fatal complications of fractures include fat or pulmonary embolism, hemorrhage, and shock. Approximately 20% of persons with a hip fracture die as a result of surgical complications.

EVALUATION AND TREATMENT. Generally, osteoporosis is detected radiographically as increased radiolucency of bone. By the time abnormalities are detected by x-ray examination, as much as 25% to 30% of bone tissue may have been lost.

Types of radiologic examinations include single- or dual-photon absorptiometry (SXA, DXA) and computed

tomography (CT) scans. Because osteoporosis is asymptomatic unless a fracture occurs, diagnosis is often delayed. At present, DXA is the current examination of choice for diagnosis. Unfortunately, DXA does not provide information about bone strength or fracture risk.

Because fractures are the primary complication of osteoporosis, the World Health Organization has developed an assessment tool to estimate an individual's 10-year risk of fracture. The WHO's Fracture Risk Assessment (FRAX) is a downloadable computer-drive questionnaire that has been developed for use in Europe, North America, Asia, and Australia. Once completed, the imbedded algorithms predict the 10-year probability of hip, spine, forearm, or shoulder fractures. This tool can be downloaded from www.shef.ac.uk/FRAX. Other evaluation procedures include tests for levels of serum calcium, phosphorus, and alkaline phosphatase as well as protein electrophoresis. Body calcium levels also can be measured by neuron activation analysis, a procedure involving use of radioactive calcium-49, whose gamma activity can be measured with a whole-body counter.

Though prevention of osteoporosis is paramount, treatment is more common and is focused on preventing fractures and maintaining optimal bone function. The role of calcium intake to prevent and treat osteoporosis is controversial. It is well accepted that oral calcium intake sufficient to maintain normal calcium balance is necessary during adolescence to ensure development of peak bone mass, and that calcium-deficient diets can aggravate bone loss associated with menopause and aging. Although recommendations have been established for young women of 1000 mg of calcium daily (particularly from dietary sources) and for postmenopausal women of 1500 mg daily (with vitamin D), it has been difficult to translate these recommendations into clear-cut clinical outcomes (see Nutrition & Disease: Postmenopausal Women Should Not Take Calcium and Vitamin D to Prevent Fractures). A significant relationship has been observed between an individual's lifetime history of calcium intake and peak bone mineral density. Diets with higher fruit and vegetable intake seem to correlate with higher BMD.[43] Other nutrients that appear to have a positive impact on bone health include magnesium, vitamin K_2, and docosahexaenoic acid or DHA (from purified fish oil).[44]

NUTRITION & DISEASE

Postmenopausal Women Should Not Take Calcium and Vitamin D to Prevent Fractures

The beneficial effects of vitamin D on fracture risk are attributed to two explanations: (1) the decrease in bone loss in older adults, and (2) the increase in muscle strength and balance mediated through vitamin D receptors in muscle tissue. Vitamin D alone, however, does not appear to reduce fracture risk. In fact, the U.S. Preventive Services Task Force (USPSTF) has made the recommendation that postmenopausal women should not take supplementary calcium (1000 mg or less) and vitamin D (400 IU or less) because, at these doses, it appears that it does not prevent primary fracture risk and poses a small increased risk for renal stones. The USPSTF also concluded there is not enough evidence either supporting or opposing the use of higher doses of calcium and vitamin D for men or premenopausal women.

Data from Moyer V: *Ann Intern Med* Feb 2013 [online].

Magnesium (Mg^{++}), another mineral important for skeletal development, is an essential mineral in many biochemical and physiologic functions, including activation of enzymes, involvement in adenosine triphosphate (ATP) synthesis and protein synthesis, regulation of membrane channels, and contraction of muscle. Mg^{++} is important to bone quality because it helps control hydroxyapatite crystal growth and thereby prevents formation of brittle bones. It seems reasonable that Mg^{++} is required for normal calcium (Ca^{++}) absorption because severe Mg^{++} deficiency results in hypocalcemia.

Regular, moderate weightbearing exercise can slow the rate of bone loss and, in some cases, reverse demineralization because the mechanical stress of exercise stimulates bone formation. It is important to reduce the risk of falls and enhance bone quality. Therefore, an exercise program to enhance muscle strength is advised. Important new findings suggest that estrogen may prevent excessive bone loss before and after menopause by limiting osteoclast life span through promotion of apoptosis.

SERMs and SARMs have been developed to provide the positive effects of estrogen on bone but minimize estrogen's negative effect on breast and endometrial tissues. As a result, in addition to reducing vertebral fractures, SERMs reduce risk of estrogen receptor breast cancer and improve lipid profiles.[45] Raloxifene and tamoxifen are examples of SERMs.

Bisphosphonates are a class of inorganic pyrophosphate derivatives that bind bone mineral and improve osteoblast and osteocyte survival while promoting osteoclast apoptosis, thus slowing the bone remodeling process.[46] Nitrogen-containing bisphosphonates are highly effective in reducing both vertebral and nonvertebral osteoporotic fractures; because of this, bisphosphonates are the mainstay of osteoporosis treatment. Side effects include alterations in TGF-β signaling that may cause osteonecrosis of the jaw.[47] There also is a small risk of atypical femoral fractures, atrial fibrillation, and possibly esophageal cancer associated with bisphosphonates.[48-51] The optimal length of treatment with bisphosphonates has not yet been determined.[52]

One of the most promising treatments for osteoporosis is denosumab, a monoclonal antibody that that binds the cytokine receptor activator of NF-κβ ligand (RANKL). RANKL inhibition blocks the maturation, function, and survival of osteoclasts, thus reducing bone resorption.[53]

Teriparatide, also called PTH 1-34, is a biosynthetic form of parathormone and contains the first 34 amino acids of parathyroid hormone; PTH 1-84 is a recombinant PTH that contains all 84 amino acids of naturally occurring PTH. Both work by stimulating osteoblasts when administered intermittently.[54] Given by subcutaneous injection, PTH reduces vertebral fractures but use is limited to a period of 24 months because of the risk of developing osteosarcoma. A recent large meta-analysis of osteoporosis treatment found improved BMD and reduced fractures with bisphosphonates, SERMs, and denosumab, though each regimen has potential adverse effects.[55] Restoration of a balanced RANKL/OPG ratio (see p. 1553) or inhibition of RANK responsiveness is known to prevent osteoclast activation and bone resorption. Anti-RANKL therapy significantly reduces bone resorption. Other biologic agents under

investigation include cathepsin K inhibitors, antisclerostin, and anti-dickkopf antibodies that affect the Wnt/β-catenin signaling pathway in osteoblasts.[56]

Osteomalacia

Osteomalacia is a metabolic disease characterized by inadequate and delayed mineralization of osteoid in mature compact and spongy bone. In osteomalacia the remodeling cycle proceeds normally through osteoid formation, but mineral calcification (hydroxyapatite formation) does not occur. Bone volume remains unchanged, but the replaced bone consists of soft osteoid instead of rigid bone. The result is abnormal bone matrix mineralization. Rickets is similar to osteomalacia in pathogenesis, but it occurs in the growing bones of children, whereas osteomalacia occurs in adult bone. Chronically low serum phosphate levels can be caused by tumors resulting in osteomalacia.[57] Fibroblast growth factor-23 (FGF-23) plays a significant role in maintaining normal serum phosphate levels. Primarily produced by osteocytes, FGF-23 functions to inhibit reabsorption of phosphate in the renal proximal tubule.[58] (Rickets is described in Chapter 45.)

Osteomalacia and rickets are rare in the United States and Western Europe but are significant health problems in Great Britain, Ethiopia, Pakistan, Iran, and India. In the United States these diseases occur in older adults, in premature infants of very low birth weight, and in individuals adhering to rigid macrobiotic vegetarian diets. Breast-fed black infants who do not receive vitamin D supplementation have been shown to be at risk for developing nutritional rickets.[59,60]

Many factors contribute to the development of osteomalacia, but the most important is a deficiency of vitamin D. The major causes of vitamin D deficiency are diets deficient in vitamin D, decreased endogenous production of vitamin D, intestinal malabsorption of vitamin D, renal tubular diseases, and anticonvulsant therapy. Classic vitamin D deficiency is rare in the United States because of the addition of synthetic vitamin D to dairy products and bread. Still, disorders of the small bowel, kidneys, hepatobiliary system, and pancreas do cause vitamin D deficiency in the United States. In malabsorptive disease of the small bowel, vitamin D and calcium absorption are decreased, so vitamin D is lost in feces. Liver disease interferes with the metabolism of vitamin D to its more active form, and diseases of the pancreas and biliary system cause a deficiency of bile salts, which are necessary for normal intestinal absorption of vitamin D.

The mechanism by which anticonvulsant drug therapy results in decreased bone mineral density is not completely understood, but appears to be from direct impact on bone or effects on other regulators of bone metabolism such as calcium, vitamin D, and parathyroid hormone.[61] The anticonvulsants phenobarbital and phenytoin interfere with calcium absorption and increase degradation of vitamin D metabolism in the liver through activation of the cytochrome P-450 pathway.[62]

PATHOPHYSIOLOGY. Crystallization of minerals in osteoid requires adequate concentrations of calcium and phosphate. When the concentrations are too low, crystallization (and hence ossification) does not proceed normally.

Vitamin D deficiency disrupts mineralization because vitamin D normally regulates and enhances the absorption of calcium ions from the intestine. A lack of vitamin D causes the plasma calcium concentrations to fall. Low plasma calcium levels stimulate increased synthesis and secretion of parathyroid hormone (PTH). Although the increase in the level of circulating PTH raises the plasma calcium concentration, it also stimulates increased renal clearance of phosphate. When the concentration of phosphate in the bone decreases below a critical level, mineralization cannot proceed normally.

Abnormalities occur in spongy as well as compact bone. Trabeculae in spongy bone become thinner and fewer, whereas haversian systems in compact bone develop large channels and become irregular. Because osteoid continues to be produced but not mineralized, abnormal quantities of osteoid accumulate, coating the trabeculae and the linings of the haversian canals. Excessive osteoid also can accumulate in areas beneath the periosteum. The excess of osteoid leads to gross deformities of the long bones, spine, pelvis, and skull.

CLINICAL MANIFESTATIONS. Osteomalacia causes varying degrees of diffuse skeletal pain and tenderness. Bone pain is typically between joints, rather than within them.[59] Pain is noted particularly in the hips, and the individual may be hesitant to walk. Muscular weakness, particularly of the proximal muscles, is common and may contribute to a waddling gait. Facial deformities and bowed knees, or “knock-knees,” may be present. Bone fractures and vertebral collapse occur with minimal trauma. Low back pain may be an early complaint, but pain also may involve ribs, feet, other areas of the vertebral column, and other sites. Uremia may be present in renal osteodystrophy.

EVALUATION AND TREATMENT. Laboratory data may include elevated blood urea nitrogen (BUN) and creatinine levels, normal or low serum calcium levels, and a serum inorganic phosphate level that is usually higher than 5.5 mg. Alkaline phosphatase and PTH levels are usually elevated. Radiographic findings show pseudofractures and radiolucent bands perpendicular to the surface of involved bones. Bone biopsy is useful in determining bone structure and remodeling.[63] Diagnosis of certain types of osteomalacia is becoming easier because of the ability to measure an individual’s serum FGF-23 level. Elevated FGF-23 levels are common in X-linked hypophosphatemic and tumor-induced osteomalacia.[64]

Treatment of osteomalacia includes the following:

1. Adjusting serum calcium and phosphorous levels to normal
2. Suppressing secondary hyperthyroidism
3. Chelating bone aluminum if needed
4. Administering calcium carbonate to decrease hyperphosphatemia
5. Adding dietary supplements of vitamin D
6. Performing renal dialysis
7. Considering renal transplant for renal osteodystrophy

Paget Disease

Paget disease of bone (PDB or **osteitis deformans)** is a state of increased metabolic activity in bone characterized by abnormal and excessive bone resorption and formation (remodeling).

Genetic manipulations involving the RANK-NF-κβ signaling pathways are significant in the development of Paget disease, resulting in increased osteoclast activity.[65] Chronic accelerated remodeling eventually enlarges and softens the affected bones. Classic PDB arises as a consequence of disorderly bone resorption and formation.

PDB most often affects the axial skeleton, especially the vertebrae, skull, sacrum, sternum, pelvis, and femur. The disease process may occur in one or more bones without causing significant clinical manifestations.

The disease is seldom found before age 40 years, but its incidence almost doubles each decade from age 50. It affects men more than women in a proportion of 1.8:1. Because it is often symptomless and can be diagnosed only by invasive procedures, few epidemiologic data are available. Autopsy data from England and Germany indicate that approximately 3% to 4% of persons older than 40 years have Paget disease. It is most prevalent in Australia, Great Britain, New Zealand, and the United States.

The cause of PDB is unknown; however, studies have implicated both genetic and environmental factors. About 10% to 30% of individuals with PDB have mutations of a specific gene, sequestosome-1.[66-68] Even viral etiologies have been proposed.[65]

PATHOPHYSIOLOGY. Paget disease begins with excessive resorption of spongy bone and deposition of disorganized bone. The trabeculae diminish, and bone marrow is replaced by extremely vascular fibrous tissue. The resorption phase of Paget disease is followed by the formation of abnormal new bone at an accelerated rate. The collagen fibers are disorganized, and glycoprotein levels in the matrix decrease. Mineralization may extend into the bone marrow. Bone formation is excessive around partially resorbed trabeculae, causing them to thicken and enlarge. Eventually, Paget disease progresses to an inactive phase, in which abnormal remodeling is minimal or absent. Osteoclasts of individuals with Paget disease have increased responses to RANKL.[65]

CLINICAL MANIFESTATIONS. In the skull, abnormal remodeling is first evident in the frontal or occipital regions, and then encroaches on the outer and inner surfaces of the entire skull. The skull thickens and assumes an asymmetric shape (Figure 44-14). Thickened segments of the skull may compress areas of the brain, producing altered mentality and dementia. Impingement of new bone on cranial nerves causes sensory abnormalities, impaired motor function, deafness, atrophy of the optic nerve, and obstruction of the lacrimal duct. Headache is commonly noted.

Extensive alterations of the facial bones are rare except in the jaw, where sclerosis and thickening of the maxilla and mandible displace teeth and produce malocclusion. In long bones, resorption begins in the subchondral regions of the epiphysis and extends into the metaphysis and diaphysis. Warmth over the affected area, bone and joint pain, and bone deformity may occur. Occasionally, Paget disease affects both ends of a long bone. In the femur, PDB produces an exaggerated lateral curvature. In the tibia, anterior curvature is also exaggerated. Stress fractures are common in the lower extremities.

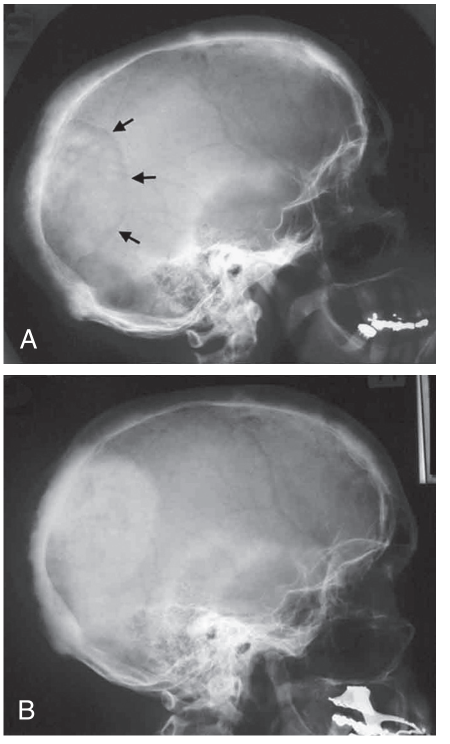

FIGURE 44-14 **Paget disease of the skull A,** Active Paget disease of the skull, with marked cortical thickening and an area of osteoporosis circumscripta *(arrows)*. **B,** The same individual several years later (after bisphosphonate treatment), with the lytic lesion largely replaced by sclerotic bone. (From Walsh JP: *Med J Aust* 181[5]:263, 2004.)

Clinical manifestations of PDB in the vertebral column depend on the level of involvement and are caused by compression of adjacent structures. In the cervical spine, cord compression can lead to spastic quadriplegia. Approximately 1% of persons with PDB develop osteogenic sarcoma. Paget-related sarcoma has a poor prognosis.

EVALUATION AND TREATMENT. Evaluation of PDB is made on the basis of radiographic findings of irregular bone trabeculae with a thickened and disorganized pattern. A typical V-shaped lesion in long bones and rounded areas of thinning bone in the skull are often seen on plain x-ray. Bone scanning can more readily detect early disease as well as extent of PDB through increased uptake of bone radionuclides. Serum total alkaline phosphatase and urinary hydroxyproline levels are elevated.[69]

Most individuals require no treatment because the disease is localized and does not cause symptoms. Treatment during active disease is for pain relief, prevention of deformity, or fracture. Bisphosphonates (alendronate, risedronate, and pamidronate) and calcitonin (salmon and human) are the mainstays of treatment. Surgery is indicated if there are neurologic complications or severe bony deformities.

Infectious Bone Disease: Osteomyelitis

Osteomyelitis is a bone infection most often caused by bacteria; however, fungi, mycobacteria, parasites, and viruses also can infect bone (Figure 44-15). Exogenous osteomyelitis is an infection that enters from outside the body, for example, through

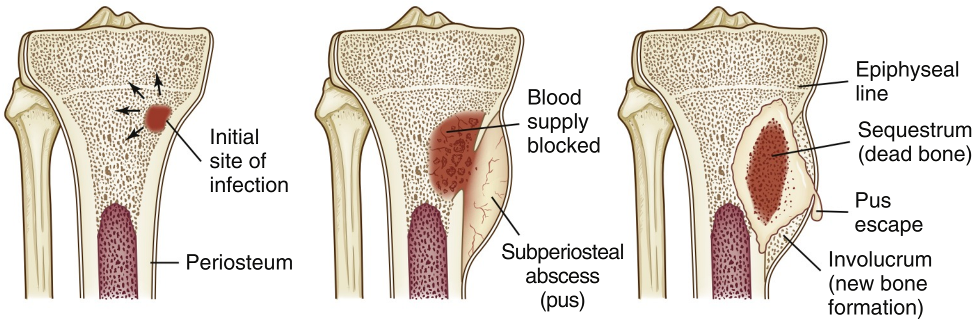

FIGURE 44-15 Osteomyelitis Showing Sequestration and Involucrum.

open fractures, penetrating wounds, or surgical procedures. In exogenous osteomyelitis, infection spreads from soft tissues into adjacent bone. Endogenous osteomyelitis is caused by pathogens carried in the blood from sites of infection elsewhere in the body. In hematogenous osteomyelitis, infection spreads from bone to adjacent soft tissues. Hematogenous osteomyelitis is commonly found in infants, children, and older adults. (Osteomyelitis in children is discussed in Chapter 45.) In infants, incidence rates among males and females are approximately equal. In children and older adults, however, males are most commonly affected. Osteomyelitis is a common complication of sickle cell anemia and low oxygen tension.

Staphylococcus aureus (including methicillin-resistant *Staphylococcus aureus* [MRSA]) is the primary cause of hematogenous osteomyelitis.[70] Other microorganisms include group B streptococci, *Haemophilus influenzae, Salmonella,* and gram-negative bacteria. Group B streptococci and *H. influenzae* tend to infect young children; *Salmonella* infection is associated with sickle cell anemia; and gram-negative infections are most common in older adults and individuals with impaired immunity. Mycobacterial and fungal infections occur in immunocompromised individuals.

Cutaneous, sinus, ear, and dental infections are the primary sources of bacteria in hematogenous bone infections. Soft tissue infections, disorders of the gastrointestinal tract, infections of the genitourinary system, and respiratory tract infections are also sources of bacterial contamination. In addition, infections contracted after total joint replacement surgeries can be causes of osteomyelitis. The vulnerability of specific bone depends on the anatomy of its vascular supply. In adults, hematogenous osteomyelitis is more common in the spine, pelvis, and small bones.

Microorganisms reach the vertebrae through arteries, veins, or lymphatic vessels. The spread of infection from pelvic organs to the vertebrae is well documented. Vaginal, uterine, ovarian, bladder, and intestinal infections can lead to iliac or sacral osteomyelitis.

Exogenous osteomyelitis can be caused by human bites or fist blows to the mouth. Superficial animal or human bites inoculate local soft tissue with bacteria that later spread to underlying bone. Deep bites can introduce microorganisms directly onto bone. The most common infecting organism in human bites is *S. aureus.* In animal bites the most common infecting organism is *Pasteurella multocida,* which is part of the normal mouth flora of cats and dogs.

Direct contamination of bones with bacteria also can occur in open fractures or dislocations with an overlying skin wound. Intervertebral disk surgery and operative procedures involving implantation of large foreign objects, such as metallic plates or artificial joints, are associated with exogenous osteomyelitis. Local injections and venous punctures are significant causes of exogenous osteomyelitis. Exogenous osteomyelitis of the arm and hand bones tends to occur in drug abusers. *S. aureus* is the most common pathogen. In general, persons who are chronically ill, have diabetes or alcoholism, or are receiving large doses of corticosteroids or immunosuppressive drugs are particularly susceptible to exogenous osteomyelitis or recurring episodes of this disease.

PATHOPHYSIOLOGY. Regardless of the source of the pathogen, the pathologic features of bone infection are similar to those in any other body tissue (see Chapter 10). First, the invading pathogen provokes an intense inflammatory response. Inflammation in bone is characterized by vascular engorgement, edema, leukocyte activity, small blood vessel thrombosis, and abscess formation.[71] Once inflammation is initiated, the small terminal vessels thrombose and exudate seals the bone's canaliculi. Inflammatory exudate extends into the metaphysis and the marrow cavity and through small metaphyseal openings into the cortex. In children, exudate that reaches the outer surface of the cortex forms abscesses that lift the periosteum off underlying bone. Lifting of the periosteum disrupts blood vessels that enter bone through the periosteum, which deprives underlying bone of its blood supply; this leads to necrosis and death of the area of bone infected, producing **sequestrum,** an area of devitalized bone (see Figure 44-15). Lifting of the periosteum also stimulates an intense osteoblastic response. Osteoblasts lay down new bone that can partially or completely surround the infected bone. This layer of new bone surrounding the infected bone is called an **involucrum.** Openings in the involucrum allow the exudate to escape into surrounding soft tissue and ultimately through the skin by way of sinus tracts. Involucrum in adults is rare because the periosteum is firmly attached to the cortex and resists displacement. Instead, infection disrupts and weakens the cortex, which predisposes the bone to pathologic fracture.

CLINICAL MANIFESTATIONS. Clinical manifestations of osteomyelitis vary with the age of the individual, site of involvement,

initiating event, infecting organism, and whether the infection is acute, subacute, or chronic. Acute osteomyelitis causes an abrupt onset of inflammation. If an acute infection is not completely eliminated, the disease may become subacute or chronic. In subacute osteomyelitis, signs and symptoms are usually vague. In the chronic stage, infection is indolent or silent between exacerbations. The microorganisms persist in small abscesses or fragments of necrotic bone and produce occasional flare-ups of acute osteomyelitis. The progression from acute to subacute osteomyelitis may be the result of inadequate or inappropriate therapy or the development of drug-resistant microorganisms.

In the adult, hematogenous osteomyelitis has an insidious onset. The symptoms are usually vague and include fever, malaise, anorexia, and weight loss. Recent infection (urinary, respiratory, skin) or instrumentation (catheterization, cystoscopy, myelography, diskography) usually precedes onset of symptoms.

Back pain is the primary symptom in vertebral osteomyelitis. Pain may be intermittent or constant, aggravated by motion, and throbbing at rest. It may radiate in a radicular distribution and is commonly accompanied by spinal tenderness and rigidity. Hip contracture can occur in the presence of soft tissue inflammation as a result of irritation of the psoas muscle.[72]

Signs and symptoms of sacroiliac osteomyelitis are generally severe and include local pain, tenderness, and a limp. The pain may radiate to the buttock or the abdomen.

Single or multiple abscesses (Brodie abscesses) characterize subacute or chronic osteomyelitis. Brodie abscesses are painless, circumscribed lesions 1 to 4 cm in diameter, usually in the ends of long bones, and surrounded by dense ossified bone matrix. The abscesses are thought to develop when the infectious microorganism has become less virulent or the individual's immune system is resisting the infection somewhat successfully.

In exogenous osteomyelitis, signs and symptoms of soft tissue infection predominate. Inflammatory exudate in the soft tissues disrupts muscles and supporting structures and forms abscesses. Low-grade fever, lymphadenopathy, local pain, and swelling usually occur within days of contamination by a puncture wound. Osteomyelitis in the hand causes exquisite tenderness over the course of tendon sheaths. The fingers are usually in a semiflexed position, and extension usually causes severe pain. Palmar swelling or symmetric swelling of the fingers may be present.

EVALUATION AND TREATMENT. Laboratory data show an elevated white cell count. Radiographic studies include radionuclide bone scanning, CT, and MRI. MRI is especially useful in detecting early bone changes associated with infection.[73]

Infectious bone disease is expensive and difficult to treat and often culminates in extensive physical disability. The following factors contribute to the difficulty in treating bone infection:

1. Bone contains multiple microscopic channels that are impermeable to the cells and biochemicals of the body's natural defenses. Once bacteria gain access to these channels, they are able to proliferate unimpeded.
2. The microcirculation of bone is highly vulnerable to damage and destruction by bacterial toxins. Vessel damage causes local thrombosis (blockage) of the small vessels, which leads to ischemic necrosis (death) of bone.
3. Bone cells have a limited capacity to replace bone destroyed by infections. Initially, osteoclasts are stimulated by infection to resorb bone, which opens up isolated bone channels so that cells of the inflammatory and immune system can gain access to the infected bone. At the same time, however, resorption weakens the structural integrity of the bone. New bone formation usually lags behind resorption, and the haversian systems in the new bone are incomplete.

Treatment of osteomyelitis includes surgical débridement with bone biopsy and culture before or as soon after initiating antibiotics as possible. Initial antibiotic therapy should be intravenous. Chronic conditions may require surgical removal of the inflammatory exudate followed by continuous wound irrigation with antibiotic solutions in addition to systemic treatment with antibiotics. **Hyperbaric oxygen therapy** of 100% oxygen, given at 2 atmospheres of pressure for 2 hours' duration per day for 30 treatments, is also beneficial for chronic refractory osteomyelitis. Implanted hardware may require removal to more thoroughly treat an infected joint.

Bone Tumors

Primary bone cancer is rare but metastatic disease commonly affects bone. Many different types of tumors involve the skeleton. Based on the tissue of origin, bone tumors are classified as osteogenic, chondrogenic, collagenic, or myelogenic. Each of the four types arises from one of the four stem cells that are ultimately derived from the primitive mesoderm (Figure 44-16). In addition, bone tumors may be classified as being of histiocytic, notochordal, lipogenic, and neurogenic origins (Box 44-3).

The mesoderm contributes the primitive fibroblast and reticulum cells. The fibroblast is the progenitor of the osteoblast and the chondroblast. Each cell synthesizes a specific type of intercellular ground substance, and the type of ground substance produced by the cell generally characterizes the tumor derived from the cell. For example, osteogenic tumors usually contain cells that have the appearance of osteoblasts and produce an intercellular substance that can be recognized as osteoid. Chondrogenic tumors contain chondroblasts and produce an intercellular substance similar to chondroid (cartilage). Collagenic tumors contain fibrous tissue cells and produce an intercellular substance similar to the type of collagen found in fibrous connective tissue.

Tumors are also classified as benign or malignant. The criteria used to identify tumor cells as malignant are: (1) an increased nuclear/cytoplasmic ratio, (2) an irregular nuclear border, (3) an excess of chromatin, (4) a prominent nucleolus, and (5) an increase in the number of cells undergoing mitosis. However, many young, rapidly growing, normal cells and cells subjected to inflammation and change in their blood supply also exhibit many of these same characteristics. (Tumor characteristics in general are described in Chapter 12.)

Epidemiology

The incidence of bone tumors varies with age. Osteosarcoma is the most common primary malignant bone tumor in children

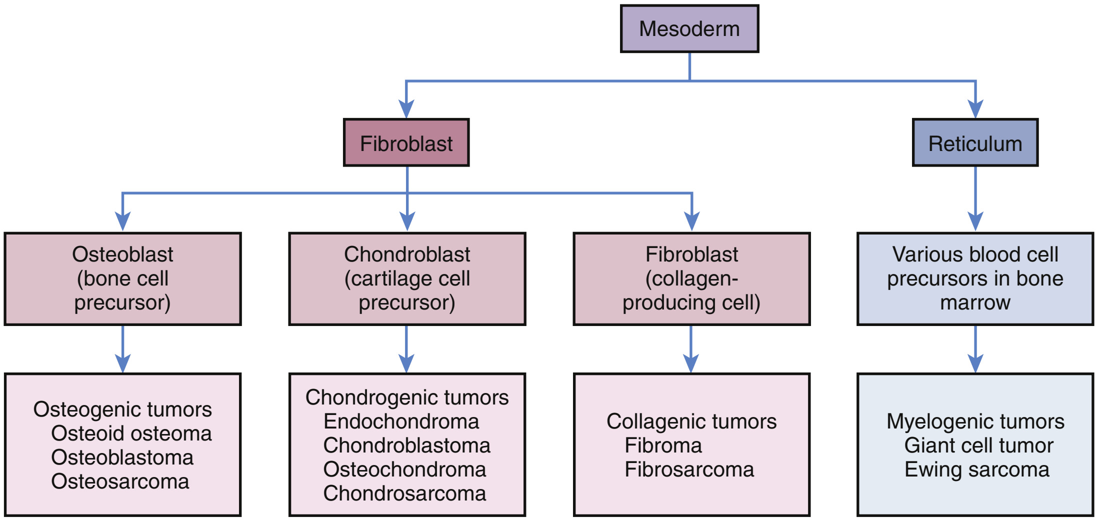

FIGURE 44-16 Derivation of Bone Tumors.

BOX 44-3 WORLD HEALTH ORGANIZATION (WHO) CLASSIFICATION OF BONE TUMORS

Cartilage Tumors
Chondrosarcoma (M)
Chondroma (B)
Osteochondroma (B; but may become malignant)
Chondroblastoma (B)

Osteogenic Tumors
Osteoblastoma (B)
Osteoid osteoma (B)
Osteosarcoma (M)

Fibrogenic Tumors (Often Produce Collagen; Do Not Have a Mineralizing Matrix)
Fibrosarcoma (M)

Fibrohistiocytic Tumors (Comprised of Fibroblasts)
Benign fibrous histiocytoma (B)
Malignant fibrous histiocytoma (M)

Ewing Sarcoma
Ewing sarcoma (M)

Hematopoietic Tumors
Plasma cell myeloma (M)
Malignant lymphoma (M)

Giant Cell Tumor
Giant cell tumor (B, but can grow aggressively)
Malignancy in giant cell tumor (M; very rare tumor)

Smooth Muscle Tumors
Leiomyoma (B)
Leiomyosarcoma (M)

Miscellaneous Tumors
Adamantinoma (M; almost exclusively found in tibia)
Metastatic malignancy (M; most common skeletal malignancy)

Miscellaneous Lesions
Aneurysmal bone cyst (B)
Simple cyst (B)
Fibrous dysplasia (B; rarely can become malignant)
Osteofibrous dysplasia (B)
Langerhans cell histiocytosis (B, but can aggressively grow)
Chest wall hamartoma (B; is excessive growth of mesenchymal tissue [mostly cartilage])

Joint Lesions
Synovial chondromatosis (B; rarely becomes M)

Data from Dorfman HD et al: WHO classification of tumours of bone: introduction. In Christopher DM et al, editors: *World Health Organization classification of tumours, International Agency for Research on Cancer (IARC) pathology and genetics of tumours of soft tissue and bone,* p 226, Lyon, France, 2002, IARC Press.
B, Benign lesion; *M,* malignant lesion.

and young adults.[74-76] Adolescents have the highest incidence of bone tumors, and adults between 30 and 35 years of age have the lowest incidence. After age 35, the incidence slowly increases until, at age 60, it equals the incidence in adolescents, primarily related to metastatic tumors.

Patterns of Bone Destruction

The general pathologic features of bone tumors include bone destruction, erosion or expansion of the cortex, and periosteal response to changes in underlying bone. The least amount of pathologic damage occurs with benign bone tumors that push against neighboring tissue. Because they usually have a symmetric, controlled growth pattern, benign bone tumors tend to compress and displace neighboring normal bone tissue, which weakens the bone's structure until it is incapable of withstanding the stress of ordinary use, leading to pathologic fracture. Other tumors invade and destroy adjacent normal bone tissue by producing substances that promote resorption by increasing

osteoclast activity or by interfering with a bone's blood supply. Three patterns of bone destruction by bone tumors have been identified: (1) the geographic pattern, (2) the moth-eaten pattern, and (3) the permeative pattern (Table 44-5).

Tumors that erode the cortex of the bone usually stimulate a periosteal response, that is, new bone formation at the interface between the surface of the bone and the periosteum. Slow erosion of the cortex usually stimulates a uniform periosteal response. Additional layers of bone are added to the exterior surface of the bone to buttress the cortex. Eventually the additional layers expand the bone's contour. Aggressive penetration of the cortex usually elevates the periosteum and stimulates erratic patterns of new bone formation. Examples of erratic patterns include concentric layers of new bone; a sunburst pattern, in which delicate rays of new bone radiate toward the periosteum from a single focus on the underlying surface; and rays of new bone that grow perpendicularly, creating a brush or bristle pattern.

Diagnosis

Malignant bone tumors account for less than 0.2% of all cancers.[76] A tumor must be identified early to allow survival of the individual and the preservation of the affected limb. However, individuals often have only vague symptoms that may be attributed to minor trauma, degenerative changes, or inflammatory conditions. In addition, other conditions may obscure the diagnosis.

Thorough diagnostic studies are needed to determine the exact type and extent of bone tumor present, which also helps determine the optimal treatment regimen. Staging of any bone tumor is critical to determine future treatment and results. The American Joint Committee on Cancer (AJCC) staging system (also known as Enneking or TNM Staging System) is the most commonly used arrangement (Table 44-6). This system classifies tumors as to grade (G), tumor site (T), and metastasis (M). Benign tumors are given a numeric value of zero, whereas malignant tumors are low grade (G_1) or high grade (G_2).

Serum alkaline phosphatase levels are elevated in bone lytic tumors, and they are significantly elevated in osteosarcoma and Ewing sarcoma. Radiologic studies include plain radiologic film, technetium-99 bone scan, CT scan, and MRI, which has become the examination of choice for the local staging of bone tumors, especially the staging of peripheral osteosarcomas (see Table 44-5). MRI is also used to monitor the response of osteosarcomas to radiation or chemotherapy and to detect recurrent disease. A CT scan can evaluate involvement of osteosarcoma in flat bones when the tumor is not well defined on a plain film, can assist in differentiating the tumor, and can locate pulmonary metastases. Radionucleotide bone scans show an increased uptake at the tumor site. Before any surgical procedure, bone biopsy or core needle biopsy should be performed. Core needle biopsy has less risk of tumor seeding.[76]

Additional diagnostic studies performed for specific bone tumors include a complete blood count and erythrocyte sedimentation rate (to rule out infection, myeloma, or Ewing sarcoma) and measurement of serum levels of calcium and phosphorus to detect hypercalcemia. Serum glucose levels may be elevated in chondrosarcoma. Acid phosphatase level may be moderately elevated in bone metastases, multiple myeloma, and advanced Paget disease. Serum protein electrophoresis and immunoelectrophoresis are done to rule out multiple myeloma. Fine-needle biopsy is done, usually at the time of surgery, to determine the exact tumor type.

TABLE 44-5 PATTERNS OF BONE DESTRUCTION BY BONE TUMORS

TYPE OF DESTRUCTION	PATTERN SEEN
Geographic	Well-defined margins separated from surrounding normal bone; well-defined lytic area in affected bone
Moth-eaten	Less-defined margin not easily separated from normal bone; areas of partially destroyed bone adjacent to completely lytic areas
Permeative	Poorly demarcated margins; abnormal lytic bone merges imperceptibly with surrounding normal bone

Types

A very large number of lesions are classified as bone tumors. The bone tumors most representative of the four derivative types (see Figure 44-16)—osteogenic, chondrogenic, collagenic, and myelogenic tumors—are described here.

Osteogenic Tumors: Osteosarcoma. **Osteogenic (bone-forming) tumors** are characterized by the formation of bone or osteoid tissue with a sarcomatous tissue. The tissue can have the appearance of compact or spongy bone. The most common malignant primary bone tumor is osteosarcoma.

TABLE 44-6 THE ENNEKING SURGICAL STAGING SYSTEM FOR MALIGNANT BONE TUMORS

STAGE	GRADE	SITE (T)	METASTASIS (M)
IA	Low (G_1)	Intracompartmental (T_1)	None (M_0)
IB	Low (G_1)	Extracompartmental (T_2)	None (M_0)
IIA	High (G_2)	Intracompartmental (T_1)	None (M_0)
IIB	High (G_2)	Extracompartmental (T_2)	None (M_0)
IIIA	Low (G_1)	Intracompartmental or extracompartmental (T_1 or T_2)	Regional or distant (M_1)
IIIB	High (G_2)	Intracompartmental or extracompartmental (T_1 or T_2)	Regional or distant (M_1)

Data from National Comprehensive Cancer Network: *Recent updates to NCCN clinical practice guidelines in oncology: bone cancer, National Comprehensive Cancer Network,* Version 1, Fort Washington, PA, 2013, Author.

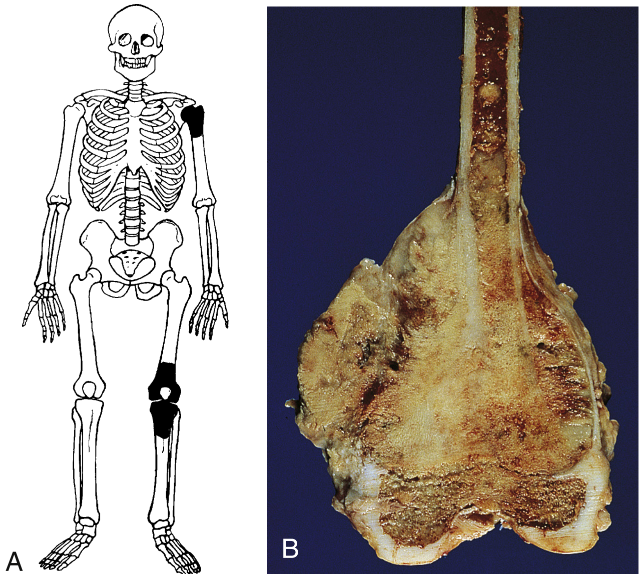

FIGURE 44-17 Osteosarcoma. **A,** Common locations of osteosarcoma. **B,** Femur has a large mass involving the metaphysis of the bone; the tumor has destroyed the cortex, forming a soft tissue component. (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

Osteosarcomas account for 38% of bone tumors. The male/female ratio is 3:2, and osteosarcoma occurs predominantly in adolescents and young adults; 60% of osteosarcomas occur in persons younger than 20 years. A secondary peak incidence for osteosarcoma occurs in the 60 and older age group, primarily in individuals with a history of radiation therapy several years previously for pelvic or other malignancies (Figure 44-17).

An osteosarcoma is a malignant bone-forming tumor. It is aggressive and most often found in bone marrow; it has a moth-eaten pattern of bone destruction. The borders of the tumor are indistinct and merge into adjacent normal bone. Osteosarcomas always contain osteoid and callus (osteoblastic sarcoma) produced by anaplastic stromal cells, which are atypical, abnormal cells not seen in normal developing bone; they are neither normal nor embryonal. The osteosarcoma also may contain chondroid (cartilage) (chondroblastic sarcoma) and fibrinoid tissue (fibroblastic sarcoma) that may form the bulk of the tumor. The osteoid is deposited in thick masses or "streamers" between the trabeculae of callus, which infiltrate the normal compact bone, destroy it, and replace it with dense callus and masses of osteoid. Demonstrating the presence of osteoid aids in the diagnosis of osteosarcoma. Bone tissue produced by osteosarcomas never matures to compact bone.

Ninety percent of osteosarcomas are located in the metaphyses of long bones, especially the distal femur and proximal tibia, with 50% around the knee area. The tumor typically breaks through the cortex, lifts the periosteum, and forms a soft tissue mass that is *not* covered by a smooth shell of new bone. Lifting of the periosteum stimulates bizarre patterns of new bone formation called a *periosteal reaction.* Distinct osteosarcomas occur on the surface of long bones, called parosteal, periosteal, or high-grade surface osteosarcomas; dedifferentiated parosteal and central osteosarcomas also occur.

The most common initial symptoms are pain and swelling. Initially the pain is slight and intermittent, but within a short time it increases in severity and duration. Pain is usually worse at night and gradually requires medication. Systemic symptoms are uncommon. Usually a coincidental history of trauma is noted. Occasionally the individual may have a pathologic fracture.

Systemic chemotherapy and surgery are the treatments of choice, with the location of the tumor and its size, malignancy grade, and evidence of metastasis dictating the type and extent of surgery. Preoperative chemotherapy has greatly increased the number of individuals qualifying for limb salvage surgery. Limb salvaging procedures have been made possible by advances in reconstructive techniques and endoprosthetics. Limb salvage ultimately may be successful in as many as 80% of persons. Individuals must have achieved most of their bone growth to be candidates for limb salvage procedures, which are preferred to amputation. Skeletally immature individuals may have a limb salvage operation, referred to as a *rotationplasty,* in which the major portions of the thigh, the tumor, and contaminated knee are resected while preserving the nerve supply (sciatic) to the leg and foot. The proximal tibia is internally fixed to the stump of the proximal femur after it has been rotated 180 degrees. The foot is positioned at a desired spot or direction, allowing the ankle joint to function as a knee joint with the foot supplying the traditional role of the tibial stump in a below-knee amputation.

If an amputation is done, individuals are monitored closely with chest roentgenograms and CT. Pulmonary metastases are surgically resected, and chemotherapy is now a common therapy given both before and after surgery, using combinations of chemotherapeutic agents. Promising agents under investigation include monoclonal antibodies, hormone antagonists, gene therapy, and other biologic agents that may dramatically improve survival.[77,78]

Chondrogenic Tumors: Chondrosarcoma. **Chondrogenic (cartilage-forming) tumors** produce cartilage or **chondroid,** a primitive cartilage or cartilage-like substance. The most common chondrogenic tumor is chondrosarcoma, accounting for 20% of bone tumors.

Chondrosarcoma, the second most common primary malignant bone tumor, is a tumor of middle-age and older adults; incidence peaks in the sixth decade of life.[79] The tumor is found more commonly in men than in women. Pre-existing chondral lesions, such as osteochondromas, can give rise to secondary chondrosarcoma, which, generally, has a fairly good prognosis.[80]

A chondrosarcoma is a large ill-defined malignant tumor that infiltrates trabeculae in spongy bone. It produces cartilage-forming cells but there is no ossification, as in normal endochondral bone formation.[81] It occurs most often in the metaphysis or diaphysis of long bones, especially the femur, and in the bones of the pelvis (Figure 44-18). The tumor contains large lobules of hyaline cartilage that are separated by bands of fibrous tissue and anaplastic cells. Chondrosarcomas typically implant in surrounding tissue ("seeding").

Symptoms associated with chondrosarcoma have an insidious onset. Local swelling and pain are the usual symptoms that cause a person to seek treatment. At first the pain is dull and

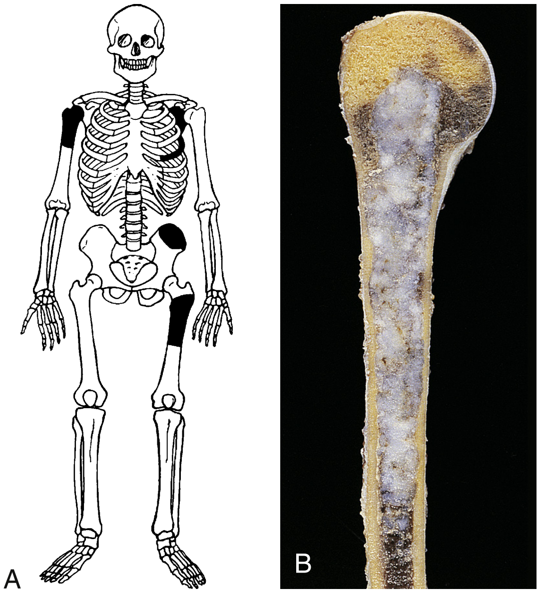

FIGURE 44-18 **Chondrosarcoma. A,** Common locations of chondrosarcoma. **B,** Chondrosarcoma of humerus. (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

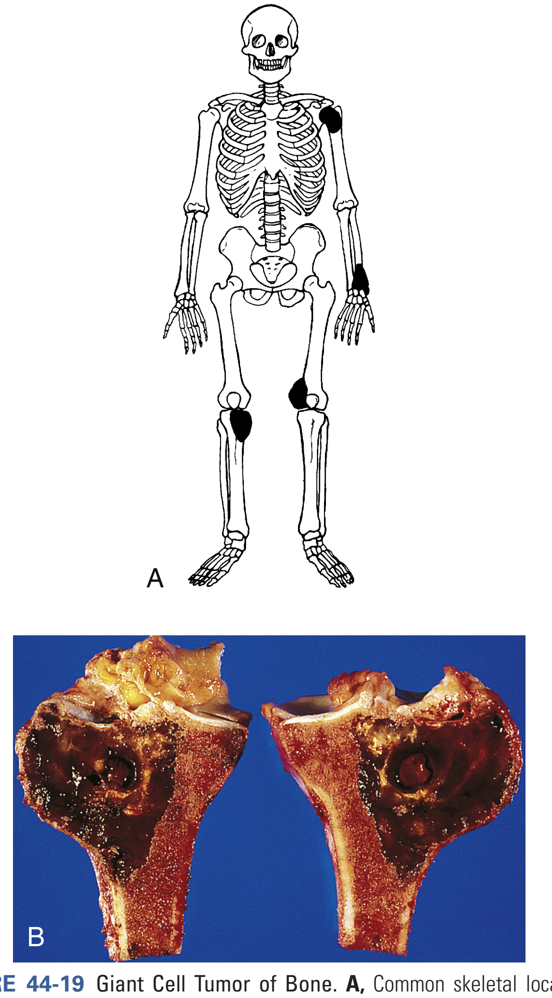

FIGURE 44-19 **Giant Cell Tumor of Bone. A,** Common skeletal locations. **B,** Gross picture of cell tumor of bone (epimetaphysis). (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

intermittent, then gradually intensifies and becomes constant. It may awaken the person at night.

Diagnostic studies include radiographs, which must be reviewed carefully for an accurate diagnosis. Biopsy is done at the time of surgery. (If biopsy is done before scheduled surgical incision, seeding of tumor cells could occur.) Sufficient tumor material must be obtained to facilitate an accurate diagnosis.

Wide surgical excision is generally regarded as the treatment of choice because chemotherapy and radiation seem to have little effect.[81] Many surgically treated individuals demonstrate recurrences, however, so amputation is becoming one treatment of choice. Therefore, individuals with tumors located in the limbs have a better prognosis than those with pelvic lesions.

Collagenic Tumors: Fibrosarcoma. **Collagenic (collagen-forming) tumors** produce fibrous connective tissue. The most typical collagenic tumor is the fibrosarcoma.

Fibrosarcomas come from fibroblasts that originate from mesenchymal stem cells and represent 4% of primary malignant bone tumors, with a broad age distribution. They may occur at any age but are most common in adults between 30 and 50 years of age. Fibrosarcoma also may be a secondary complication of radiation therapy, Paget disease, and long-standing osteomyelitis; secondary fibrosarcoma tends to be more aggressive, with poorer outcome.

Fibrosarcoma is a solitary tumor that most often affects the metaphyseal region of the femur or tibia. The tumor is composed of a firm fibrous mass of tissue that contains collagen, malignant fibroblasts, and occasional osteoclast-like giant cells.

The tumor begins in the marrow cavity of the bone and infiltrates the trabeculae. It demonstrates a permeative growth pattern, destroys the cortex, and extends into the soft tissue. Metastasis to the lung is common.

Symptoms associated with the tumor have an insidious onset, which delays diagnosis. Pain and swelling, the usual symptoms that cause the individual to seek treatment, usually indicate that the tumor has broken through the cortex. Local tenderness, the presence of a palpable mass, and limitation of motion also may be present. A pathologic fracture in the affected bone is often the reason for seeking medical help. Diagnostic studies include radiographs and MRI.

Radical surgery and amputation are the treatments of choice for fibrosarcoma. Radiation therapy is generally considered ineffective treatment for this tumor.

Myelogenic Tumors. **Myelogenic tumors** originate from various bone marrow cells. Two types of myelogenic tumors are giant cell tumor and myeloma. Myeloma is discussed in Chapter 29.

Giant Cell Tumor. Giant cell tumor is the sixth most common of the primary bone tumors, accounting for 4% to 5% of bone tumors. Giant cell tumors have a wide age distribution; however, they are rare in persons younger than 10 years or older than 70 years. Most giant cell tumors are found in persons between 20 and 40 years of age. Unlike most other bone tumors, giant cell tumors affect females more often than males.[82]

Giant cell tumors are generally benign, solitary, circumscribed tumors that cause extensive bone resorption because of their osteoclastic origin (Figure 44-19). There is a high

rate of recurrence but metastasis is rare. The tumor is rich in osteoclast-like giant cells and anaplastic stromal cells. It also may contain osteoid, callus, and collagen. Overexpression of several genes, including osteoprotegerin ligand (OPGL), occurs in giant cell tumors. The giant cell tumor is typically located in the center of the epiphysis in the femur, tibia, radius, or humerus. The tumor has a slow, relentless growth rate and is usually contained within the original contour of the affected bone. Tumors are often associated with pathologic fractures because of aggressive bone resorption.[83] It may, however, extend into the articular cartilage. When the tumor extends, it is usually covered by periosteum or periosteal bone growth.

The most common symptoms associated with giant cell tumor are pain, local swelling, and limitation of movement. Diagnostic studies include radiographs, CT, and MRI. Cryosurgery and resection of the tumor with the use of adjuvant polymethylmethacrylate (PMMA) for bone grafts decrease recurrence and are more successful treatments than curettage and radiation.[84] Amputation may be necessary but is not common.

DISORDERS OF JOINTS

The American College of Rheumatology (ACR) recognizes 13 groups of joint disease—**arthropathies.** Most of these disorders can be placed into two major categories: noninflammatory joint disease and inflammatory joint disease. With recent improvements in detection methods, conditions such as osteoarthritis that were previously classified as noninflammatory have now had inflammatory pathways identified.

Osteoarthritis

Osteoarthritis (OA) is a common age-related disorder of synovial joints. It is characterized by local areas of loss and damage of articular cartilage, new bone formation of joint margins (osteophytosis), subchondral bone changes, variable degrees of mild synovitis, and thickening of the joint capsule (Figure 44-20). OA has been commonly classified as **noninflammatory joint disease.** However, it is clear that specific markers of inflammation are present in OA and inflammation is an important feature of OA. The use of MRI and arthroscopy has made it clear that osteoarthritic changes are not defined by changes noted on x-ray films alone.

The exact cause of OA is uncertain; however, pathology centers on load-bearing areas. Advancing disease reveals narrowing of the joint space because of cartilage loss, bone spurs **(osteophytes),** and sometimes changes in the subchondral bone. It is uncommon in people younger than 40 years but rises in incidence with age. Low-grade inflammation, calcification of articular cartilage, genetic alterations, and metabolic disorders combined with the interaction of transcription factors, cytokines, growth factors, matrix molecules, and enzymes affect development and progression of OA.[85,86] OA is generally distributed throughout the peripheral and central joints of the body (hips, hands, knees, and spine). With aging, the quality and quantity of the proteoglycans in cartilage decrease in direct proportion to the severity of OA.

OA can be caused by any condition that damages cartilage directly; subjects the joint surfaces or underlying bone to chronic, excessive, or abnormal forces; or causes instability in the joint. Specific risk factors include the following:

1. Trauma, particularly sprains, strains, joint dislocations, and fractures
2. Long-term mechanical stress associated with athletics, ballet dancing, or repetitive physical tasks worsened by obesity
3. The presence of inflammation in joint structures, during which inflammatory cells release enzymes capable of digesting cartilage cells
4. Joint instability caused by damage to supporting structures, such as the joint capsule, ligaments, or tendons
5. Neurologic disorders (e.g., diabetic neuropathy, Charcot neuropathic joint) in which pain and proprioceptive reflexes are diminished or lost, increasing the tendency for abnormal movement, positioning, or weightbearing
6. Congenital or acquired skeletal deformities
7. Hematologic or endocrine disorders, such as hemophilia, which causes chronic bleeding into the joints, or hyperparathyroidism, which causes bone to lose calcium
8. Drugs (e.g., colchicine, indomethacin, steroids) that stimulate the activity of collagen-digesting enzymes in the synovial membrane
9. Obesity

All of these factors alter articular cartilage in some way and accelerate the rate of cartilage loss.

PATHOPHYSIOLOGY. The primary defect in OA is loss of articular cartilage. Early in the disease, the articular cartilage loses its glistening appearance, becoming yellow-gray or brownish gray. As the disease progresses, surface areas of the articular cartilage flake off and deeper layers develop longitudinal fissures (fibrillation). The cartilage becomes thin and may be absent over some areas, leaving the underlying bone (subchondral bone) unprotected. Consequently, the unprotected subchondral bone becomes sclerotic (dense and hard). Cysts sometimes develop within the subchondral bone and communicate with the longitudinal fissures in the cartilage. Pressure builds in the cysts until the cystic contents are forced into the synovial cavity, breaking through the articular cartilage on the way. As the articular cartilage erodes, cartilage-coated osteophytes may grow outward from the underlying bone and alter the bone contours and joint anatomy. These spur-like bony projections enlarge until small pieces, called *joint mice,* break off into the synovial cavity. If osteophyte fragments irritate the synovial membrane, synovitis and joint effusion result. The joint capsule also becomes thickened and at times adheres to the deformed underlying bone, which may contribute to the limitation of movement (see Figure 44-20).

Articular cartilage is lost through a cascade of cytokine and anabolic growth factor pathways.[87] Enzymatic processes, particularly those involving matrix metalloproteinases, break down the macromolecules of proteoglycans, glycosaminoglycans, and collagen into large, diffusible fragments. The fragments are then taken up by the cartilage cells (chondrocytes) and digested by the cell's own lysosomal enzymes. (Processes of cellular uptake and lysosomal digestion are described in Chapter 1.) The loss of

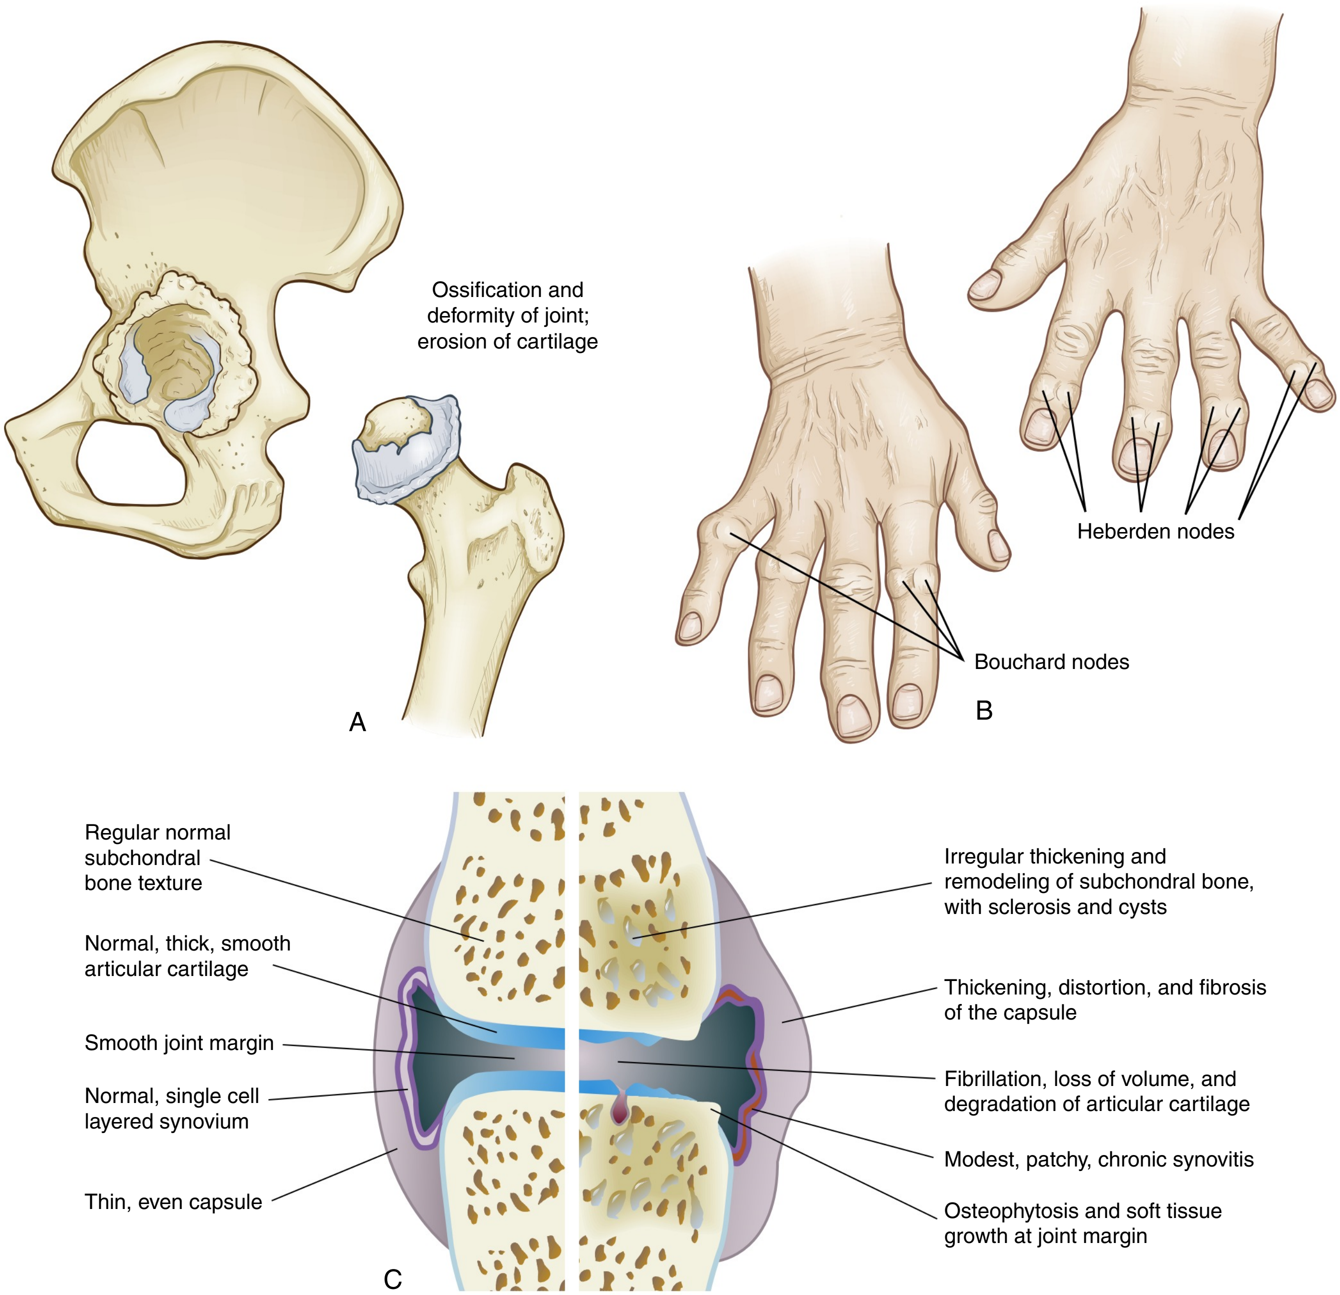

FIGURE 44-20 Osteoarthritis (OA). **A,** Cartilage and degeneration of the hip joint resulting from osteoarthritis. **B,** Heberden nodes and Bouchard nodes. **C,** Characteristics of OA. Normal vs. osteoarthritic synovial joint.

proteoglycans from articular cartilage is a hallmark of the osteoarthritic process.

Enzymatic destruction of articular cartilage begins in the matrix, with destruction of proteoglycans and collagen fibers. Enzymes, particularly stromelysin and matrix metalloproteinases (collagenase), affect proteoglycans by interfering with assembly of the proteoglycan subunit or the proteoglycan aggregate (see Chapter 43); levels of these enzymes are markedly elevated in OA. Changes in the conformation of proteoglycans disrupt the pumping action that regulates movement of water and synovial fluid into and out of the cartilage. Without the regulatory action of the proteoglycan pump, cartilage absorbs too much fluid and becomes less able to withstand the stresses of weightbearing. Also with aging, the proteoglycan content is decreased and the water content in cartilage can be increased by as much as 8%, affecting the strength of the cartilage. Persons with OA, even those with fairly extensive cartilage destruction, have elevated levels of proteoglycans or fragments of proteoglycans in their synovial fluid, perhaps indicative of a more pronounced reparative phase. Inflammatory cytokines, such as IL-1 and TNF (see Chapter 8 for a discussion of cytokines), play a major role in cartilage degradation in part through induction of nitric oxide synthase (iNOS) and nitric oxide (NO) increased generation. Cytokines release and activate proteolytic and collagenolytic enzymes, causing an imbalance of cell responses to growth factor activity.[87]

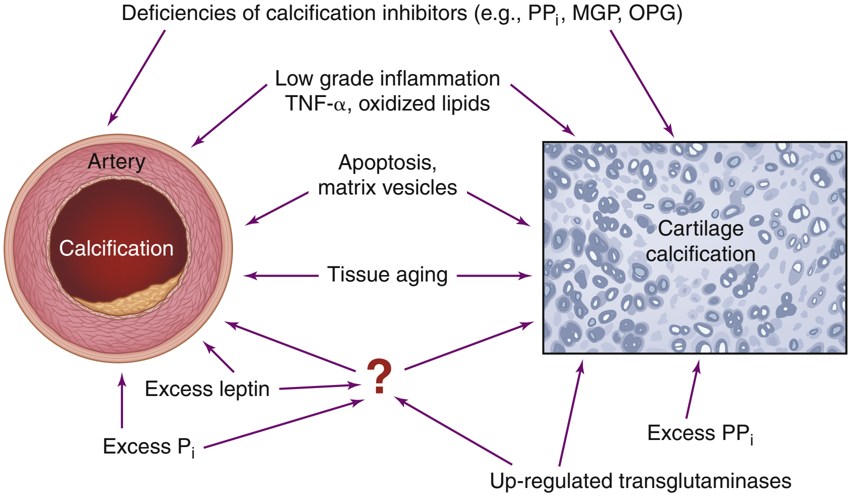

FIGURE 44-21 Possible Mechanisms Driving Artery and Cartilage Calcification. All specified factors have been demonstrated to promote calcification in either arteries and/or cartilage (see text). *MGP,* Matrix GLA-protein; *OPG,* osteoprotegerin; *Pi,* inorganic phosphate; *PPi,* inorganic pyrophosphate. (From Rutsch F, Terkeltaub R: *Joint Bone Spine* 72:110–118, 2005.)

Crosstalk between signaling pathways contributes to the development and progression of OA.[88] Some of the enzymes that degrade collagen (e.g., chemokines and metalloproteinases) are produced by the synovium. Chondrocyte apoptosis is increased in OA cartilage and is directly correlated with hydroxyapatite crystal deposition. Nitric oxide (NO) stimulates apoptosis in chondrocytes. The resultant cartilage destruction initiates the IL-1β and TNF-α pathways of inflammation. Genetic deficiencies of inhibitors of calcification also may contribute to "run away" calcification (Figure 44-21). Collagen breakdown destroys the fibrils that give articular cartilage its tensile strength and exposes the chondrocytes to mechanical stress and enzyme attack. Thus a cycle of destruction begins that involves all the components of articular cartilage—proteoglycans, collagen fibers, and chondrocytes.

CLINICAL MANIFESTATIONS. Clinical manifestations of OA typically appear during the fifth or sixth decade of life, although asymptomatic articular surface changes are common after age 40. Pain and stiffness in one or more joints, usually weightbearing or load-bearing joints, are the first symptoms of the disease. Use-related joint pain relieved by rest is a key feature. Examination usually shows general involvement of peripheral and central joints. Peripheral joints most often involved are in the hands, wrists, knees, and feet. Central joints most often affected are in the lower cervical spine, lumbosacral spine, shoulders, and hips.

Pain and stiffness are the predominant symptoms of OA; others include swelling, tenderness, or enlargement/deformity of joints. Symptoms are usually aggravated by weightbearing or use of the joint and relieved by resting the joint. Sometimes pain is referred to another part of the body. For example, osteoarthritis of the lumbosacral spine may mimic sciatica, causing severe pain in the back of the thigh along the course of the sciatic nerve. OA in the lower cervical spine may cause brachial neuralgia (pain in the arm) aggravated by movement of the neck. Osteoarthritic conditions in the hip cause pain that may be referred to the lower thigh and knee area.

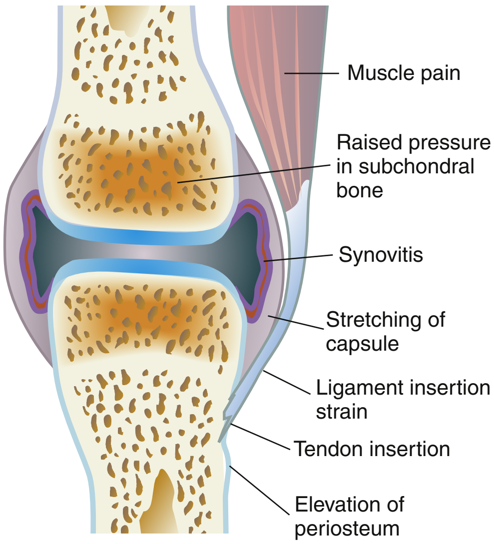

FIGURE 44-22 Possible Causes of Pain in Osteoarthritis.

The actual mechanisms of joint pain are complex and poorly understood, but several explanations are possible. Subchondral bone changes, weightbearing stress, and inflammatory mediators may be sources of joint pain in OA.[89,90] Nonetheless, there is little correlation between radiologic appearance of OA and an affected person's pain level.[91] Articular distention and stretching of the fibrous joint capsule, which has an abundant nerve supply may also contribute to pain. In addition, inflammation of the joint capsule causes fibrous shrinking, so that movement of the joint in any direction causes painful stretching (Figure 44-22).

The origin of joint stiffness is unknown. **Joint stiffness** is generally defined as difficulty in initiating joint movement, immobility, or a loss of range of motion. The extent of cartilage degeneration also limits range of motion to some degree. The stiffness usually occurs as joint movement begins and dissipates within 30 minutes. Enlargement and bulging of joint

contour, commonly described as swelling, may be caused by bone enlargement or the proliferation of osteophytes around the margins of the joint. These types of typical joint swelling in the fingers are termed Heberden and Bouchard nodes. Swelling also occurs if inflammatory exudate or blood enters the joint cavity, thereby increasing the volume of synovial fluid. This condition, termed **joint effusion,** is caused by (1) the presence of osteophyte fragments in the synovial cavity, (2) drainage of cysts from diseased subchondral bone, or (3) acute trauma to joint structures, resulting in hemorrhage and inflammatory exudation into the synovial cavity.

Abnormal knee alignment (either varus or valgus of more than 5 degrees) has been shown to increase progression of OA.[92] Gait abnormalities may ensue attributable to knee malalignment.

EVALUATION AND TREATMENT. Evaluation consists of clinical assessment and radiologic studies, CT scan, arthroscopy, and MRI. Treatment is based on severity of symptoms. Research is ongoing to evaluate the use of specific biomarkers to allow earlier detection of OA and monitor its progress.[93] Conservative treatment includes rest of the involved joint until inflammation, if present, subsides; participation in aerobic exercise and range-of-motion exercise to prevent joint capsule contraction; use of a cane, crutches, or walker to decrease weightbearing; weight loss if obesity is present; and analgesic and anti-inflammatory drug therapy to reduce pain and swelling. Glucosamine and chondroitin, so-called nutraceuticals, are not currently recommended.[94] Other alternative therapies, including magnetic bracelets and acupuncture, seem to improve symptoms in some people as do intra-articular injection of high-molecular-weight viscosupplements, particularly hyaluronic acid. New technologies, including tissue engineering, hold promise for reversing degenerative joint changes (see What's New? Tissue Engineering for Cartilage and Tendon).

Surgery is used to improve joint movement, correct deformity or malalignment, or create a new joint with artificial implants. There are nearly 250,000 total hip replacements yearly in the United States, most of which are related to OA.

Classic Inflammatory Joint Disease

Inflammatory joint disease commonly is called *arthritis.* Inflammatory joint disease is characterized by damage or destruction in the synovial membrane or articular cartilage and by systemic signs of inflammation (fever, leukocytosis, malaise, anorexia, hyperfibrinogenemia).

Inflammatory joint disease can be infectious or noninfectious. In infectious inflammatory joint disease, inflammation is caused by invasion of the joint by bacteria, mycoplasmas, viruses, fungi, or protozoa. These agents can invade the joint through a traumatic wound, surgical incision, or contaminated needle, or they can be delivered by the bloodstream from sites of infection elsewhere in the body, typically bones, heart valves, or blood vessels. In noninfectious inflammatory joint disease, inflammation is caused by the deposition of crystals of monosodium urate in and around the joint (gout) or by immune reactions (rheumatoid arthritis and ankylosing spondylitis).

WHAT'S NEW?

Tissue Engineering for Cartilage and Tendon

Chronic musculoskeletal disorders involving joints and soft tissue cause significant disability and loss of productivity. Articular cartilage degeneration related to osteoarthritis affects a majority of people over the age of 65 and often results in chronic pain and disability. After laceration or rupture of a tendon, healing can take months to occur and return of normal function is often limited.

Efforts to surgically repair or replace damaged cartilage and tendon have been frustrated by inferior mechanical and functional qualities of repaired tissue compared to healthy, noninjured tissue. New techniques, however, promise improved return of preinjury characteristics.

Nanotechnology has allowed development of a scaffold for cartilage repair that mimics the body's natural endochondral framework for cartilage and bone development. This biomimetic structure has been used to treat osteochondral cartilage defects in a recent clinical trial. Future nanocomposites that mimic bone are also under exploration.

Tendon scaffolds using nanofibers are being investigated. In soft tissue such as tendon, use of scaffolds for implanting mesenchymal stem cells (MCSs) and growth factors can increase tendon strength and improve biomechanical properties of healing tissue. Other ongoing research is focusing on combining MCSs, type I collagen sponges, and constructs treated with mechanical stimulation to improve mechanical and cellular properties of tissue.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic, systemic inflammatory autoimmune disease distinguished by joint swelling and tenderness and destruction of synovial joints, leading to disability and premature death.[95] (Autoimmune disease is described in Chapter 9.) The first joint tissue to be affected is the synovial membrane, which lines the joint cavity (see Chapter 43 and Figure 43-9). Multiple immunoregulatory cytokines (such as interleukins, B cells, and matrix metalloproteinases) contribute to joint damage. Eventually, inflammation may spread to the articular cartilage, fibrous joint capsule, and surrounding ligaments and tendons, causing pain, joint deformity, and loss of function (Figure 44-23). The joints most commonly affected are in the fingers, feet, wrists, elbows, ankles, and knees, but the shoulders, hips, and cervical spine also may be involved, as well as the tissues of the lungs, heart, kidneys, and skin.

Over the past five decades, the incidence and prevalence of RA have decreased, and RA now affects between 0.5% and 1% of the adult population in developed countries.[96] The frequency of RA increases with age. Besides inflammation of the joints, RA can cause fever, malaise, rash, lymph node or spleen enlargement, and Raynaud phenomenon (transient lack of circulation to the fingertips and toes).

Despite intensive research, the cause of RA remains obscure. It is likely a combination of genetic factors interacting with inflammatory meditators. The intricate interplay of chemokines (powerful mediators of inflammation) is largely responsible for RA's chronic inflammatory characteristics. Ligand/receptor chemokines attract T cells and produce inflammatory changes.[97]

A key genetic element has been localized to the human leukocyte antigen-death receptor 4 *(HLA-DR4)*, *HLA-DRB1* (death receptor beta), and *HLA-DP* genes of the major histocompatibility complex in all ethnic groups. A surprising new discovery is the presence of T-cell abnormalities in individuals with RA, indicating a defect in telomere repair that may result in faster aging of telomeres with subsequent loss of efficient immune function.[97] Types of infectious arthritis are summarized in Table 44-7. With long-term or intensive exposure to the antigen, normal antibodies (immunoglobulins [Igs]) become autoantibodies—antibodies that attack host tissues (self-antigens). Because they are usually present in individuals with rheumatoid arthritis, the altered antibodies are termed **rheumatoid factors (RFs).** RFs usually consist of two classes of immunoglobulin antibodies (antibodies for IgM and IgG) but occasionally involve antibodies for IgA. Their main antigenic targets are portions of the immunoglobulin molecules. RFs bind with their target self-antigens in blood and synovial membrane, forming immune complexes (antigen-antibody complexes) (see Chapter 8).

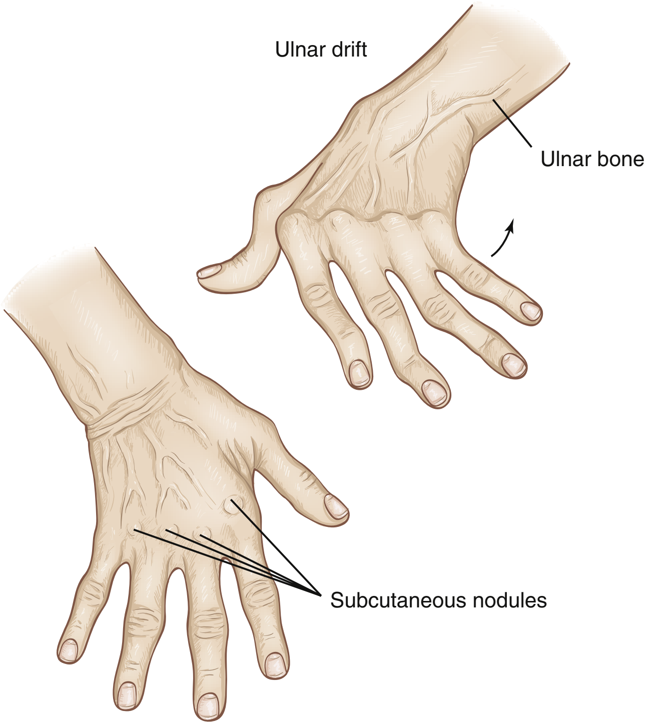

FIGURE 44-23 **Rheumatoid Arthritis of the Hand.** Note swelling from chronic synovitis of metacarpophalangeal joints, marked ulnar drift, subcutaneous nodules, and subluxation of metacarpophalangeal joints with extension of proximal interphalangeal joints and flexion of distal joints. Note also deformed position of thumb. Hand has wasted appearance. (From Mourad L: *Orthopedic disorders*, St Louis, 1991, Mosby.)

Environmental factors including geographic area of birth, length of breast-feeding, socioeconomic status, and especially smoking have been identified as risk factors for developing RA.[98] RA and other autoimmune diseases have a higher prevalence among women.[99] The reasons for this are unclear, but hormones and genetics play a role as shown by RA symptom improvement during pregnancy and flares with breast-feeding.

PATHOPHYSIOLOGY. Although no specific events (such as trauma, illness, or environmental conditions) have been identified that would cause immune abnormalities to develop into localized tissue and joint inflammation, the pathology of RA is fairly well understood. During inflammation, arginine (an α-amino acid) can be enzymatically modified into another α-amino acid, citrulline. This process (citrullination) changes the structure and function of the protein. Other proteins, like fibrin and vimentin, can become citrullinated during cell death and tissue inflammation.[100] In turn, the citrullinated proteins can be seen as antigens by the body's immune system. Thus, both T and B cells play a role in the autoimmune response. T cells express receptor activator of nuclear factor $\kappa\beta$ ligand (RANKL), which promotes osteoclast formation, causing bony erosion.[97]

Inflammatory cytokines, particularly tumor necrosis factor-alpha (TNF-α), interleukin-1 beta (IL-1β), interleukin-6

TABLE 44-7 TYPES OF INFECTIOUS ARTHRITIS

TYPE AND MICROORGANISM	COMMENTS
Lyme arthritis	Initial infection of skin followed by spreading to other sites including joints in days or weeks
Spirochete *Borrelia burgdorferi* Transmitted via ticks *(Ixodes scapularis* or *I. pacificus)*	Arthritis is a predominant feature involving mainly large joints; possibly caused by immune reactions against *Borrelia* antigens (such as Osp A) that cross-react with tissue antigens in joints
Tuberculous arthritis	Weightbearing joints most susceptible
Complication of osteomyelitis or visceral, usually pulmonary, infection	Fibrous ankylosis and destruction of joint space; onset is insidious and gradual
Suppurative arthritis	Classic is a sudden onset of symptoms—painful, hot, swollen joint with decreased range of motion
Bacterial infections with *Gonococcus, Staphylococcus, Streptococcus, Haemophilus influenzae,* and gram-negative bacilli; *H. influenzae* arthritis more common in children younger than 2 years; *S. aureus* in older children and adults	Prompt therapy prevents joint destruction
Viral arthritis	Symptoms vary from acute to subacute
Many viruses including parvovirus B19, rubella, hepatitis C virus, human immunodeficiency virus	Unclear if effects are from direct invasion of the virus or an autoimmune reaction

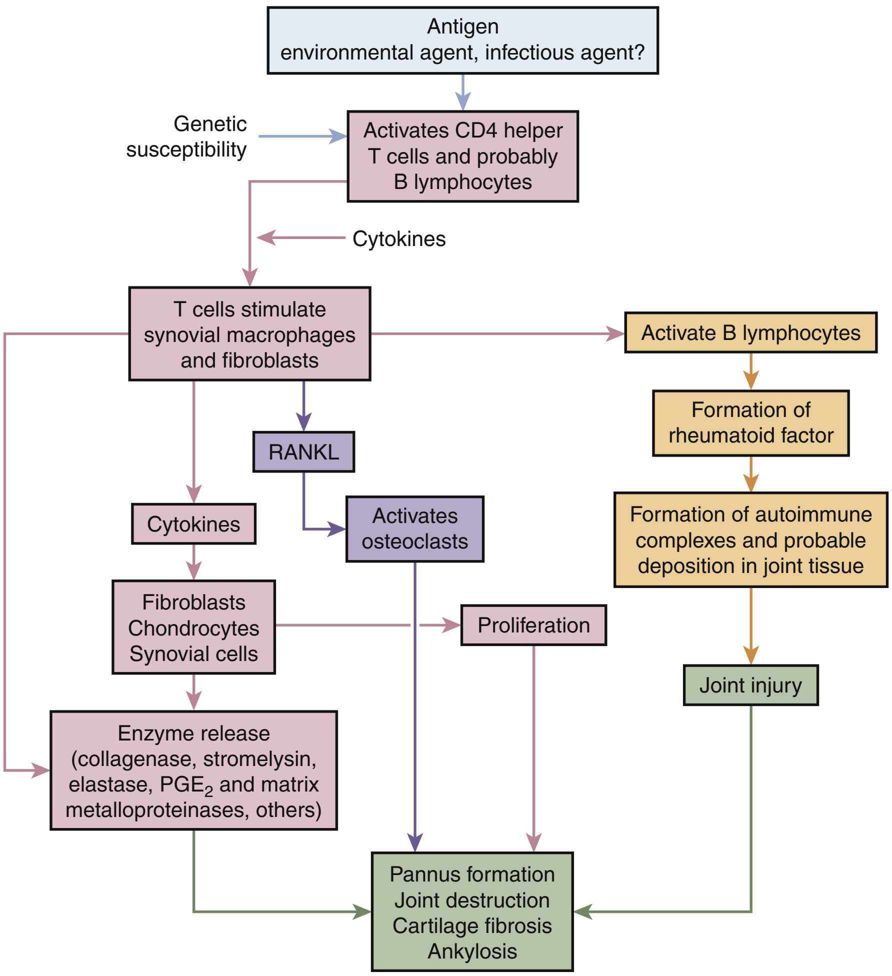

FIGURE 44-24 **Emerging Model of Pathogenesis of Rheumatoid Arthritis.** Rheumatoid arthritis is an autoimmune disease of a genetically susceptible host triggered by an unknown antigenic agent. Chronic autoimmune reaction with activation of CD4+ helper T cells and possibly other lymphocytes and the local release of inflammatory cytokines and mediators eventually destroys the joint. T cells stimulate cells in the joint to produce cytokines that are key mediators of synovial damage. Apparently immune complex deposition also plays a role. Tumor necrosis factor *(TNF)* and interleukin-1 *(IL-1)*, as well as some other cytokines, stimulate synovial cells to proliferate and produce other mediators of inflammation, such as prostaglandin E_2 *(PGE_2)*, matrix metalloproteinases, and enzymes, which all contribute to destruction of cartilage. Activated T cells and synovial fibroblasts also produce receptor activator of nuclear factor κβ ligand *(RANKL)*, which activates the osteoclasts and promotes bone destruction. Pannus is a mass of synovium and synovial stroma with inflammatory cells, granulation tissue, and fibroblasts that grows over the articular surface and causes its destruction.

(IL-6), interleukin-7 (IL-7), and interleukin-21 (IL-21), that induce enzymatic (metalloproteinase) breakdown of cartilage and bone and T cells also interact with synovial fibroblasts (synoviocytes) through TNF-α, converting synovium into a thick, abnormal layer of granulation tissue known as **pannus** (see Figures 44-25 and 44-26, *A*). Composed of these macrophages, plus osteoclasts and fibroblast-like synoviocytes, the pannus acts like a locally invasive tumor.[101,102] Macrophages, components of pannus (Figure 44-24), stimulate the release of IL-1, platelet-derived growth factor (PDGF), and fibronectin. The pathogenesis of rheumatoid arthritis is summarized in Figure 44-24.

Several types of leukocytes are attracted out of the circulation and into the synovial membrane. The phagocytes of inflammation (neutrophils and macrophages) ingest the immune complexes and, in the process of doing so, release powerful enzymes that degrade synovial tissue and articular cartilage (Figure 44-25). The immune system's B and T lymphocytes are also activated. The B lymphocytes are stimulated to produce more RFs, and the T lymphocytes eventually cause release of enzymes that amplify and perpetuate the inflammatory response. Cartilage destruction is mediated by matrix metalloproteinases (MMPs) that activate the synoviocytes to invade and attack the synovium and matrix.[103] In addition, RANKL is expressed by various cells in the synovium and induces osteoclast maturation and activation, thus producing increased bone resorption (see p. 1553).

Inflammatory and immune processes have several damaging effects on the synovial membrane. Along with the swelling caused by leukocyte infiltration, the synovial membrane undergoes hyperplastic thickening as its cells proliferate and become

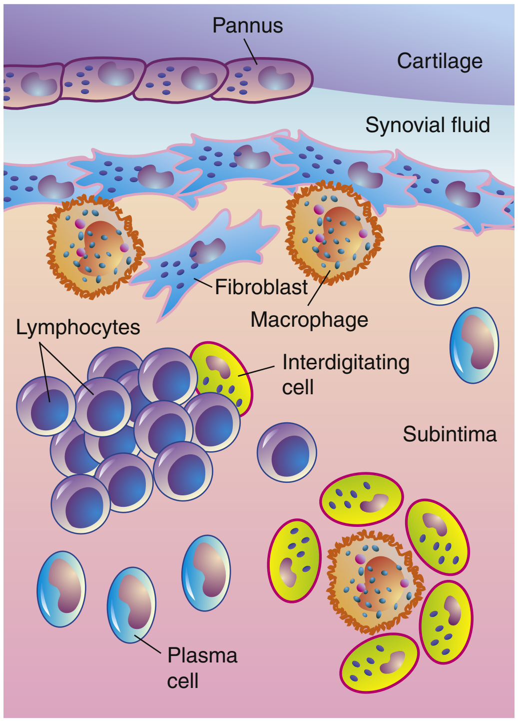

FIGURE 44-25 **Synovitis.** Inflamed synovium showing typical arrangements of macrophages and fibroblastic cells.

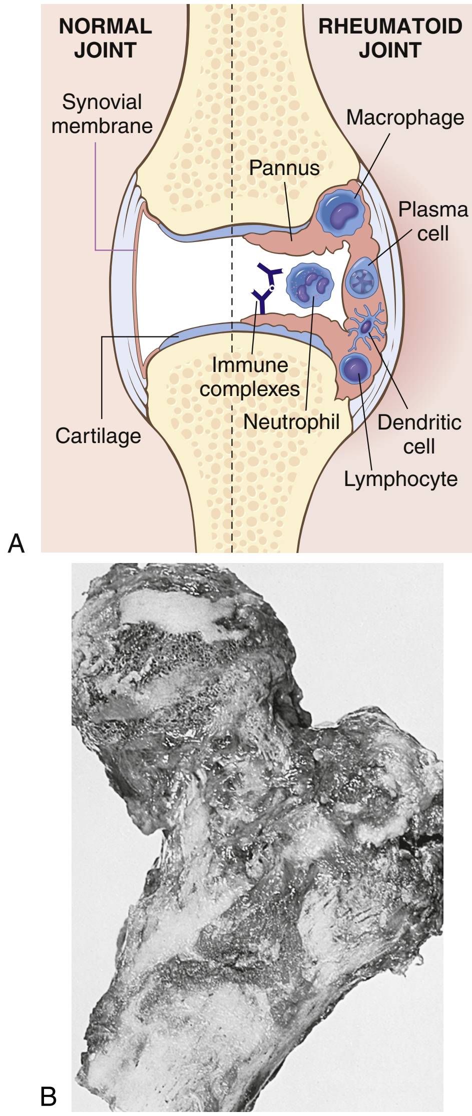

FIGURE 44-26 **Rheumatoid Arthritis. A,** Schematic view of the joint lesion. **B,** Advanced rheumatoid arthritis involving femur. There is prominent proliferation of synovium and almost complete destruction of overlying articular cartilage. (**A** modified from Feldmann M: *Nat Rev Immunol* 2:364, 2002; **B** from Rosai J: *Ackerman's surgical pathology*, ed 10, Philadelphia, 2011, Mosby.)

abnormally large. As synovial inflammation progresses to involve its blood vessels, small venules become occluded by the hypertrophied endothelial cells, fibrin, platelets, and inflammatory cells, which decrease vascular flow to the synovial tissue. Compromised circulation, coupled with increased metabolic needs because of hypertrophy and hyperplasia, causes hypoxia and metabolic acidosis. Acidosis stimulates the release of hydrolytic enzymes from synovial cells into the surrounding tissue, initiating erosion of the articular cartilage and inflammation in the supporting ligaments and tendons. Inflammation causes hemorrhage, coagulation, and fibrin deposition on the synovial membrane, in the intracellular matrix, and in the synovial fluid. (Figure 44-26, *A* and *B*).

CLINICAL MANIFESTATIONS. The onset of RA is usually insidious, although as many as 15% of cases have an acute onset. RA begins with general systemic manifestations of inflammation, including fever, fatigue, weakness, anorexia, weight loss, and generalized aching and stiffness. Local manifestations also appear gradually over weeks or months. Typically the joints become painful, tender, and stiff. Pain early in the disease is caused by pressure from swelling; later it is caused by sclerosis of subchondral bone and new bone formation. Stiffness usually lasts for about 1 hour after arising in the morning and may be caused by synovitis. Initially most commonly involved joints are the metacarpophalangeal (MCP), proximal interphalangeal (PIP), and wrists, with later involvement of larger weightbearing joints.

Widespread and symmetric joint swelling is caused by increasing amounts of inflammatory exudate (leukocytes, plasma, plasma proteins) in the synovial membrane, hyperplasia of inflamed tissues, and formation of new bone. On palpation, the swollen joint feels warm and the synovial membrane feels "boggy." The skin over the joint may have a ruddy or cyanotic hue and may look thin and shiny.

An inflamed joint may lose some of its mobility; even mild synovitis can lead to loss of range of motion. Extension becomes limited and is eventually lost if flexion contractures form. Chronic synovitis weakens ligamentous structures leading to deformities of the fingers, toes, and limbs, including ulnar deviation of the hands, boutonnière and swan-neck deformities of the finger joints,[104] plantar subluxation of the metatarsal heads of the foot, and hallux valgus (angulation of the great toe toward the other toes). Flexion contractures of the knees and hips are also common.

Joint deformities cause the physical limitations experienced by persons with RA. Loss of joint motion is quickly followed by secondary atrophy of the surrounding muscles. With secondary

muscle atrophy the joint becomes unstable, which further aggravates joint pathology.

Two complications of chronic RA are caused by an excessive amount of inflammatory exudate in the synovial cavity. One complication is the formation of cysts in the articular cartilage or subchondral bone. Occasionally these cysts communicate with the skin surface (usually the sole of the foot) and can drain through passages called fistulae. The second complication is rupture of a cyst or of the synovial joint itself, usually caused by strenuous physical activity that places excessive pressure on the joint.

Extrasynovial **rheumatoid nodules,** or swellings, are observed in areas of pressure or trauma in 20% of individuals with RA. Each nodule is an aggregate of inflammatory cells surrounding a central core of fibrinoid and cellular debris. T lymphocytes are the predominant leukocytes in the nodule; B lymphocytes, plasma cells, and phagocytes are found around the periphery. Nodules are found most often in subcutaneous tissue over the extensor surfaces of elbows and fingers. Less common sites are the scalp, back, feet, hands, buttocks, and knees.

Rheumatoid nodules also may invade the skin, cardiac valves, pericardium, pleura, lung parenchyma, and spleen. These nodules are identical to those encountered in some individuals with rheumatic fever and are characterized by central tissue necrosis surrounded by proliferating connective tissue. Also noted are large numbers of lymphocytes and occasional plasma cells. Acute glaucoma may result, with nodules forming on the sclera. Pulmonary involvement may result in diffuse pleuritis or multiple intraparenchymal nodules. Together, the occurrence of pulmonary nodules and pneumoconiosis (chronic inflammation of the lungs from inhalation of dust) creates **Caplan syndrome.** Diffuse pulmonary fibrosis may occur because of immunologically mediated immune complex deposition.

Rheumatoid nodules within the heart may cause valvular deformities, particularly of the aortic valve leaflets. Pericardial effusion or other pericardial problems occur in almost 50% of individuals with RA. Lymphadenopathy of the nodes close to the affected joints may develop. Rheumatoid nodules within the spleen result in splenomegaly. Involvement of blood vessels results in an acute necrotizing vasculitis, characteristic of that noted in other immunologic/inflammatory states. Thromboses of such involved vessels may give rise to myocardial infarctions, cerebrovascular occlusions, mesenteric infarction, kidney damage, and vascular insufficiency in the hands and fingers (Raynaud phenomenon). Vascular changes are noted primarily in individuals receiving corticosteroid therapy; thus there is some concern that the therapy may play a role in initiating these lesions. Changes in skeletal muscle are often noted in the form of nonspecific atrophy secondary to joint dysfunction.

EVALUATION AND TREATMENT. The autoantibodies rheumatoid factor (RF) and the much more specific serum marker anti–citrullinated protein antibody (ACPA) can be present for years to decades before synovial or radiographic changes become apparent.[95,100,105] Early, aggressive treatment of RA can prevent disability and joint destruction. In 2010 the American College of Rheumatology (ACR) and the European League Against Rheumatism (EULAR) revised their classification criteria to better identify early stages of RA.[95] Box 44-4 summarizes the criteria for diagnosing RA.

Early treatment of RA begins with disease-modifying antirheumatic drugs (DMARDs) such as methotrexate (MTX), azathioprine, sulfasalazine, hydroxychloroquine, leflunomide, and cyclosporine. MTX remains the first line of treatment. More recently, targeted treatment of RA has involved use of agents aimed at interrupting the pathogenesis of the disease. Known as biological DMARDs (bDMARDs), these medications affect specific processes in the development of RA and include tumor necrosis factor inhibitors such as etanercept, adalimumab, and infliximab. They recently have been augmented by the monoclonal antibodies golimumab and certolizumab. Other agents interfere with cytokine function (anakinra inhibits IL-1 function; tocilizumab targets IL-6), inhibit T-cell activation (abatacept), or deplete B cells (rituximab). Combination therapy with a DMARD and a biologic agent, such as infliximab (a TNF inhibitor), is more effective than using a single agent.[106]

Education is fundamental in treating RA. Other treatments and therapies include nonsteroidal anti-inflammatory drugs (NSAIDs), glucocorticoids, intra-articular steroid injections, physical and occupational therapy with therapeutic exercise, and use of assistive devices. Surgery is used to treat deformities or mechanical deficiencies of joints and can include synovectomy or joint replacement.

Ankylosing Spondylitis

Ankylosing spondylitis (AS) is the most common of a group of inflammatory arthropathies known as spondyloarthropathies. It is a chronic inflammatory joint disease characterized by stiffening and fusion (ankylosis) of the spine and sacroiliac joints. The exact cause of AS is unknown but its high association with the histocompatibility antigen human leukocyte antigen (HLA-B27) has been known for decades. New research has shown that misfolding of HLA-B27 occurs in the endoplasmic reticulum (ER). As misfolded proteins accumulate, it results in a stress response of the ER and increased production of interleukin-23 (IL-23), a potent cytokine that may also act on T-helper 17 cells, promoting their survival.[107] Th17 cells, in turn, produce the inflammatory cytokine IL-17.

Although inflammation is the primary pathologic process in both RA and AS, the two diseases possibly differ in the primary site of inflammation and the end result. In RA the primary site of inflammation is the synovial membrane, resulting in the destruction and instability of synovial joints. In AS, the primary pathologic problem is uncontrolled bone formation, rather than bone destruction seen with most other types of arthritis.[108] The end results of AS are fibrosis, ossification, and fusion of the joint, primarily the sacroiliac joints and the vertebral column. MRI studies demonstrate changes in the sacroiliac joints before they become clinically apparent or visible on plain radiographs.[109]

The prevalence of AS in the United States is approximately 0.5% to 1% among whites, 3% to 4% among blacks, and 18% to 50% in various nations of American Indians. Worldwide, the disease appears to be most prevalent in whites. The prevalence

BOX 44-4 THE 2010 AMERICAN COLLEGE OF RHEUMATOLOGY/EUROPEAN LEAGUE AGAINST RHEUMATISM CLASSIFICATION CRITERIA FOR RHEUMATOID ARTHRITIS

Target population (Who should be tested?) Individuals:

1. who have at least one joint with definite clinical synovitis (swelling)*
2. who have synovitis not better explained by another disease†

Classification criteria for RA (score-based algorithm: add scores of categories A to D; a score of ≥6/10 is needed for classification of a patient as having definite RA)‡

Clinical Finding	Score
A. Joint involvement§	
1 large joint¶	0
2-10 large joints	1
1-3 small joints (with or without involvement of large joints)#	2
4-10 small joints (with or without involvement of large joints)	3
>10 joints (at least 1 small joint)**	5
B. Serology (at least 1 test result is needed for classification)††	
Negative RF *and* negative ACPA	0
Low-positive RF *or* low-positive ACPA	2
High-positive RF *or* high-positive ACPA	3
C. Acute-phase reactants (at least 1 test result is needed for classification)‡‡	
Normal CRP *and* normal ESR	0
Abnormal CRP *or* abnormal ESR	1
D. Duration of symptoms§§	
<6 weeks	0
≥6 weeks	1

Data from Aletaha D: *Arthritis Rheum* 62(9):2574, 2010.

*The criteria are aimed at classification of newly presenting patients. In addition, patients with erosive disease typical of rheumatoid arthritis (RA) with a history compatible of prior fulfillment of the 2010 criteria should be classified as having RA. Patients with longstanding disease, including those whose disease is inactive (with or without treatment), who, based on retrospectively available data, have previously fulfilled the 2010 criteria should be classified as having RA.

†Differential diagnoses vary among patients with different presentations, but may include conditions such as systemic lupus erythematosus, psoriatic arthritis, and gout. If it is unclear about the relevant differential diagnoses to consider, an expert rheumatologist should be consulted.

‡Although patients with a score ≥6/10 are not classifiable as having RA, their status can be reassessed and the criteria might be fulfilled cumulatively over time.

§Joint involvement refers to any swollen or tender joint on examination, which may be confirmed by imaging evidence of synovitis. Distal interphalangeal joints, first metacarpophalangeal joints, and first metatarsophalangeal joints are excluded from assessment. Categories of joint distribution are classified according to the location and number of involved joints, with placement into the highest category possible based on the pattern of joint involvement.

¶"Large joints" refer to shoulders, elbows, hips, knees, and ankles.

#"Small joints" refer to the metacarpophalangeal joints, proximal interphalangeal joints, second through fifth metatarsophalangeal joints, thumb interphalangeal joints, and wrists.

**In this category, at least 1 of the involved joints must be a small joint; the others can include any combination of large and additional small joints, as well as other joints not specifically listed elsewhere (e.g., temporomandibular, acromioclavicular, sternoclavicular, etc.).

††Negative refers to IU values that are less than or equal to the upper limit of normal (ULN) for the laboratory and assay; low-positive refers to values that are higher than the ULN but ≤3 times the ULN for the laboratory and assay; high-positive refers to IU values that are >3 times the ULN for the laboratory and assay. Where rheumatoid factor (RF) information is only available as positive or negative, a positive result should be scored as low-positive for RF. *ACPA,* Anti-citrullinated protein antibody.

‡‡Normal/abnormal is determined by local laboratory standards. *CRP,* C-reactive protein; *ESR,* erythrocyte sedimentation rate.

§§Duration of symptoms refers to patient self-report of the duration of signs and symptoms of synovitis (e.g., pain, swelling, tenderness) of joints that are clinically involved at the time of assessment, regardless of treatment status.

of AS in males is at least 10 times greater than previously considered. It affects men three times as often as women. In women, AS may affect the peripheral joints of the appendicular skeleton rather than the axial skeleton, progress less rapidly, and cause less dramatic spinal changes. Many individuals with AS remain undiagnosed.

Primary AS usually develops in late adolescence or young adulthood, with peak incidence at about 20 years of age. Secondary AS affects older age groups and is often associated with other inflammatory diseases (e.g., psoriatic arthropathy, inflammatory bowel disease, Reiter syndrome).

PATHOPHYSIOLOGY. AS has a strong association with the histocompatibility antigen HLA-B27. Several hypotheses have been suggested to explain this association including the arthritogenic peptide theory that proposes that certain HLA-B27 alleles bind certain arthritogenic peptides because of their specific anchoring proteins. Cartilage antigens are proposed as the targets for the immune response and the presentation of such antigens to CD8+ T cells. In the early phases of AS, T cells and macrophages invade and cause erosion of the cartilage at different sites. Based on these observations, it is thought that the cartilage is the primary target for the immune response. **Aggrecan,** a proteoglycan, forms a major part of the extracellular matrix of cartilage and helps maintain its stability. A specific CD4+ T-cell response to proteins derived from aggrecan has been found in animals and humans. Although these T cells have been found in AS, their role as a causative agent in AS remains unclear and necessitates future study.

AS involves inflammation of fibrocartilage in cartilaginous joints, primarily the vertebrae. The fibrous tissue of the joint capsule, the cartilage that surrounds intervertebral disks, the entheses, and the periosteum are infiltrated by inflammatory cells. As inflammatory cells (chiefly macrophages) and lymphocytes infiltrate and erode bone and fibrocartilage in joint structures, repair begins. Repair of cartilaginous structures begins with the proliferation of fibroblasts. Fibroblasts synthesize and

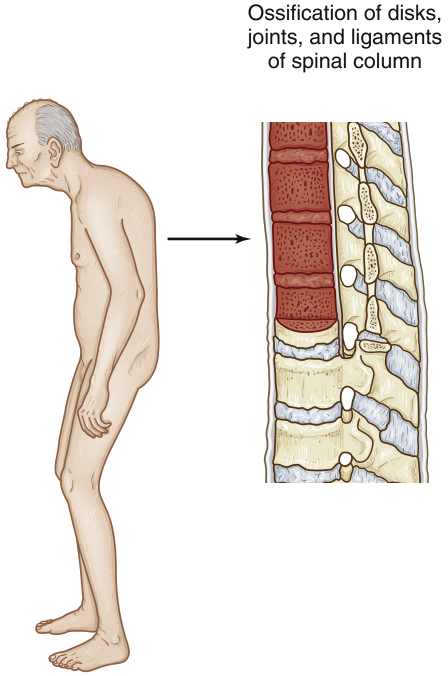

FIGURE 44-27 **Ankylosing Spondylitis.** Characteristic posture and primary pathologic sites of inflammation and resulting damage.

secrete collagen. The collagen becomes organized into fibrous scar tissue that eventually undergoes calcification and ossification. With time, all the cartilaginous structures of the joint are replaced by ossified scar tissue, causing the joint to fuse, or lose flexibility.

Repair of eroded bone begins with osteoblast activation and proliferation. Osteoblasts lay down new bone (callus), which is remodeled and replaced by compact, lamellar bone. Bone repair changes the contour of the bone's surface because the new bone grows outward to form a new enthesis with the end of the eroded ligament. The new enthesis, which forms on top of the old one, is called a **syndesmophyte.** As calcification of the spinal ligaments progresses, the vertebral bodies lose their concave anterior contour and appear square. On radiographs the spine assumes the classic "bamboo spine" appearance of AS.

CLINICAL MANIFESTATIONS. The most common signs and symptoms of early AS are low back pain and stiffness. Typically the individual with primary disease develops low back pain during the early twenties. The pain is at first insidious but progressively becomes persistent. It is often worse after prolonged rest and is alleviated by physical activity. Early morning stiffness usually accompanies the low back pain, and the individual typically has difficulty sitting up or twisting the spine. Forward flexion, rotation, and lateral flexion of the spine are restricted and painful. Early pain and resultant loss of motion are caused by the underlying inflammation and reflex muscle spasm rather than by soft tissue or bony fusion.

As the disease progresses, the normal convex curve of the lower spine (lumbar lordosis) diminishes and concavity of the upper spine (kyphosis) increases. The individual becomes increasingly stooped. The thoracic spine becomes rounded, the head and neck are held forward on the shoulders, and the hips are flexed (Figure 44-27).

Inflammation in the tendon insertions of the many costosternal and costovertebral muscles can cause pleuritic chest pain and restricted chest movement. The pain is usually worse on inspiration. Movement in the diaphragm is normal and full. Pressure on the anterior chest wall over the sternum, ribs, and costal cartilages may cause tenderness. Tenderness over the pelvic brim may cause discomfort at night and interfere with sleep because turning onto the iliac crests causes pain. Tenderness over the ischial tuberosities may make sitting on hard seats unbearable. Tenderness in the heels may contribute to a limp or the cautious placement of the feet during walking.

Along with low back pain, many individuals have peripheral joint involvement, uveitis, fibrotic changes in the lungs, cardiomegaly, aortic incompetence, amyloidosis, and Achilles tendinitis. Symptoms may include fatigue, weight loss, low-grade fever, hypochromic anemia, and an increased erythrocyte sedimentation rate.

EVALUATION AND TREATMENT. Diagnosis of AS is made on the basis of both clinical and radiologic findings. Low back pain and stiffness lasting more than 3 months that improves with exercise but is not relieved by rest, limited spine range of motion (ROM) in both frontal and sagittal planes, and limited chest expansion relative to normal values for age and gender are the classic clinical criteria. Radiologic changes at the sacroiliac joint are graded according to severity of abnormality; abnormalities include sclerosis, widening, narrowing, or ankylosis.[110] Laboratory tests, including serum analysis for the presence of the histocompatibility antigen HLA-B27, elevated erythrocyte sedimentation rate (ESR) (normal is 0 to 9 mm/hr in males, 0 to 2 mm/hr in females), and elevated alkaline phosphatase levels, can be used to help monitor the course of the disease.

Treatment of individuals with AS consists of a multidisciplinary approach: physical therapy to maintain skeletal mobility and prevent the natural progression of contractures, support groups, nonsteroidal anti-inflammatory drugs (NSAIDs) to provide relief of symptoms, analgesic medications to suppress some of the pain and stiffness and to facilitate exercise, and corticosteroid injections to locally inflamed joints. The medications do not prevent disease progression, but they do provide relief from symptoms. DMARDs such as gold, methotrexate, and sulfasalazine have little or no effect in AS. Three TNF inhibitors (etanercept, infliximab, and adalimumab) have been approved for severe AS. Surgery can help if there is severe disabling deformity.[110]

Gout

Gout is a syndrome caused by an inflammatory response to uric acid production or excretion resulting in high levels of uric acid in the blood (hyperuricemia) and in other body fluids, including synovial fluid. Although hyperuricemia is essential for the development of gout, it is not the only factor. Other factors include age (rare before 30 years), genetic predisposition (X-linked alteration of the enzyme hypoxanthine-guanine phosphoribosyltransferase [HGPRT]), excessive alcohol consumption, obesity, certain drugs (especially thiazides), and lead toxicity. When the uric acid concentration is >6.8 mg/dl in fluids, it crystallizes and forms insoluble precipitates of

TABLE 44-8 MEAN URATE CONCENTRATIONS BY AGE AND GENDER

CHARACTERISTIC	MEAN URATE LEVELS
Prepuberty	3.5 mg/dl
Males (at puberty)	Steep rise to 5.2 mg/dl
Females (puberty to premenopause)	Slow rise to ≅4 mg/dl
Females (after menopause)	4.7 mg/dl
Hyperuricemia	
Men	7 mg/dl
Women	6 mg/dl

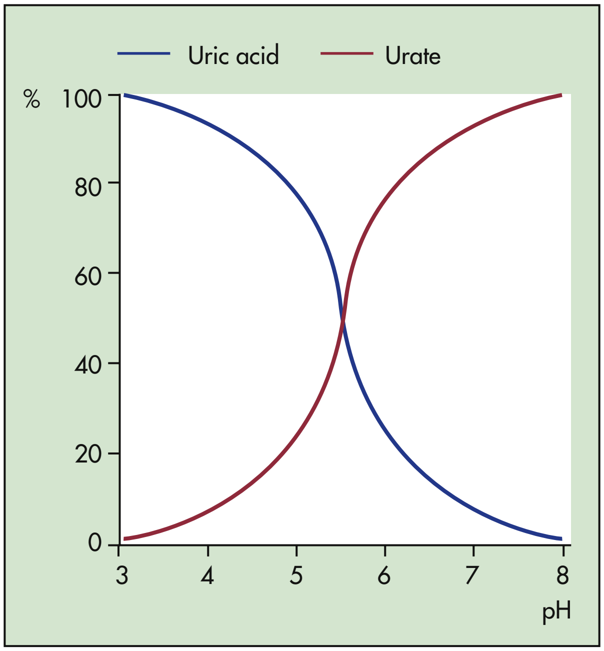

FIGURE 44-28 Effect of pH on Uric Acid and Urate Equilibrium. At pH 5.7, equal amounts of uric acid and urate are present in the solution. (Redrawn from Klippel JH, Dieppe PA, editors: *Rheumatology,* ed 2, London, 1998, Mosby-Wolfe.)

monosodium urate (MSU) that are deposited in connective tissues throughout the body. Crystallization in synovial fluid causes acute, painful inflammation of the joint, and triggers an inflammatory response by macrophages. When macrophages phagocytize MSU crystals, they form a protein scaffold known as an inflammasome. Inflammasomes then convert inactive interleukins of IL-1β and IL-18 into their active forms.[111,112] Prolonged accumulation results in joint damage, a condition known as **gouty arthritis.** With time, crystal deposition in subcutaneous tissues causes the formation of small, white nodules, or **tophi,** that are visible through the skin. Crystal aggregates deposited in the kidneys can form urate renal stones and lead to renal failure.

In classic gouty arthritis, monosodium urate crystals form and cause joint inflammation. **Pseudogout** is caused by the formation of calcium pyrophosphate dihydrate (CPPD) crystals. The effect of either crystal is the same—the onset of a cytokine-mediated acute inflammatory response (see Chapter 7).

Gout is rare in children and premenopausal women and is uncommon in males younger than 30 years. The peak age of onset in males is between 40 and 50 years, whereas it is somewhat later in females. The risk of developing gouty arthritis is similar in males and females for a particular urate concentration. The plasma urate concentration is an important determinant of the risk of developing gout (Table 44-8).

Uric acid (UA) is a byproduct of protein metabolism that normally assists with removal of nitrogen waste from the body. At lower levels, UA is an important antioxidant but at higher levels it acts as a pro-oxidant where it increases levels of free radicals and causes other inflammatory changes.[113] When ionized, uric acid can form salts with various cations but 98% of extracellular uric acid is in the form of monosodium urate (uric acid salt). At any time the proportion of uric acid or urate is pH dependent, so the ratio of these two forms varies considerably in urine (Figure 44-28).

The solubility of urate and uric acid is critical to the development of crystals. Urate is more soluble in plasma, synovial fluid, and urine than in aqueous solutions; solubility in urine rises dramatically as the pH increases to more than 4. There is little change, however, in the solubility of urate within the normal pH range that exists in the plasma, synovial fluid, and other tissues. Decreasing temperatures cause both urate and uric acid solubility to fall. The pathways of production of uric acid are shown in Figure 44-29.

PATHOPHYSIOLOGY. The pathophysiology of gout is closely linked to purine metabolism and kidney function. At the cellular level, purines are synthesized to purine nucleotides, which are used in the synthesis of nucleic acids, adenosine triphosphate, cyclic adenosine monophosphate (cAMP), and cyclic guanosine monophosphate (GMP). Uric acid is a breakdown product of purine nucleotides (uric acid synthesis and elimination are illustrated in Figure 44-30). Some individuals with gout have an accelerated rate of purine synthesis accompanied by an overproduction of uric acid. Other individuals break down purine nucleotides at an accelerated rate that also results in an overproduction of uric acid. A deficiency of the enzyme HGPRT (see earlier) can lead to an increased production of uric acid. A complete absence of HGPRT is uncommon but can occur in the X-linked Lesch-Nyhan syndrome, with males at risk for hyperuricemia, neurologic alterations, and sometimes gouty arthritis. The majority of individuals with gout, however, have an unknown metabolic defect, which is referred to as **primary gout.** When the etiology is known, it is referred to as **secondary gout.**

Most uric acid is eliminated from the body through the kidneys. Urate is filtered at the glomerulus and undergoes reabsorption and excretion within the proximal renal tubules. In primary gout, urate excretion by the kidneys is sluggish; this may be the result of a decrease in glomerular filtration of urate or acceleration in urate reabsorption. In addition, MSU crystals deposited in renal tubules can cause acute nephropathy.[113] (Kidney function is described in Chapter 37.)

Monosodium urate crystals can stimulate and perpetuate the inflammatory response (Figure 44-31). The presence of MSU crystals triggers the acute inflammatory response. Initiation of the complement system activates cytokines and produces other

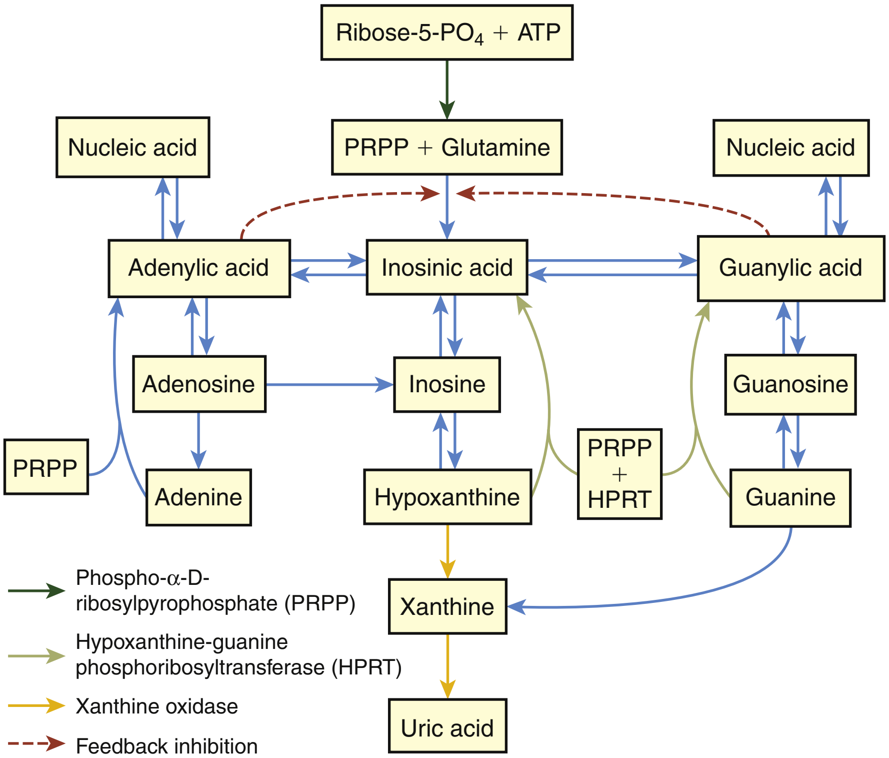

FIGURE 44-29 **Production of Uric Acid.** The major pathways involved in purine nucleotide synthesis. (Redrawn from Klippel JH, Dieppe PA, editors: *Rheumatology,* ed 2, London, 1998, Mosby-Wolfe.)

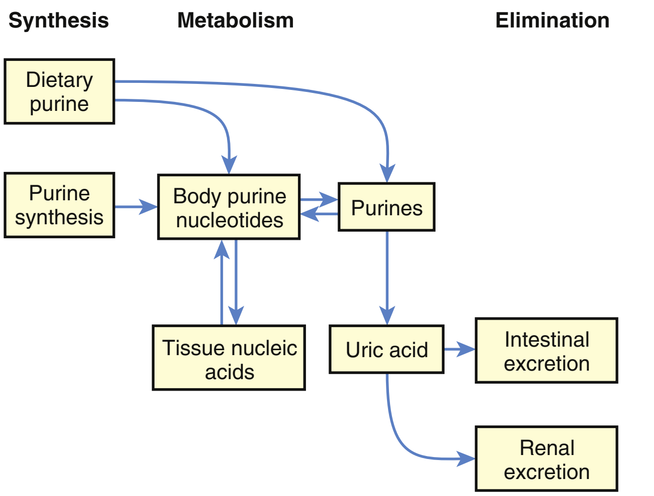

FIGURE 44-30 **Uric Acid Synthesis and Elimination.** Uric acid is derived from ingested purines or synthesized from ingested foods, as well as being recycled following cell breakdown. Uric acid is then eliminated through the kidneys and gastrointestinal tract. (Redrawn from Klippel JH, Dieppe PA, editors: *Rheumatology,* ed 2, London, 1998, Mosby-Wolfe.)

substances, called chemoattractants, that draw neutrophils out of the circulation to begin phagocytizing (ingesting) the crystals.

A variety of inflammatory mediators are released during the crystal/cell response, of which IL-1β appears to be of prime importance. Other factors including chemotactic factors, lysosomal enzymes, eicosanoids, prostaglandin E (PGE_2), reactive oxygen species, and collagenase also are released (see Figure 44-31, *B*). Some of these mediators stimulate the influx of neutrophils, monocytes, and lymphocytes. (Acute inflammation and phagocytosis are described in Chapter 7.)

Within the joint fluid, urate crystals react particularly with neutrophils and monocytes. Tissue damage begins to occur, principally when the neutrophils release the contents of their phagolysosomes. These contents also perpetuate inflammation. At an early phase of an acute gouty attack, synovial microtophi have been demonstrated. As the process continues, numerous microtophi may be present on the synovial membrane (see Figure 44-31, *C*).

CLINICAL MANIFESTATIONS. Gout is manifested by (1) an increase in serum urate concentration (hyperuricemia); (2) recurrent attacks of monoarticular arthritis (inflammation of a single joint); (3) deposits of monosodium urate monohydrate (tophi) in and around the joints; (4) renal disease involving glomerular, tubular, and interstitial tissues and blood vessels; and (5) the formation of renal stones. These manifestations appear in three clinical stages:

1. **Asymptomatic hyperuricemia:** The serum urate level is elevated but arthritic symptoms, tophi, and renal stones are not present; may persist throughout life.
2. **Acute gouty arthritis:** Attacks develop with increased serum urate concentrations; tends to occur with sudden or sustained increases of hyperuricemia but also can be triggered by trauma, drugs, and alcohol.
3. **Tophaceous gout:** The third and chronic stage of disease; can begin as early as 3 years or as late as 40 years after the initial attack of gouty arthritis. Progressive inability to excrete uric acid expands the urate pool until urate crystal deposits (tophi) appear in cartilage, synovial membranes, tendons, and soft tissue.

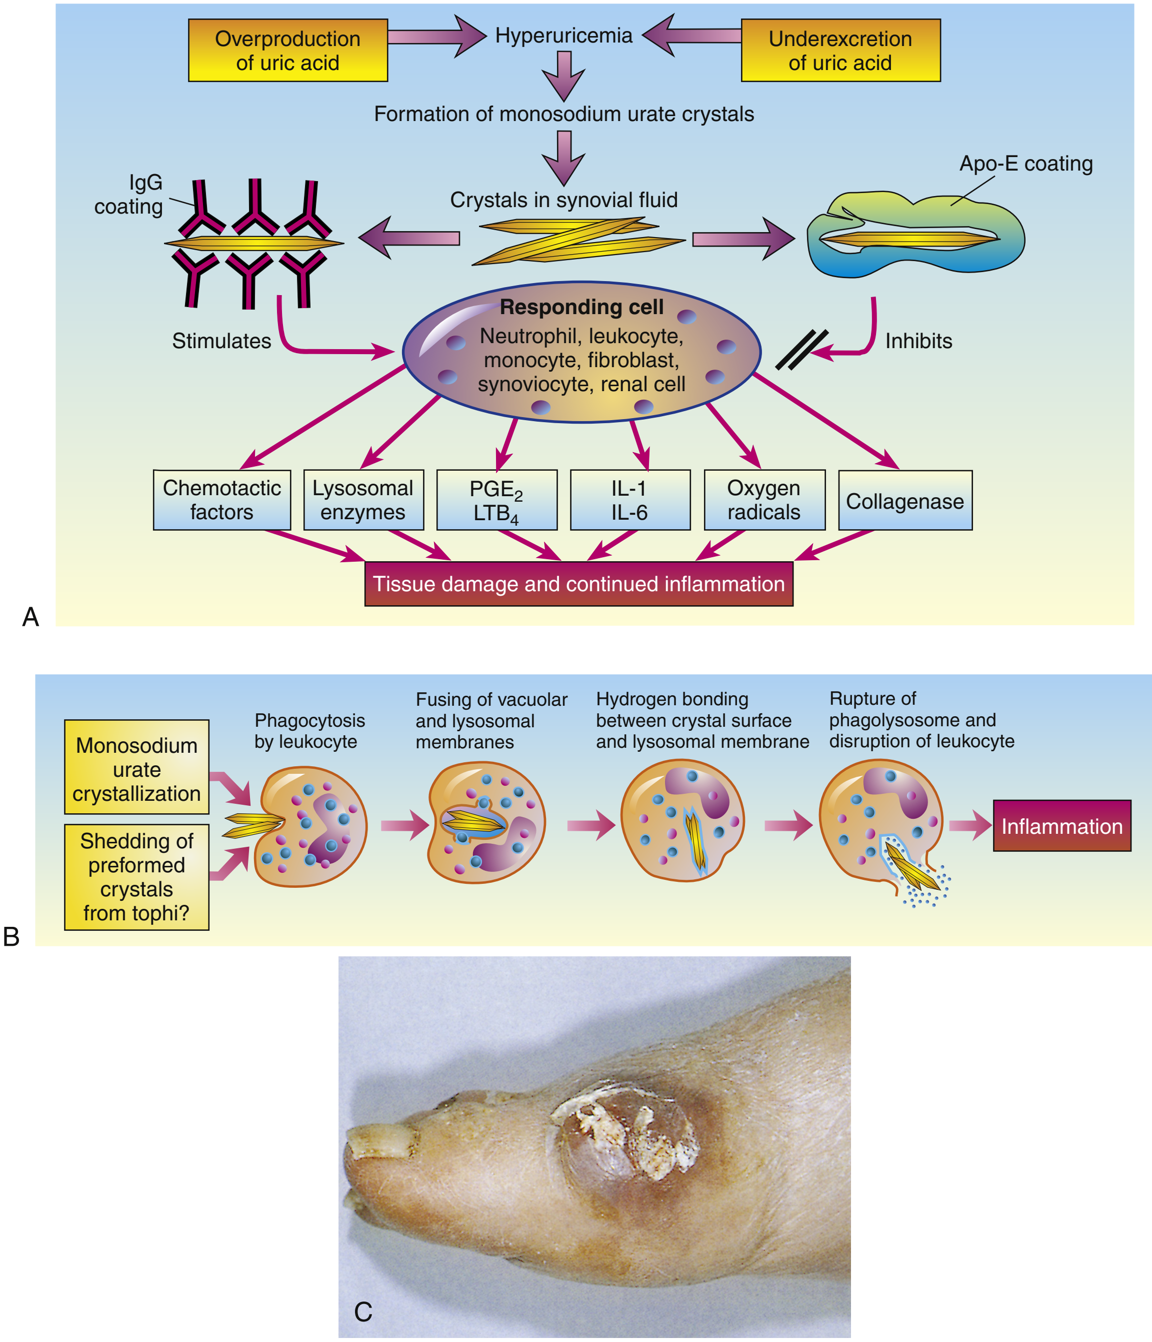

FIGURE 44-31 Pathogenesis of Acute Gouty Arthritis. **A,** Depending on the urate crystal coating, a variety of cells may be stimulated to produce a wide range of inflammatory mediators. **B,** Sequence of events in the production of inflammatory response to urate crystals. **C,** Gouty tophus on right foot. *Apo-E,* Apolipoprotein E; *IgG,* immunoglobulin G; *IL,* interleukin; *LTB_4,* leukotriene B_4; *PGE,* prostaglandin E. (**C** from Dieppe P et al: *Arthritis and rheumatism in practice,* London, 1991, Gower.)

Attacks of gouty arthritis occur abruptly, usually in a peripheral joint. The primary symptom is severe pain. Approximately 50% of the initial attacks occur in the metatarsophalangeal joint of the great toe. The other 50% involve the heel, ankle, and instep of the foot; knee; wrist; or elbow. The pain is usually noticed at night. Within a few hours the affected joint becomes hot, red, and extremely tender and may be slightly swollen. Lymphangitis and systemic signs of inflammation (leukocytosis, fever, elevated sedimentation rate) occasionally are present. Untreated, mild attacks usually subside in several hours but may persist for 1 or 2 days. Severe attacks may persist for several days or weeks. After recovery, the symptoms resolve completely. Intervals between acute attacks of gouty arthritis are called *intercritical periods.* Some individuals never have a second attack; others experience subsequent attacks within days to as long as 5 to 10 years after the first.

The helix of the ear is the most common site of tophi, which are the characteristic diagnostic lesions of chronic gout. Each tophus consists of a deposit of urate crystals, surrounded by a granuloma made up of mononuclear phagocytes (macrophages)

that have developed into epithelial and giant cells. (Granuloma formation is described in and illustrated in Chapter 7.)

Tophaceous deposits produce irregular swellings of the fingers, hands, knees, and feet. Tophi commonly form lumps along the ulnar surface of the forearm, the tibial surface of the leg, the Achilles tendon, and the olecranon bursa. Tophi may produce marked limitation of joint movement and eventually cause grotesque deformities of the hands and feet. Although the tophi themselves are painless, they often cause progressive stiffness and persistent aching of the affected joint. Tophi in the upper extremities may cause nerve compressions such as carpal tunnel syndrome; in the lower extremities tophi may cause tarsal tunnel syndrome. They also may erode and drain through the skin.

Renal stones are 1000 times more prevalent in individuals with primary gout than in the general population. Renal stones can form in the collecting tubules, pelvis, or ureters, causing obstruction, dilation, and atrophy of the more proximal tubules and leading eventually to acute renal failure. Stones deposited directly in renal interstitial tissue initiate an inflammatory reaction that leads to chronic renal disease and progressive renal failure.

EVALUATION AND TREATMENT. The goals of gout treatment are to terminate the acute gouty attack as promptly as possible; avoid recurring attacks; prevent or reverse complications associated with urate deposits in the joints, soft tissues, and kidneys; and prevent formation of kidney stones. Acute gouty arthritis is treated with anti-inflammatory drugs. The drugs of choice are NSAIDs and xanthine oxidase inhibitors, such as allopurinol and febuxostat. Colchicine and NSAIDs are used for acute episodes of gout. Hydrocortisone may be injected into the joint to relieve pain. Drugs that block IL-1 have shown promise and investigation into certain plant-based extracts may lead to new therapies.[111,114,115] Ice also may relieve some of the inflammation of the joint. Weightbearing on the involved joint is avoided until the acute attack subsides. Reducing body weight, avoiding alcohol, and increasing consumption of low-fat dairy products, cherries, soybeans, and vegetable sources of protein may reduce recurrent gouty episodes.[112]

DISORDERS OF SKELETAL MUSCLE

Common symptoms of disorders of skeletal muscle are weakness and fatigue. In many cases, neural, traumatic, and psychogenic causes provide an adequate explanation for the failure to generate force (weakness) or sustain force (fatigue) seen in myopathies. The pathophysiologic mechanisms in some of the metabolic and inflammatory muscle diseases have been explored, but the cause of many of the myopathies remains obscure. Recognition and improved understanding of ryanodine receptor (RyR1) function has allowed identification of therapeutic targets in treating central core disease (CCD). The term CCD refers to the mitochondrial lack of oxidative enzyme activity in the central cytoplasmic area of the muscle caused by a genetic abnormality on chromosome 19. Complex interactions between muscles and nerves affect muscular function as well. Only inherited and acquired disorders of skeletal muscles are discussed here.

Secondary Muscular Dysfunction

Muscular symptoms arise from a variety of causes unrelated to the muscle itself. Secondary muscular phenomena (contracture, stress-related muscle tension, immobility) are common disorders that influence muscular function.

Contractures

Contractures are termed pathologic or physiologic. A physiologic muscle contracture occurs in the absence of a muscle action potential in the sarcolemma. Muscle shortening is explained on the basis of failure of the calcium pump in the presence of ATP. A physiologic contracture is seen in McArdle disease (muscle myophosphorylase deficiency) and malignant hyperthermia. The contracture is usually temporary if the underlying pathology is reversed.

A pathologic contracture is a permanent muscle shortening caused by muscle spasm or weakness. Heel cord (Achilles tendon) contractures are examples of pathologic contractures. They are associated with plentiful ATP and occur in spite of a normal action potential. The most common form of contracture is seen in such conditions as muscular dystrophy, cerebral palsy (see Chapter 45), and central nervous system (CNS) injury. Contractures also may develop secondary to scar tissue contraction in the flexor tissues of a joint, for example, contracture of burned tissues in the antecubital area of the forearm leading to a flexion contracture.

Stress-Induced Muscle Tension

Abnormally increased muscle tension has been associated with chronic anxiety, as well as a variety of stress-related muscular symptoms, including neck stiffness, back pain, and headache.[116] Abnormalities in the CNS, reticular activating system, and autonomic nervous system (ANS) have been implicated. The underlying pathophysiology may be related to the fact that as a muscle contracts, the muscle spindle is activated. This gamma-feedback system produces a series of impulses that are transmitted to the brain by the sensitive 1A afferent fibers. Unconscious tension is thought to increase the activity of the reticular activating system as well. This influences increasing firing of the efferent loop of the gamma fibers and produces further muscle contraction and increases muscle tension. ANS function that regulates increased blood flow to the muscle during sympathetic activity may be related to increased muscle contraction tension.

Various forms of treatment have been used to reduce the muscle tension associated with stress. Progressive relaxation training, yoga, meditation, and biofeedback are examples of stress reduction therapies. **Biofeedback** uses an integrated electromyogram (EMG) to make recordings from the skin surface. The goal is to teach the individual to control tension that has been functioning maladaptively. It is particularly useful in individuals who have a connection between skeletal muscle tension and pain.

Progressive relaxation training emphasizes the individual's ability to perceive the difference between tension and relaxation. This technique involves sequential tensing and a relaxing environment. The individual is taught to practice this routine daily, often with the use of audiotaped instructions. By teaching the

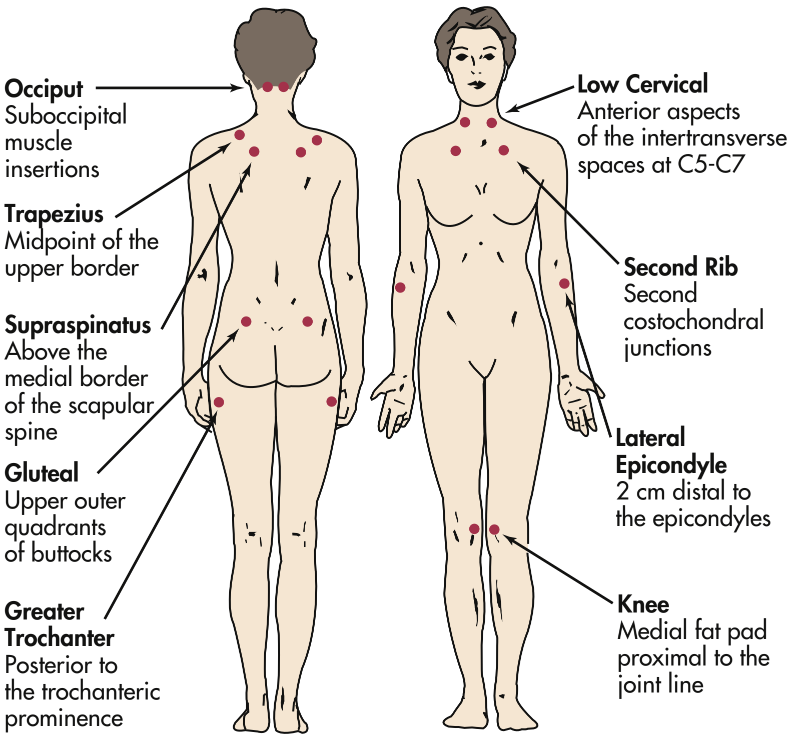

FIGURE 44-32 Location of Specific Tender Points for Diagnostic Classification of Fibromyalgia. (Redrawn from Freundlich B, Leventhal L: The fibromyalgia syndrome. In Schumacher HR Jr, Klippel JH, Koopman WJ, editors: *Primer on the rheumatic diseases,* ed 11, Atlanta, 1997, Arthritis Foundation. Copyright ©1997. Reprinted with permission of the Arthritis Foundation.)

individual to recognize excessive contraction of skeletal muscle, one hopes to enhance the ability to relax specific muscle groups to relieve tension and thus reduce CNS as well as ANS arousal.

Fibromyalgia

Fibromyalgia (FM) is a chronic musculoskeletal syndrome characterized by widespread joint and muscle pain, fatigue, and tender points. Increased sensitivity to touch (i.e., tender points); the absence of systemic or localized inflammation, fatigue, and nonrestorative sleep; and anxiety and depression are common. FM and its symptoms are viewed as the result of CNS dysfunction, where pain transmission and interpretation are amplified, a condition known as central sensitization. In the past, a common misdiagnosis has been chronic fatigue syndrome and there is overlap of symptoms between these two conditions. From 80% to 90% of individuals affected are women, and the peak age is 30 to 50 years. Although the incidence is unknown, the prevalence is reported to be 2% to almost 6% and increases with age. The ACR classification criteria include diffuse soft tissue pain of at least 3 months' duration and pain on palpation of at least 11 of 18 tender points (Figure 44-32). It is more common than RA, but its cause is still unknown.

The etiology of fibromyalgia has been debated for more than a century. It is unlikely that it is caused by a single factor. The most common precipitating factors include the following:

- Flulike viral illness
- Chronic fatigue syndrome
- Human immunodeficiency virus (HIV) infection
- Lyme disease
- Physical trauma
- Emotional trauma
- Medications, especially steroid withdrawal

Certain rheumatic diseases, such as RA or systemic lupus erythematosus, may coexist if not initially manifested with fibromyalgia. In addition, fibromyalgia may overlap with myofascial pain syndromes[117] (Table 44-9).

PATHOPHYSIOLOGY. Fibromyalgia as a chronic pain syndrome is defined by subjective symptoms and not unique pathophysiologic characteristics. Altered circadian activity of several neuroendocrine axes and ANS dysfunction have been reported.[118,119] Genetic factors are increasingly being suggested as important in developing FM. Aggregation of fibromyalgia within families and other coexisting conditions, such as irritable bowel syndrome, chronic fatigue, and mood disorders, suggest a major role for neuroendocrine and stress-response alterations (see Chapter 11).

TABLE 44-9 COMPARISON OF FIBROMYALGIA AND MYOFASCIAL PAIN SYNDROMES

VARIABLE	FIBROMYALGIA	MYOFASCIAL PAIN
Location	Generalized	Regional
Examination	Tender points	Trigger points
Response to local therapy	Not sustained	Curative
Gender	Female/male ratio: 10:1	Equal or unknown
Systemic features	Characteristic	Unknown

Studies of genetic factors have implicated alterations in genes affecting serotonin, catecholamines, and dopamine—all of these substances are involved in stress response and sensory processing.[120,121] In spite of these studies, the role of genetic factors in FM has not yet been fully identified. External stressors such as infection, psychosocial stress, and physical or emotional trauma may precipitate onset of FM.

Functional magnetic resonance imaging (fMRI) and molecular imaging techniques of positron emission tomography (PET) of the brains of persons with FM have shown activity in different areas of the brain than in healthy individuals when exposed to painful stimuli.[122] Individuals with fibromyalgia have lowered mechanical and thermal pain thresholds, high pain ratings for provoking stimuli, and altered temporal summation of pain stimuli. Functional abnormalities within the CNS are shown in Figure 44-32. Other pathophysiologic evidence includes hypothalamic-pituitary-adrenal (HPA) axis alterations that demonstrate abnormal response to pain;[123] recent investigations suggest cytokines are involved in the pathogenesis of FM. Corticotropin-releasing hormone (CRH) and locus ceruleus–norepinephrine (LC/NE), their peripheral effectors, and the hypothalamic-pituitary-adrenal axis are the main components of the stress system. Impaired functioning of the HPA axis and LC/NE system may be associated with fibromyalgia.

CLINICAL MANIFESTATIONS. The prominent symptom of fibromyalgia is diffuse, chronic pain. The locations of nine pairs of tender points for diagnostic classification of fibromyalgia are shown in Figure 44-32. Along with a history of diffuse pain, tenderness in 11 of these 18 points is necessary for diagnosis. Tender points must include areas on both sides of the spine as well as above and below the waist. In an effort to simplify and more accurately diagnose FM, the American College of Rheumatology (ACR) recently expanded the diagnostic criteria to include a widespread pain index (WPI) as "axial pain, left- and right-sided pain, and upper and lower segment pain."[124] Pain often begins in one location, especially the neck and shoulders, but then becomes more generalized. Some investigators have found that the majority of women experienced pain and fatigue for more than 90% of their time awake. Fatigue is most notable when arising from sleep and during the midafternoon. Headaches, symptoms of irritable bowel syndrome, and excess sensitivity to cold (Raynaud-like) are reported in 50% of individuals.

Almost 25% of individuals seek psychologic support for depression. Anxiety, particularly in regard to their diagnosis and future, is almost universal. Again, the only reliable finding on examination is the presence of multiple tender points.

EVALUATION AND TREATMENT. Because the manifestations of chronic, generalized pain and fatigue are present in many musculoskeletal (e.g., rheumatic) disorders, these disorders should be considered in the diagnosis of fibromyalgia (Tables 44-10 and 44-11).

No single regimen of medication has proved successful for fibromyalgia. Medications that improve sleep may be helpful as well as vitamin D supplementation. Anti-inflammatories have been used despite the fact there is no evidence of tissue inflammation, but these medications have not been effective. Certain CNS-active medications, most notably pregabalin, were better than placebo in controlled trials.[125] Probably the best approach is a combination of modalities, including education, medication, exercise, and cognitive-behavioral therapy.[126] Box 44-5 lists some of these modalities.

TABLE 44-10 DIFFERENTIAL DIAGNOSIS OF FIBROMYALGIA

DIFFERENTIAL DIAGNOSIS	HELPFUL DIFFERENTIAL FEATURES
Rheumatoid arthritis*	Synovitis, serologic tests, elevated erythrocyte sedimentation rate (ESR)
Systemic lupus erythematosus*	Dermatitis, serositis (renal, central nervous system, etc.)
Polymyalgia rheumatic*	Elevated ESR, older adults, response to corticosteroids
Myositis	Increased muscle enzymes, weakness more than pain
Hypothyroidism*	Abnormal thyroid function tests
Neuropathies	Clinical and electrophysiologic evidence of neuropathy

Data from Klippel JH, Dieppe PA, editors: *Rheumatology,* ed 2, London, 1998, Mosby-Wolfe.
*Fibromyalgia may also more commonly coexist with these conditions.

TABLE 44-11 CONCOMITANT CONDITIONS WITH FIBROMYALGIA

CONCOMITANT CONDITION	RELATIONSHIP TO FIBROMYALGIA
Depression	Present in 25-60% of fibromyalgia cases
Irritable bowel	Present in 50-80% of fibromyalgia cases
Migraine	Present in 50% of fibromyalgia cases
Chronic fatigue syndrome (CFS)	70% of CFS cases meet criteria for fibromyalgia
Myofascial pain	May be a localized form of fibromyalgia

Data from Klippel JH, Dieppe PA, editors: *Rheumatology,* ed 2, London, 1998, Mosby-Wolfe.

Chronic Fatigue Syndrome

Chronic fatigue syndrome (CFS), also known as myalgic encephalomyelitis (ME), is a debilitating and complex disorder characterized by profound fatigue, neurologic energy production, and immune impairments. Though controversy about its etiology persists, recent evidence indicates symptoms are the result of central nervous system dysregulation, cardiovascular and immune system abnormalities, and dysfunction of cellular energy metabolism and ion transport.[127] As a result, CFS/ME is less a musculoskeletal disorder than one related to hypersensitivity of the central nervous system, a condition also known as central sensitization. Although individuals with CFS have widespread pain and fatigue, they do not have the tender points associated with fibromyalgia.[128]

PATHOPHYSIOLOGY. A recent International Consensus Criteria have recommended use of the term myalgic encephalomyelitis (ME) rather than chronic fatigue syndrome, because ME indicates an underlying pathophysiology.[127] In support of this,

BOX 44-5 EDUCATION AND REASSURANCE FOR INDIVIDUALS WITH FIBROMYALGIA

- Stress that the illness is real, not imagined.
- Explain that fibromyalgia is not a deforming or deteriorating condition.
- Explain that fibromyalgia is neither life threatening nor markedly debilitating, although it is an irritating presence.
- Discuss the role of sleep disturbances and the relationship of neurohormones to pain, fatigue, abnormal sleep, and mood.
- Reassure that although the cause is unknown, some information is known about the physiologic changes responsible for the symptoms.
- Use muscle "spasms" and perhaps low muscle blood flow to lay the groundwork for exercise recommendations.
- Assist individual to use aerobic exercise to reduce stress and increase rapid eye movement (REM) sleep.

functional MRI (fMRI) has shown lower blood perfusion to the brainstem in individuals affected by CFS.[128] Other researchers have shown apparent central nervous system abnormalities, immunologic dysregulation, and higher-than-normal levels of proinflammatory cytokines. Certain points in skeletal muscle may be affected by oxidative stress reactions (see Chapter 2), accounting for the muscle pain and fatigue associated with CFS; but other research implicates central sensitization of the CNS.[129]

CLINICAL MANIFESTATIONS. Unrestful sleep is a hallmark of CFS. Defining symptoms include debilitating fatigue made worse by physical or mental exercise (postexertional fatigue), muscle pain, noninflammatory joint pain, headaches, flu-like symptoms, and memory or concentration problems. Other common symptoms include bloating, morning joint stiffness, chest or jaw pain, chills and night sweats, visual disturbances, sore throat, and tender axillary or cervical lymph nodes. Symptoms and their consequences can be severe.

EVALUATION AND TREATMENT. Diagnosis of CFS is often delayed or missed because there is no biologic marker or specific laboratory test for CFS, many CFS symptoms are shared with other illnesses, individuals with CFS do not necessarily look sick, and symptoms typically have a variable course. Currently, the CDC recommends considering a diagnosis of CFS if the following two criteria are met[130]:

1. Unexplained, persistent fatigue is not due to ongoing exertion, is not substantially relieved by rest, is of new onset (not lifelong), and results in a significant reduction of previous levels of activity.
2. Four or more of the following symptoms are present for 6 months or more:
   - Impaired memory or concentration
   - Postexertional malaise (extreme, prolonged exhaustion and exacerbation of symptoms following physical or mental exertion)
   - Unrefreshing sleep
   - Muscle pain
   - Multijoint pain without swelling or redness (adults)
   - Headaches of a new type or severity
   - Sore throat that is frequent or recurring
   - Tender cervical or axillary lymph nodes

Treatment of CFS is primarily based on the person's individual needs and involves consideration of psychosocial factors as well as symptomatic and supportive care. Acknowledging the validity of the person's symptoms is important. Collaborative decision-making between the individual and healthcare provider with regard to treatment, professional counseling, medication, diet, and activity helps CFS sufferers deal with the limitations imposed by the disease. Alternative therapies such as acupuncture, massage, and therapeutic touch can relieve anxiety.

Disuse Atrophy

The term **disuse atrophy** describes the pathologic reduction in normal size of muscle fibers after prolonged inactivity from bed rest, trauma (casting), or local nerve damage. The effects of muscular deconditioning associated with lack of physical activity may be apparent in a matter of days. Oxidative stress from lack of muscle activity causes decreased protein synthesis and increased proteolysis, leading to muscle atrophy.[131] The normal individual on bed rest loses muscle strength from baseline levels at a rate of 3% per day. Bed rest also is associated with cardiovascular, skeletal, and other organ system changes. As muscles age, they lose strength and mass, a condition known as sarcopenia.

Certain genes and transcription factors play a role in muscle atrophy.[132,133] Measures to prevent atrophy include adequate nutrition, frequent forceful isometric muscle contractions, and passive lengthening exercises. If reuse is not restored within 1 year, regeneration of muscle fibers becomes impaired.

Muscle Membrane Abnormalities

Two defects of the muscle membrane (plasma membrane of the muscle fiber) have been linked to clinical syndromes: the hyperexcitable membrane seen in the myotonic disorders and the intermittently unresponsive membrane seen in periodic paralyses. Although these are infrequent disorders, research into the pathologic processes has led to an improved understanding of the cell membrane.

Skeletal Muscle Channelopathies

Generally speaking, skeletal muscle channelopathies can be divided into two primary groups: those presenting with myotonia (nondystrophic myotonias) and those associated with episodes of weakness (periodic paralysis). In **myotonic channelopathies,** muscle relaxation is delayed after voluntary contractions such as handgrip or eye closure. With periodic paralysis, depolarization of the sarcolemma is severe enough that the muscle cannot be "fired" again, resulting in paralysis.[134] (Ion channels are discussed in Chapter 1.)

Myotonia can be reproduced by removing extracellular chloride, thus reducing chloride conductance across the plasma membrane. The delicate balance in which sodium diffuses into the intracellular fluid, potassium diffuses out of the intracellular fluid, and chloride is in flux is thus interrupted. Because the normal diffusion processes (described in Chapter 3) stabilize the membrane, the shift in chloride ions is thought to increase membrane excitability. The chloride abnormality may explain

the resting membrane hyperexcitability, but it does not explain the delayed relaxation present in myotonia and has not been detected in human myotonia.

Myotonia is seen in several disorders: myotonia congenita, paramyotonia congenita, myotonic muscular dystrophy, and some forms of periodic paralysis. Most are inherited disorders and are mild in symptomatology, with the exception of myotonic muscular dystrophy (see Chapter 45). Myotonia is treated by drugs that reduce muscle fiber excitability, such as procaine, procainamide, and phenytoin. Other treatments include the carbonic anhydrase inhibitors acetazolamide and dichlorphenamide.

Central core disease (CCD) is another inherited channelopathy that involves mutations in ryanodine receptors (RyR1) and affects calcium channels. In CCD, RyR1 channels are defective and either too much or too little calcium is released from the cell's sarcoplasmic reticulum. Classified as a neuromuscular disorder, CCD typically manifests during infancy as decreased muscle tone, delayed motor development, muscle weakness (particularly around the hip girdle), and other skeletal deformities, such as scoliosis.[135] Associated malignant hyperthermia susceptibility is common. Thought to be the most common congenital myopathy, pathology relates to the lack of "cores" within skeletal myofibers that do not contain mitochondria and their oxidative enzymes.[12]

Periodic Paralysis

Periodic paralysis (PP) is caused by autosomal dominant inherited mutations of skeletal muscle sodium, calcium, or potassium channels.[136] During an attack of PP the muscle membrane is unresponsive to neural stimuli and the resting membrane potential is reduced from −90 to −45 mV. Periodic paralysis can be either hyper- or hypokalemic. As the name implies, PP is usually transient.

The paralysis, which leaves the individual flaccid and weak, does not affect the respiratory muscles. In most cases the weakness is accompanied by a change in serum potassium level, although in some individuals the change may be negligible. Cardiac dysrhythmias have been present during attacks.

Hypokalemic periodic paralysis is most often triggered by thyrotoxicosis caused by alterations in potassium ion channels that are regulated by triiodothyronine (T_3).[137] (The effect of potassium on the resting membrane potential is discussed in Chapter 3.) Glucose and insulin infusions and oral potassium loading are used as provocative tests; oral and intravenous potassium can relieve acute attacks. Treatment includes potassium-sparing diuretics and a high-salt diet. Acetazolamide, dichlorphenamide, and a low-salt diet are useful for long-term therapy. **Hyperkalemic periodic paralysis** is caused by a genetic mutation of sodium channels. Attacks are usually less severe than the hypokalemic form. Treatment includes small carbohydrate-rich meals, light exercise, and intravenous calcium gluconate.

Metabolic Muscle Diseases

Disorders in muscle metabolism can be caused by endocrine abnormalities or diseases of energy metabolism, such as glycogen storage disease, enzyme deficiencies, and abnormalities in lipid metabolism and mitochondrial function.

Endocrine Disorders

Often the systemic effects of hormonal imbalance overshadow the individual's muscular symptoms. For example, individuals with thyrotoxicosis may have signs of proximal weakness, paresis of the extraocular muscles (exophthalmic ophthalmoplegia), and, rarely, hypokalemic periodic paralysis. Hypothyroidism is often associated with a decrease in muscle mass and strength, with weak, flabby skeletal muscles and sluggish movements. Thyroid hormone is believed to regulate muscle protein synthesis and electrolyte balance. Changes in muscle protein synthesis and electrolyte balance may therefore explain the changes in muscle mass and contractility seen in endocrine disorders. The muscle symptoms subside with appropriate treatment of the primary hormonal disorder.

Familial hypomagnesemia is an autosomal recessive disease that primarily affects the renal system, causing hypomagnesemia and secondary hypocalcemia and can result in tetany and convulsions.[138] Other endocrine disorders affecting the musculoskeletal system include Dent disease, a syndrome that causes bone deformities, rickets or osteomalacia, and elevated urine calcium levels. Osteopetrosis (also known as Albers-Schönberg disease), caused by failure of osteoclasts to resorb bone, results in increased bone mass but increased bone fragility; growth abnormalities; and in the infantile form, bone marrow failure as bone marrow is replaced by bone.[139]

Diseases of Energy Metabolism

Muscle relies on carbohydrates, such as glycogen and lipids (free fatty acids), for energy. When stored glycogen or lipids cannot be used because of a lack of the enzyme necessary to convert energy for contraction, the individual experiences cramps, fatigue, and exercise intolerance. Disorders of muscle metabolism can be self-limiting, such as is seen in McArdle disease and some lipid disorders, or cause widespread irreparable muscle destruction, as in acid maltase deficiency.

McArdle Disease. **McArdle disease,** or glycogen myophosphorylase deficiency, was the first myopathy in which a single enzyme defect was identified (Figure 44-33). Individuals with McArdle disease lack muscle phosphorylase, which is responsible for the breakdown of glycogen in muscle. Normally after the body uses the short-term ATP and phosphocreatine stores, intramuscular lactic acid accumulates as glycogen is used (see Chapter 43). The individual with McArdle disease is not able to break down glycogen or produce lactic acid.

The altered energy production manifests itself in exercise intolerance, fatigue, and painful muscle cramps. When exercise is carried to an extreme, painful muscle contracture and myoglobinuria develop. Some individuals describe a "second wind" phenomenon, in which exercise tolerance increases if they slow their pace once the initial sensation of fatigue commences. This is caused by the use of free fatty acids as a secondary source of energy.[140] As the disease progresses, some individuals have pronounced muscle weakness and wasting. Other organs are not involved because the absence of phosphorylase is limited to muscle. Generally, individuals with McArdle disease learn to adapt their daily routine to avoid muscle symptoms. Usually the diagnosis of McArdle disease is made by the histochemical

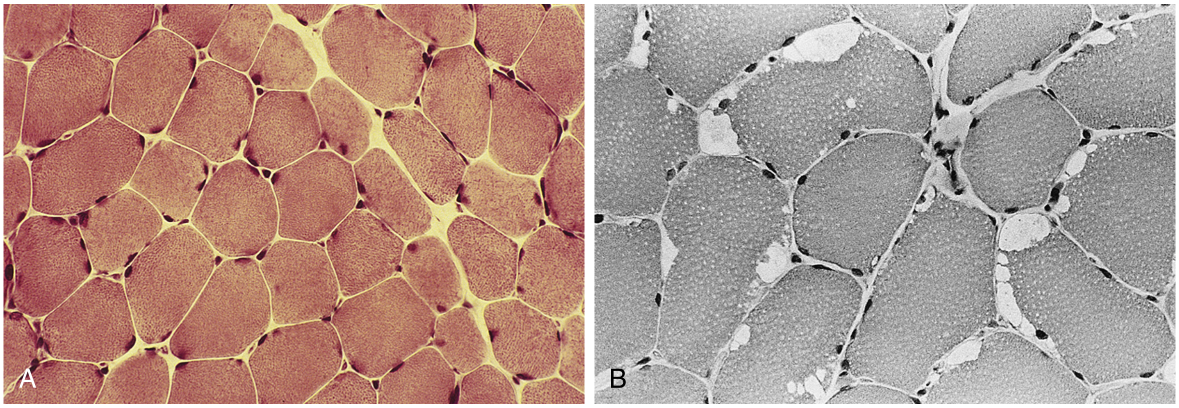

FIGURE 44-33 McArdle Disease. **A,** Normal muscle fibers. **B,** Muscle fibers of McArdle disease. Note the enlarged *(white)* peripheral vacuoles. (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

evaluation of myophosphorylase activity in frozen sections. There is no staining of myofibrils in affected individuals.

Acid Maltase Deficiency. **Acid maltase deficiency** is an uncommon glycogen storage disease associated with an accumulation of glycogen in the lysosomes of muscle and other tissue cells. The usual pathways of glycogen degradation are preserved. The absence of the enzyme acid maltase is responsible for the abnormality in glycogen metabolism, although the exact mechanism is unknown. It is an autosomal recessive disorder, with the gene located on the long arm of chromosome 17.

The infantile form, **Pompe disease,** is an autosomal recessive disease that causes lysosomal glycogen accumulation. The adult form tends to be less dramatic than the infantile type. The infantile form is recognized shortly after birth by hypotonia, dysreflexia, and an enlarged heart, tongue, and liver. Hypertrophy of these tissues is thought to be the result of glycogen deposition. Until recently, children often died of cardiac or respiratory failure before age 2; now enzyme replacement therapy (ERT) with recombinant human acid α-glucosidase and physical therapy can markedly improve symptoms.[141] The adult variety becomes evident subacutely and muscular symptoms resemble those of muscular dystrophy or polymyositis. A distinguishing feature in adults may be severe respiratory muscle weakness.

Myoadenylate Deaminase Deficiency. **Myoadenylate deaminase deficiency (MDD)** is a fairly common enzyme deficiency that causes changes in skeletal muscles and is associated with exercise intolerance. Because these individuals lack myoadenylate deaminase, they have a poor capacity for sustained energy production. Myoadenylate deaminase is the catalytic enzyme that forms phosphocreatine and ATP during exercise through a metabolic pathway that binds the purine and phosphate molecules that constitute ATP. Persons with MDD differ from those with McArdle disease in that during the ischemic exercise test, lactate production is normal when ATP and phosphocreatine are synthesized. Symptoms range from minimal complaints to exercise-induced muscle pain, to rhabdomyolysis.[142]

Lipid Deficiencies. Inherited disorders of lipid metabolism are uncommon but account for severe changes in muscle metabolism. The lipid content of muscle cells consists of free fatty acids, which are oxidized in the mitochondria. These acids require carnitine and the enzyme carnitine palmitoyltransferase (CPT); there are two CPT enzymes, I and II. Both are necessary to transport long-chain fatty acids to the mitochondria. Individuals with CPT deficiency often have mild muscular symptoms but can experience bouts of renal failure caused by rhabdomyolysis. Individuals with a deficiency of carnitine alone have progressive muscle weakness and can experience sudden exacerbations.

Measuring the CPT and carnitine content in muscle aids in the diagnosis. Cells in the muscle biopsy show vacuoles and lipid deposits. Treatments with riboflavin, medium-chain triglycerides, oral carnitine, and prednisone have been suggested.[143]

Inflammatory Muscle Diseases: Myositis

Viral, Bacterial, and Parasitic Myositis

Viral, bacterial, and parasitic infections of varying severity are known to produce inflammatory changes in skeletal muscle, a group of conditions collectively described by the term **myositis.** In tuberculosis and sarcoidosis, chronic inflammatory changes and granulomas are found in muscle, as well as in other affected tissues. In trichinellosis, *Trichinella* larvae reside in infected pork and, after ingestion, migrate to the intestinal mucosa and from there to the lymphatics. Symptoms include severe pain, rash, and muscle stiffness. Treatment includes administration of corticosteroids and antiparasitic agents, such as mebendazole or albendazole. Unfortunately, once trichinella larvae are established they may reside for years in the muscles. Toxoplasmosis, a common parasitic infection, is also associated with a generalized polymyositis that responds rapidly to therapy.

In the tropics, more prevalent disorders include bacterial infections with *Staphylococcus aureus* and parasites such as cysticercus, the larva of the tapeworm *Taenia solium.* Viral infections can be associated with an acute myositis. Muscle pain, tenderness, signs of inflammation, and elevation of CK level are common manifestations of viral myositis. The self-limiting symptoms of muscle aches and pains during a bout of influenza may actually be a subacute form of viral myopathy.

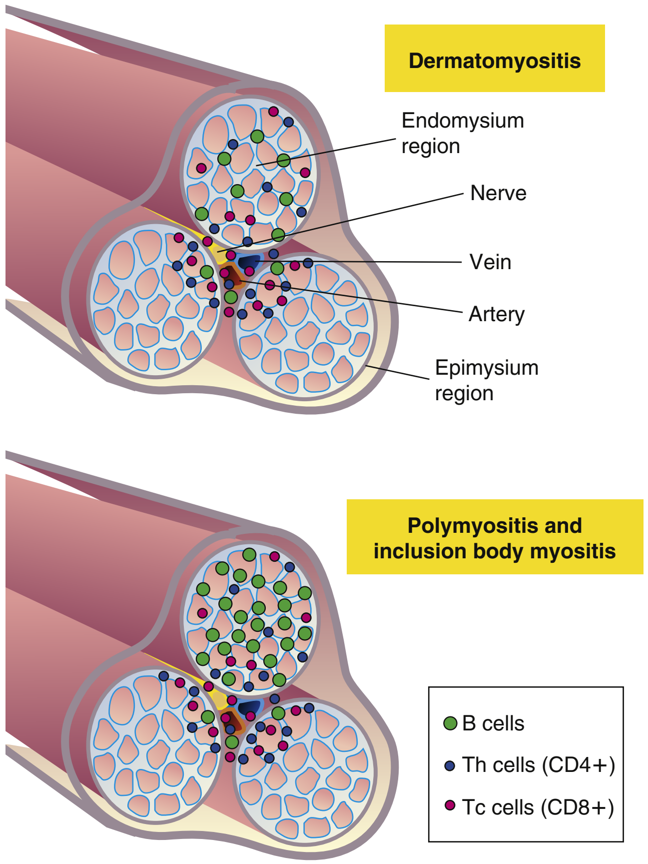

FIGURE 44-34 **Distribution of CD4+ and CD8+ Lymphocytes in Different Types of Myositis.** Dermatomyositis shows perivascular and CD4+ T cells (helper T cells). Polymyositis shows mostly CD8+ T cells (cytotoxic T cells).

FIGURE 44-35 **Dermatomyositis.** Heliotrope (violaceous) discoloration around the eyes and periorbital edema. (From Habif TP: *Clinical dermatology,* ed 3, St Louis, 1996, Mosby.)

Polymyositis, Dermatomyositis, and Inclusion-Body Myositis

Idiopathic inflammatory myopathies (IIMs) are a group of autoimmune diseases that target skeletal muscle. IIMs are characterized by symmetric proximal muscle (pelvic and shoulder girdle) weakness and myalgia that develops over weeks to months. The three principle types are polymyositis (PM), dermatomyositis (DM), and inclusion-body myositis (IBM). Non-white women over age 50 are most often affected by IIM; however, DM includes a juvenile form (JDM). Interstitial lung disease is common in both PM and DM. The incidence of IIM appears to be increasing, but this may simply reflect improved diagnosis.

PATHOPHYSIOLOGY. Polymyositis and dermatomyositis are characterized by inflammation of connective tissue and muscle fibers. Polymyositis is mediated by T cells, whereas dermatomyositis is humorally-mediated.[144] $CD8^+$ T cells and macrophages are typically found in PM-affected muscles. Figure 44-34 shows the distribution of CD4+ and CD8+ lymphocytes in myositis. Innate and adaptive immune responses are activated in these myopathies, including myositis-specific antibodies and cytokines.[145] Inflammatory cells, including T cells, macrophages, and plasma cells, surround, displace, and even invade muscle fibers in PM. Perimysial and perivascular sites are selectively enriched in B cells and helper T cells in those with DM. DM is thought to be a microvascular disorder that includes deposits of complement in capillaries; however, recent research also has shown up-regulation of interferon signaling in muscle, blood, and skin of people with DM.[146] Ability to demonstrate elevated interferon levels can aid in both diagnosis and determination of targets to treat these diseases.

CLINICAL MANIFESTATIONS. The acute symptoms include many of those seen in any inflammatory process: malaise, fever, muscle swelling, pain and tenderness, lethargy, and listlessness. In adults, weakness of the shoulder and pelvic girdle muscles is a primary manifestation of PM. Both PM and DM often are associated with symmetric proximal muscle weakness and initially can be confused with other myopathies. A thorough evaluation is required to exclude other disorders. Clinical features common to both are dysphagia, reduced esophageal motility, vasculitis, Raynaud phenomenon, cardiomyopathy, and interstitial pulmonary fibrosis. Some individuals have other coexisting collagen vascular disorders, such as RA, systemic lupus erythematosus (SLE), and progressive systemic sclerosis (formerly called *scleroderma*).

Although PM and DM have similar histories of onset, DM includes cutaneous manifestations. The two most classic signs of skin involvement are rashes: (1) a heliotrope (reddish purple) rash that generally covers the eyelids and periorbital area (Figure 44-35), and often includes the chest; and (2) erythematous, scaly lesions (Gottron lesions) that cover joints, such as the knees and elbows. DM is slightly more common in children and older adults, with onset before age 15 or after age 50. The adult with DM occasionally has underlying malignancies.

IBM differs from both PM and DM in several important ways. Muscle biopsy and histopathologic studies of IBM show degenerative changes of muscle, accumulation of multiple proteins within muscle fibers, and evidence of endoplasmic reticular stress with misfolding of proteins.[147,148] Clinically, IBM may show weakness of the wrist and finger flexors as well as asymmetric atrophy and quadriceps weakness.[149]

EVALUATION AND TREATMENT. Muscle biopsy is striking in DM, with most individuals showing inflammatory cells grouped around blood vessels and atrophy of cells in muscle fascicles. This change, perifascicular atrophy, is absent in PM. Creatine kinase (CK) and other muscle enzymes, including aspartate transaminase (AST), lactate dehydrogenase (LDH), and alanine transaminase (ALT), and sedimentation rate are often extremely elevated in both disorders. The presence of serum antinuclear antibodies also may be helpful in diagnosing DM. EMG abnormalities include signs of muscle irritability and myopathic changes—usually large numbers of low-amplitude action potentials of brief duration. The EMG also shows a typical "myopathic" pattern, with short, low-amplitude polyphasic potentials, as well as signs of marked muscle irritability. Muscle biopsy is indispensable for determining a diagnosis of polymyositis or dermatomyositis as opposed to other myotonic diseases. MRI reveals inflammation and edema of the muscles.

Treatment primarily includes immunosuppressive drugs, although they are not always successful if uniformly applied. Most clinicians choose corticosteroids initially, though their utility has recently come into question.[150] High-dose intravenous immunoglobulin administration is sometimes used during active disease. Successful treatment with azathioprine and methotrexate has been reported. Creatine supplements and physical therapy may improve muscle strength.

Myopathy

Myopathy is the term applied to a primary muscle disorder. Many pathologic processes affect muscles and cause loss of functional muscle cells. Myopathies affect muscle strength, tone, and bulk. Primary muscle disease is invariably associated with weakness—usually marked weakness. The distribution of the weakness in myopathy is usually symmetric and proximal, although occasionally the weakness is predominantly distal, such as in myotonic dystrophy. The weakness is associated with mild fatigue. Tone is decreased, as are the tendon reflexes. Atrophy may be present. Some myopathies are associated with muscle hypertrophy as in cretinism and the familial progressive muscular dystrophies of childhood, in which hypertrophied muscles are rubbery and weak. Fasciculations are not present with myopathy because no denervation is present. No sensory changes are found. (Specific neurologic-associated myopathies are discussed in Chapter 17.)

Toxic Myopathies

A number of agents, including corticosteroids, chloroquine, alcohol, phenytoin, azathioprine, organophosphates, and reverse transcriptase inhibitors, have been shown to cause **toxic myopathy.** Alcohol remains the most common cause of toxic myopathy. The incidence of acute alcoholic myopathy has been estimated at up to 20% of individuals admitted with acute alcoholic withdrawal.

The mechanisms by which alcohol affects the muscle include disturbances of energy cell turnover, gene dysregulation, and initiation of apoptosis. Pathologic abnormalities include necrosis of individual muscle fibers, particularly type II fibers; whole segments can be found in the same stage of degeneration.

Acute alcoholic myopathy can range from benign cramps and pain resolving in a matter of hours to severe weakness and markedly increased CK level associated with myoglobinuria and renal failure. Individuals are prone to repeated attacks following recovery. The only treatment is abstinence from alcohol and improved nutrition. An individual with chronic alcoholic myopathy often has a coexisting peripheral neuropathy that complicates the diagnosis.

Repeated intramuscular injections have been associated also with changes in muscle fibers. Local necrosis of muscle fiber and elevated CK concentration have been reported after intramuscular injections of certain cephalosporins, lidocaine, diazepam, and digoxin; these effects were not produced with injections of saline. When drugs are injected over long periods, a chronic focal myopathy develops. Proliferation of connective tissue both in the muscle fiber and in the overlying skin and subcutaneous tissue has been reported. Over time, segments of the muscles, particularly the deltoid and quadriceps, are converted into fibrotic bands. Pathophysiologic mechanisms for these changes include repeated needle trauma and infection, along with the nonphysiologic acidity and alkalinity of the injected material. Box 44-6 lists some of the causes of toxic myopathy.

Muscle Tumors

Rhabdomyoma

Rhabdomyoma is an extremely rare benign tumor of striated muscle that generally occurs in the tongue, neck muscles, larynx, uvula, nasal cavity, axilla, vulva, and heart. These tumors are usually treated by surgical excision and do not recur.

Rhabdomyosarcoma

A rare malignant tumor of striated muscle is called **rhabdomyosarcoma,** which is a subgroup of sarcoma. These tumors are highly malignant, with rapid metastasis. They are located in the muscle tissue of the head, neck, and genitourinary tract in 75% of cases. The remaining 25% of these tumors are located in the trunk and extremities. Rhabdomyosarcomas are the most common soft tissue tumors in children and young adults.

Three types of rhabdomyosarcoma are differentiated on pathologic section: pleomorphic, embryonal, and alveolar. The pleomorphic, or spindle cell, type is considered to be one of the most highly malignant tumors of the extremities seen in adulthood, but has a better outcome in children. Embryonal tumors are most commonly seen in childhood and appear on biopsy to be shaped like a tadpole or tennis racquet. Alveolar-type tumors, which appear lattice-like and look like lung tissue alveoli, have the poorest outcome.[151]

The diagnosis of rhabdomyosarcoma is made by history, physical examination, serologic testing, CT, and MRI, and is confirmed by incisional biopsy and examination of the specimen by a pathologist. On electron microscopy the tissue demonstrates myofilaments and Z-band material; CT scan helps

BOX 44-6 AGENTS THAT CAN CAUSE TOXIC MYOPATHY

Drug-Induced
Alcohol
Amiodarone (and others that inhibit CYP3A4 when combined with simvastatin)
Amphotericin B
Azathioprine
AZT (zidovudine)
Chloroquine
Clofibrate
Cocaine
Colchicine
Ethanol
Ipecac (withdrawn from U.S. markets)
3,4-Methylenedioxymethamphetamine (MDMA, "ecstasy")
Pentachlorophenol (PCP)
Statins
Steroids (especially with prolonged high doses; doses >25 mg/day; fluorinated steroids)

Endocrine Disorders
Adrenal disorders (Addison disease, Cushing disease)
Hyperparathyroidism
Hyperthyroidism (CK may be normal)
Hypothyroidism (CK may be mildly elevated)

Infectious
Coxsackie A and B viruses
Human immunodeficiency virus (HIV)
Influenza
Lyme disease
Staphylococcus aureus muscle infection (frequent cause of pyomyositis)
Toxoplasmosis
Trichinosis

Miscellaneous
Licorice
Certain edible wild mushrooms
Lead poisoning
Organophosphates
Red yeast rice
European migratory quail (quail eat toxic hemlock, hellebore seeds)
Any medication that alters serum concentrations of sodium, potassium, calcium, phosphorus, or magnesium

Data from Kuncl RW: *Curr Opin Neurol* 22(5):506–515, 2009; Valiyil R, Christopher-Stine L: *Curr Rheumatol Rep* 12(3):213–220, 2010.

define the tissue borders. Staging is based on pathologic grade of the tumor and is helpful in determining prognosis and treatment.

Treatment consists of a combination of surgical excision, radiation therapy, and systemic chemotherapy. Overall survival of childhood rhabdomyosarcoma has improved over the past decades but adult survival remains poor (see Chapter 45).

Other Tumors

Metastatic muscle tumors are rare in spite of the extensive vascular supply of skeletal muscles. It is suggested that local pH or metabolic changes discourage metastatic involvement from other tumors. When adjacent carcinomas do cause muscle damage, it is usually related to the compression of tissue and resultant muscle atrophy.

SUMMARY REVIEW

Musculoskeletal Injuries

1. The most common skeletal injury is a fracture. A bone can be completely or incompletely fractured. A closed fracture leaves the skin intact. An open fracture has an overlying skin wound. The direction of the fracture line can be linear, oblique, spiral, or transverse. Greenstick, torus, and bowing fractures are examples of incomplete fractures that occur in children. Stress fractures occur in normal or abnormal bone that is subjected to repeated stress. Fatigue fractures occur in normal bone subjected to abnormal stress. Normal weight-bearing can cause an insufficiency fracture in abnormal bone.
2. Dislocation is complete loss of contact between the surfaces of two bones. Subluxation is partial loss of contact between two bones. As a bone separates from a joint, it may damage adjacent nerves, blood vessels, ligaments, tendons, and muscle.
3. Tendon tears are called *strains,* and ligament tears are called *sprains.* A complete separation of a tendon or ligament from its attachment is called an *avulsion.*
4. Epicondylopathy is degeneration of a tendon where it attaches to a bone. Bursitis is inflammation of the bursae (small sacs lined with synovial membrane and filled with synovial fluid). Bursitis can be inflammatory, septic, or hemorrhagic.
5. Muscle strain can range from mild injury to severe damage that can result in loss of muscle function.
6. Rhabdomyolysis can be a life-threatening complication of severe muscle trauma wherein muscle cell contents are released into the circulation. It may result in myoglobinuria, the presence of myoglobin in the urine, and is often associated with acute renal failure.

Disorders of Bones

1. Metabolic bone diseases are characterized by abnormal bone structure. In osteoporosis bone tissue is normally mineralized, but the density or mass of bone is reduced because the bone remodeling cycle is disrupted. Osteoporosis is a complex, multifactorial, chronic disease that often progresses silently for decades until fractures occur. It is the most common bone disease. Multiple factors are involved including alteration in the OPG/RANKL/RANK system.
2. Postmenopausal osteoporosis occurs in middle-aged and older women and is caused by increased osteoclast activity, probably caused by changes in osteoprotegerin, IGF, a combination of inadequate dietary calcium intake and lack of vitamin D, possibly decreased levels of magnesium, lack of exercise, decreased levels of estrogen, and family history.
3. Glucocorticoids increase RANKL expression and inhibit OPG production by osteoblasts, thus leading to lower bone density.

SUMMARY REVIEW—cont'd

4. Osteomalacia is a metabolic bone disease characterized by inadequate bone mineralization.
5. Excessive and abnormal bone remodeling occurs in Paget disease. Sporadic Paget disease involves overexpression of RANKL.
6. Osteomyelitis is a bone infection caused most often by bacteria (e.g., *S. aureus*) that can enter bone from outside the body (exogenous osteomyelitis) or from infection sites within the body (hematogenous osteomyelitis).
7. Bone tumors originate from bone cells, cartilage cells, fibrous tissue cells, or vascular marrow cells. Each cell produces a specific type of ground substance that is used to classify the tumor as osteogenic (bone cell), chondrogenic (cartilage cell), collagenic (fibrous tissue cell), or myelogenic (vascular marrow cell). Malignant bone tumors are large, aggressively destroy surrounding bone, invade surrounding tissue, and initiate independent growth outside the site of origin. Benign bone tumors are less destructive, limit their growth to the anatomic confines of the bone, and have a well-demarcated border.

Disorders of Joints

1. Noninflammatory joint disease is differentiated from inflammatory joint disease by the absence of synovial membrane inflammation, the absence of systemic signs and symptoms, and the presence of normal synovial fluid.
2. OA is now considered an inflammatory joint disease and is characterized by the degeneration and loss of articular cartilage, sclerosis of underlying bone, and formation of bone spurs (osteophytes).
3. RA is an inflammatory joint disease characterized by inflammatory destruction of the synovial membrane, articular cartilage, joint capsule, and surrounding ligaments and tendons. RA involves an aberrant immune response and the transformed antibodies are called *rheumatoid factors.* The OPG/RANKL/RANK system is also involved. Rheumatoid nodules may also invade the skin, lung, and spleen and involve small and large arteries. RA is a systemic disease that affects the heart, lungs, kidneys, and skin, as well as the joints.
4. AS is a chronic inflammatory joint disease characterized by stiffening and fusion of the spine and sacroiliac joints. Recent data show that synovitis and bone marrow inflammation, rather than solely enthesis involvement, explain the alteration in sacroiliac joints.
5. Gout is a metabolic disorder associated with high levels of uric acid in the blood and body fluids. Uric acid crystallizes in the connective tissue of a joint, where it initiates inflammatory destruction of the joint.

Disorders of Skeletal Muscle

1. A pathologic contracture is permanent muscle shortening caused by muscle spasticity, as seen in CNS injury or severe muscle weakness.
2. Stress-induced muscle tension is presumably caused by increased activity in the reticular activating system and gamma loop in the muscle fiber. Progressive relaxation training and biofeedback have been advocated to reduce muscle tension.
3. Fibromyalgia is a chronic musculoskeletal syndrome characterized by diffuse pain and tender points. It is unknown but suspected that muscle is the end organ responsible for the pain and fatigue of the disease. Comorbidities (e.g., irritable bowel syndrome, mood disorders, and chronic fatigue) suggest a major role for neuroendocrine and stress-response alterations.
4. Chronic fatigue syndrome (CFS) is a debilitating and complex disorder with profound fatigue not improved by bed rest. The actual cause of CFS is unknown and hypotheses include central nervous system alterations, immunologic disruptions, and chronic proinflammatory cytokines.
5. Atrophy of muscle fibers and overall diminished size of the muscle are seen after prolonged inactivity. Isometric contractions and passive lengthening exercises decrease atrophy to some degree in immobilized persons.
6. Hyperexcitable membranes cause the physical and electrical phenomenon of myotonia. The disorder is treated with drugs that reduce fiber excitability. Periodic paralysis is caused by an unresponsive muscle membrane and is accompanied by changes in the level of serum potassium. The biochemical defect is possibly related to changes in the muscle membrane and sarcoplasmic reticulum.
7. Metabolic muscle diseases are caused by endocrine disorders, glycogen storage disease, enzyme deficiencies, and abnormal lipid function. The muscle depends on a complex system of carbohydrates and fats converted by enzymes to produce energy for the muscle cell. Abnormalities in these pathways can inhibit function or cause damage to the muscle fiber. These illnesses are rare, yet they account for significant functional abnormalities.
8. Viral, bacterial, and parasitic infections of muscles produce the characteristic clinical and pathologic changes associated with inflammation. These are usually treatable and self-limiting disorders.
9. Polymyositis (generalized muscle inflammation) and dermatomyositis (polymyositis accompanied with skin rash) are characterized by inflammation of connective tissue and muscle fibers, and muscle fiber necrosis. Cell-mediated and humoral immune factors have been implicated. Treatment with immunosuppressive agents is effective in many cases.
10. Primary disorders with weakness and atrophy are known as myopathies.
11. The most common toxic myopathy is caused by alcohol abuse. Direct toxic effects of alcohol-producing necrosis of muscle fibers and nutritional deficiency have been suggested. The only treatment is abstinence and improved nutrition. The toxic effects of many drugs on muscle fibers cause local trauma to the muscle fibers from direct effects of the needle, secondary infection, and changes caused by nonphysiologic acidity and alkalinity in the fibers.
12. Sarcomas of muscle tissue are rare. Rhabdomyosarcoma has a uniformly poor prognosis because of an aggressive invasion and early, widespread dissemination. The usual treatment includes surgical excision, radiation therapy, and systemic chemotherapy.

- Review Questions and Answers

CHAPTER OUTLINE

Musculoskeletal alterations in children are very common. They may be congenital, such as clubfoot; hereditary, such as muscular dystrophy; or acquired, such as Legg-Calvé-Perthes disease. Some of these disorders are acute, and the child will recover completely; other disorders are chronic or, in some cases, terminal. An understanding of the pathophysiology of these alterations will aid in providing the best care possible for these children.

MUSCULOSKELETAL DEVELOPMENT IN CHILDREN

Bone Formation

Bone formation, which begins at about the sixth week of gestation, involves two phases: (1) the delivery of bone cell precursors to sites of bone formation and (2) the aggregation of these cells at **primary centers of ossification,** where they mature and begin to secrete osteoid (see Chapter 43). Some of the bone cell precursors are present in fetal connective tissues, whereas others migrate in blood to sites of bone formation after blood vessels have grown into the tissue.

Cellular aggregation and maturation occur in two types of fetal tissue, depending on which bones are being formed. The cranium, facial bones, clavicles, and parts of the jawbone (classically called “flatbones”) arise from a fetal membrane termed the *mesenchyme.* Bones that develop on or within the mesenchyme grow by the process of **intramembranous formation of bone.** As the mesenchyme becomes vascularized, the immature bone cells aggregate and mature into osteoblasts, which form the centers of ossification and create solid bone or osteoid.

Endochondral formation of bone is the development of new bone from cartilage (Figure 45-1). First, mesenchymal tissue forms a **cartilage anlage,** which defines the shape of the bone. This is usually found by 6 weeks of gestation. Blood vessel invasion to inside the anlage brings osteoprogenitor cells leading to primary centers of calcification by 8 weeks. Endochondral bone formation begins in the outer layer of the cartilage model, which consists of a layer of dense connective tissue called **perichondrium.** The perichondrium contains cells that develop into osteoblasts, forming a collar of bone, termed the **periosteal collar,** around the cartilage model. Cartilage enclosed within the periosteal collar degenerates, and capillaries from outside the

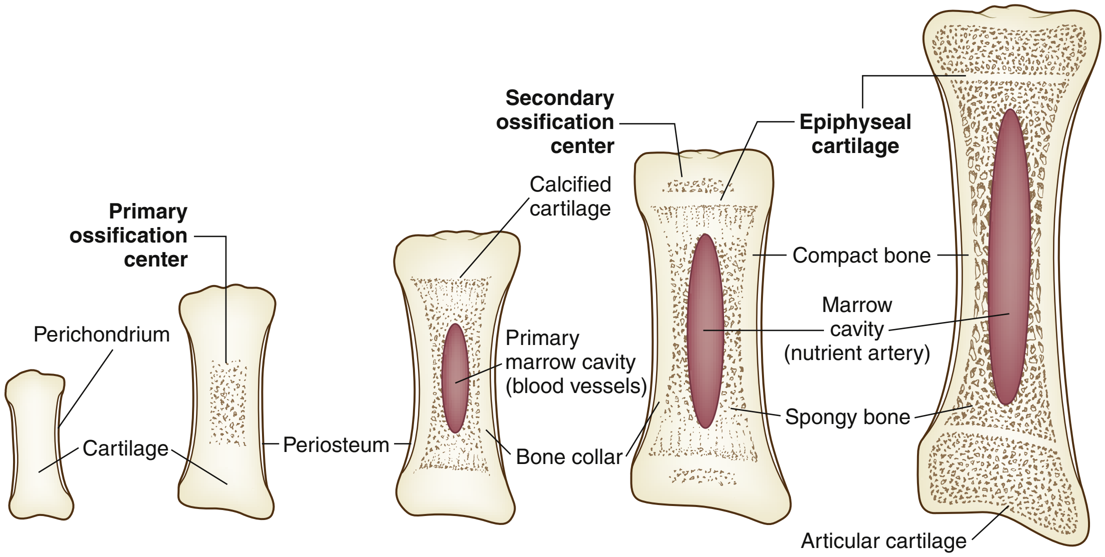

FIGURE 45-1 Stages of Endochondral Bone Formation and Centers of Ossification in Long Bone.

perichondrium invade the degenerating cartilage cells, carrying with them osteoblast precursors from the inner layer of the perichondrium and osteoclast precursors from the blood itself.

Endochondral bone formation progresses at the primary center of ossification in the middle of the cartilage model and extends toward either end of the developing bone. At the same time, the periosteal collar thickens and becomes wider toward the epiphyses. By the end of gestation **secondary centers of ossification** (i.e., the epiphyseal centers) begin to lay down bone at both ends of the cartilage model. Here, too, cartilage within the periosteal collar degenerates, and blood vessels grow inward, delivering bone cell precursors. Once the osteoblasts begin to secrete osteoid, ossification spreads from the secondary centers in all directions until all the cartilage within the model is replaced by bone.

Two regions of cartilage remain at the ends of long bones: (1) articular cartilage over the free ends of the bone, and (2) the physeal plate, a layer of cartilage between the metaphysis and epiphysis. (These structures are described and illustrated in Chapter 43; see Figure 43-3.) The physeal plate retains the ability to form and calcify new cartilage and deposit bone until the skeleton matures approximately 1 year after sexual maturity (11 to 15 years of age in females, 15 to 18 in males).

Bone Growth

Until adult stature is reached, growth in the length of long bones occurs at the physeal plate through endochondral ossification. Cartilage cells at the epiphyseal side of the physeal plate multiply and enlarge. As rapidly as new cartilage cells form, cartilage cells at the metaphyseal side of the plate are destroyed and replaced by bone.

In the shaft of new bone, where growth is relatively slow, the bone produced by accretion is compact and dense. The compact bone is thickest where it has to withstand the maximal stresses, which generally occur in the middle of the shaft.

The two physes of the long bone often have varying activity rates. For example, the distal physis in the femur contributes 80% of the overall length, whereas the proximal physis at the hip contributes only 20%. The more active of the two has more power to remodel deformity but also can be more sensitive to injury. The architecture of the physis also dictates its sensitivity to injury. The distal femur, for example, has an undulating pattern that increases its resistance to sheer force; when injured, however, growth disturbance is highly likely, whereas the distal radius, which contributes 80% of overall radial length, is a flat, smooth physis that is far more resistant to traumatic injury.

Growth in the diameter of bone occurs by deposition of new bone on an existing bone surface. Bone matrix is laid down by osteoblasts on the periosteal surface and subsequently becomes calcified. At the same time, bone resorption occurs on the endosteal surface. Endosteal resorption increases the diameter of the medullary cavity, which contains marrow and spongy bone.

Many factors affect the development, physiology, and rate of growth of the epiphyseal plate. Growth hormone must be secreted by the pituitary gland at a constant rate to stimulate the growth plate consistently. Other known factors affecting growth include peptide regulatory factors (e.g., fibroblast growth factor [FGF]); changes in cell-to-cell interactions through cell adhesion molecules (CAMs) and cell junctions; and complex interactions or changes in the extracellular matrix (ECM), nutrition, general health, and other hormones (e.g., thyroid hormone, adrenal and gonadal androgens, estrogens). When these factors are poorly controlled, skeletal dysplasias, such as achondroplasia, can occur.

Even after physeal closure at skeletal maturity, bone is constantly being destroyed and re-formed (see Chapter 43). This is a rapid process in young children, allowing them to heal bone injury more quickly than adults. By adulthood, however, bone turnover, or remodeling, occurs at a relatively slow rate. Peak bone mass is achieved by the middle to late twenties and slowly decreases throughout life; therefore, ensuring appropriate levels of calcium and phosphorous intake, performing weight-bearing lifting and exercise, and minimizing caffeine intake are especially important for a young female if she is to avoid

osteoporosis in later life. Recently, the importance of vitamin D levels also has been emphasized. In one study, nearly 70% of American children had low levels of vitamin D.[1]

Skeletal Development

The axial skeleton changes shape with growth. (The axial skeleton and appendicular skeleton are described and illustrated in Chapter 43; see Figure 43-5). In a newborn the entire spine is concave anteriorly, or **kyphosed.** In the first 3 months of life, with the infant's ability to control the head, the upper (cervical) spine begins to arch, or become **lordotic.** The normal lordotic curve of the lower (lumbar) spine begins to develop with sitting.

The appendicular skeleton (the extremities) grows faster during childhood than does the axial skeleton (see Figure 43-5). The newborn has a relatively large head and long spine with disproportionately shorter limbs than an adult. By 1 year of age, 50% of the total growth of the spine has occurred and is more than 70% complete by age 8.[2] Therefore, failure of the spine to grow (e.g., spinal fusion) does not limit eventual height as much as the premature fusion of the growth plates of the lower extremities. In children with congenital curvature of the spine, growth tends to worsen the deformity rather than to increase the length of the spine.

Besides getting longer, growing bones of the extremities undergo changes in rotation and alignment. In the newborn the proximal femur is rotated forward up to 40 degrees and the tibia is rotated inward. With growth the femur assumes its normal alignment (by 12 years of age) and tibial rotation neutralizes at 8 years of age.[3] Bowlegs and knock knees can be normal at certain stages of growth. At birth the newborn's legs are bowed because of stresses in utero. **Genu varum (bowleg)** reaches a peak by 30 months of age, whereas **genu valgum (knock knee)** maximizes by 5 to 6 years of age. If genu varum or genu valgum persists past these ages, a pathologic process rather than a physiologic phase may be present. Pathologic causes of genu varum are Blount disease, rickets, skeletal dysplasias (such as achondroplastic dwarfism), and traumatic injury. Genu valgum may persist also as a result of skeletal dysplasia or genetic predisposition.

Muscle Growth

The composition and size of muscles vary with age. In the fetus, muscle tissue contains a large amount of water and much intercellular matrix. After birth, both are reduced considerably as the muscle fibers (cells) enlarge by accumulating cytoplasm. Little information is available about the numbers of fibers in a given muscle at various ages, but the total mass of muscle in the body can be estimated from the amount of creatinine excreted in the urine, because the conversion of creatine to creatinine takes place only in muscle (see Chapter 43). Between birth and maturity the number of muscle nuclei in the body increases 14 times in boys and 10 times in girls. Muscle fibers reach their maximal size in girls at approximately 10 years of age and in boys by 14 years. Growth in length occurs at the ends of muscles, and the increase in length is accompanied by an increase in number of nuclei in the fibers. Muscle fibers increase in diameter as the fibrils become more numerous. The fibrils themselves do not increase in diameter. Connective tissue components of muscle grow where the tendon and muscle meet.

FIGURE 45-2 Syndactyly with Polydactyly.

A potent stimulus to the growth of a muscle is the separation of its attachments as the skeleton grows. The length of a muscle fiber is the direct consequence of its intended range of movement. The stimulus for the formation of a tendon is probably the pull of the muscle rudiment on undifferentiated connective tissue. If the normal opponents of a muscle are paralyzed, the muscle fails to grow properly and can result in contracture of a joint.

Muscle growth during adolescence is a major factor in weight gain. Gender differences in muscle size and weight are minor in childhood but become considerable with the onset of puberty.

In the infant, muscle accounts for approximately 25% of total body weight, compared with 40% in the adult. In the adult, approximately 55% of muscle weight is in the lower limb muscles, whereas in the infant the majority of the weight is axial musculature. The respiratory and facial muscles are well developed at birth so that the infant can perform the vital functions of breathing and sucking. Other muscle groups, such as the pelvic muscles, take several years to develop fully. Throughout life the weight of the skeletal muscles can be increased by exercise.

MUSCULOSKELETAL ALTERATIONS IN CHILDREN

Congenital Defects

Syndactyly

The most common congenital defect of the upper extremity is **syndactyly,** or webbing of the fingers (Figure 45-2). Simple webbing involves the soft tissue envelope alone and is best released surgically when the child is 6 months to 1 year of age. Complex syndactyly involves fusion of the bones and nails as well as the soft tissues; it may be associated with absence or anomaly of bony or neurovascular units. The primary goal in surgical correction of these defects is to achieve maximal function and appearance. Ideally, corrective surgery is deferred until the child is 1 to 2 years old and completed before the child enters school. **Vestigial tabs,** such as an extra digit, however, are best removed during the immediate neonatal period. Anomalies on the radial aspect of the arm, such as a foreshortened or absent

radius, are often associated with abnormalities of blood, heart, or kidneys. Lateral or ulnar-sided defects are less often associated with systemic anomalies and are far more rare.

Developmental Dysplasia of the Hip

Developmental dysplasia of the hip (DDH), formerly known as congenital dislocation of the hip, is an abnormality in the development of the proximal femur, acetabulum, or both (Figure 45-3). Although most often present at birth, it may occur at any time in the newborn or infant period.

The incidence of true dislocation of the hip or a dislocatable hip is 1 in 1000 live births. Some degree of instability of the hip is present in approximately 10 per 1000 live births. The left hip is affected in 60% of cases, whereas the right hip alone is affected only 20% of the time. Bilateral DDH occurs 20% of the time.

FIGURE 45-3 Hip Dysplasia in Children. Developmental dysplasia of the hip (DDH) with residual acetabular dysplasia. Radiographs at birth, 3, 10, and 19 years (top to bottom) show persisting dysplasia.

Risk factors for DDH include family history, female gender (6:1), metatarsus adductus (20%), torticollis (10%), oligohydramnios, first pregnancy, and breech presentation. First pregnancies and oligohydramnios (deficient volume of amniotic fluid) are thought to limit fetal movement, and breech presentation not only limits movement but also places the hips in a position of flexion and adduction, which creates a more shallow socket, or acetabulum. Although only 2% of births have breech history, as many as 40% of infants with DDH had a breech birth. Maternal hormones that reportedly increase joint laxity also have an effect on DDH, although the exact mechanism is unknown. DDH also is more common in whites and those cultures that swaddle infants with the hips in extension and adduction. It is almost unknown in African cultures where infants are carried, with legs abducted, on the back.

PATHOPHYSIOLOGY. The hip can be described as subluxated (partial contact only), dislocated (no contact between femoral head and acetabulum), and acetabular dysplasia (the femoral head is located properly but the acetabulum is shallow) (Figure 45-4). The **subluxated hip** maintains contact with the acetabulum but is not well seated within the hip joint. The acetabulum is often dysplastic (or shallow) although the femur is often normal. The **dislocatable hip** is sometimes located but can be dislocated easily. The dislocated hip has no contact between the femoral head and the acetabulum. Some degree of **acetabular dysplasia** is present in almost all cases. Typically the acetabulum is shallow or sloping rather than cup shaped.

By approximately 10 weeks of gestation, the femur, acetabulum, and hip joint capsule are well developed. It appears that most dysplasias occur within the second and third trimesters and are often the result of positioning factors. Experimentally, DDH can be produced in laboratory animals by placing the developing hip in adduction and extension, replicating the breech position. There is, however, a genetic component that is poorly understood. In addition, 2% of DDH cases are teratologic or caused by a systemic syndrome, such as arthrogryposis or spina bifida, in which muscle contracture or imbalance leads to DDH.

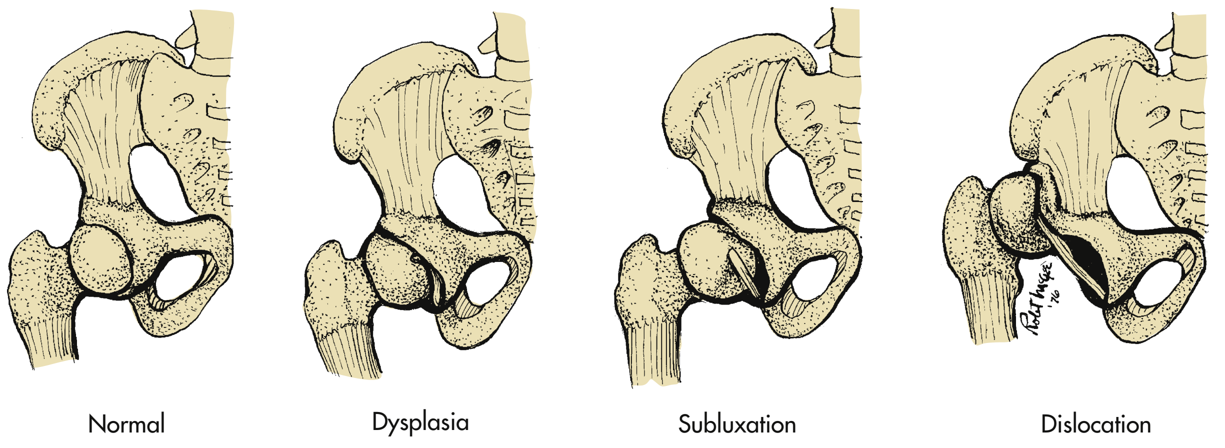

FIGURE 45-4 Configuration and Relationship of Structures in Developmental Dysplasia of the Hip. (From Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children,* ed 9, St Louis, 2011, Mosby.)

If DDH is left untreated in the growing child, secondary changes occur. If the hip remains subluxated or dislocated, the acetabulum becomes increasingly shallow and the soft tissues shorten around the proximal femur. Subluxation leads to early osteoarthritis (OA), and it is now estimated that at least 60% of all OA of the hip is related to DDH. If the hip is dislocated, the bone acetabulum fills with soft tissue and a false acetabulum forms where the femoral head contacts the iliac crest. An apparent limb length inequity and hip muscle weakness occurs, leading to a waddling gait. Back pain and hip pain develop in adulthood. Adult reconstruction of a dislocated hip, even with an artificial hip, is very difficult.[4]

CLINICAL MANIFESTATIONS. The clinical manifestations of DDH vary with the severity of the condition and the age of the child. Signs and symptoms that should be noted include the following:

1. Asymmetry of gluteal or thigh folds
2. Limb length discrepancy (Galeazzi sign)
3. Limitation of hip abduction
4. Positive Barlow maneuver (hip reduced, but dislocatable) (Figure 45-5, *A*)
5. Positive Ortolani sign (hip dislocated, but reducible) (Figure 45-5, *B*)
6. Positive Trendelenburg gait (waddling)
7. Pain (very late)

The child also should be examined for other anomalies, such as torticollis or metatarsus adductus, which can be associated with DDH.

EVALUATION AND TREATMENT. In the newborn period clinical examination is the most important diagnostic tool. Real-time ultrasound, in which the hip is examined while the ultrasound is performed, also is extremely valuable in the newborn period, especially in high-risk infants. The use of ultrasound allows visualization of the cartilaginous structures of the hip (the femoral head and the outer lip of the acetabulum), which are not seen on plain roentgenogram. Radiographs are used after age 6 months when the ossific nucleus of the femoral head appears.[5]

Treatment depends on the age of the child, severity of dysplasia, and duration of dysplasia. The earlier that treatment is begun, the better the result. In children less than 4 months of age, a Pavlik harness can brace the hip in abduction and flexion, and the acetabulum will remodel as the femoral head rests centered in the socket (Figure 45-6). With this treatment, up to 98% of children will have an excellent result. A "closed" reduction (without opening the joint) followed by spica or body casting for up to 3 months can be done in children up to 12 months of age. After 12 months, surgical intervention—including opening the joint and cutting and realigning the femur and/or acetabulum—may be required. As the child ages, the percentage of good outcomes decreases. Up to 70% of children treated surgically for DDH after age 3 develop early osteoarthritis.[6] Early intervention before age 1 is critical for a good outcome; therefore, vigilance for this problem within the first year is essential.

Deformities of the Foot

Congenital Deformity. Congenital foot deformity is found in approximately 4% of all newborns, and metatarsus adductus

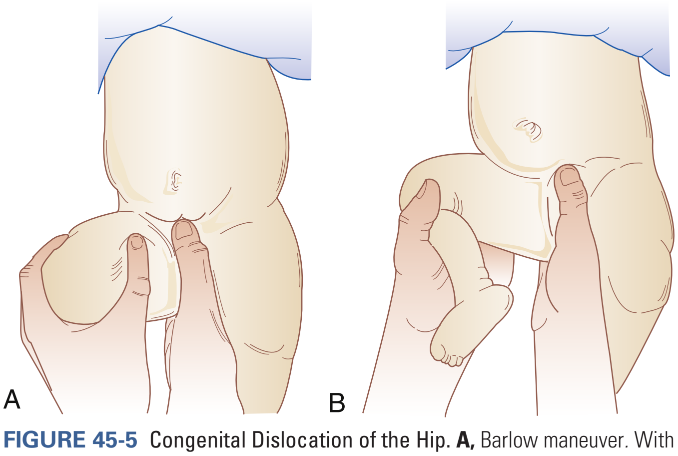

FIGURE 45-5 Congenital Dislocation of the Hip. **A,** Barlow maneuver. With one hand pressing the symphysis in front and the sacral spine in back, lateral pressure is applied to the thigh with the thumb of the other hand while pressure is applied with the palm to the knee on the side being examined. The hip that has been flexed to 90 degrees is then adducted. A positive sign is a sensation of abnormal movement, indicating dislocation of the femoral head from the acetabulum. The hands are reversed for examining the other hip. This sign and Ortolani sign may be found only in the first weeks of life. **B,** Ortolani maneuver. Sign of jerking into correct position. After the Barlow maneuver **(A),** the hip should be abducted to about 80 degrees while the femur is lifted anteriorly with the fingers along the thigh. A positive sign is a sensation of a jerk or snap with reduction into the joint socket. (Adapted from Specht EE: *Am Fam Physician* 9:88–96, 1974.)

FIGURE 45-6 Pavlik Harness for Bilateral Hip Dislocation. (From Wheaton Brace Co.)

TABLE 45-1 TERMS USED TO DESCRIBE FOOT ABNORMALITIES

TERM	DEFINITION
Position	
Abduction	Lateral deviation away from the midline of the body
Adduction	Lateral deviation toward the midline of the body
Eversion	Twisting of the foot outward along its long axis
Inversion	Twisting of the foot inward on its long axis
Dorsiflexion	Bending the foot upward and backward
Plantar flexion	Bending of the foot downward and forward
Abnormality	
Talipes	Congenital abnormality of the foot (clubfoot)
Pes	Acquired deformity of the foot
Varus	Inversion and adduction of the heel and forefoot
Valgus	Eversion and abduction of the heel and forefoot
Equinus	Plantar flexion of the foot in which the heel is lower than the toes
Calcaneus	Dorsiflexion of the foot in which the heel is lower than the toes
Planus	Flattening of the medial longitudinal arch of the foot (flatfoot)
Cavus	Elevation of the medial longitudinal arch of the foot (high arch)
Equinovarus	Coexistent equinus and varus deformities
Calcaneovarus	Coexistent calcaneus and varus deformities
Equinovalgus	Coexistent equinus and valgus deformities
Calcaneovalgus	Coexistent calcaneus and valgus deformities

accounts for 75% of these deformities (Table 45-1). **Metatarsus adductus** is a forefoot adduction deformity associated with a normal, plantigrade hindfoot and is believed to be secondary to intrauterine positioning. It is associated with developmental dysplasia of the hip in 20% of cases; consequently, the hips of these infants must be carefully evaluated. Metatarsus adductus is usually classified by two criteria: flexibility (passively correctable or rigid) and degree of deformity. The degree of deformity (mild, moderate, severe) is ascertained by the heel bisection line. A mild deformity is one in which the heel bisection line passes medial to the third toe; moderate, through the third or fourth toes; and severe, lateral to the fourth toe. Serial casts during the first 6 months of life are suggested for moderate to severe deformities and those deformities that appear less flexible. Casts are changed weekly for 6 to 12 weeks. By 6 years of age, 87% of children usually correct spontaneously, and 95% by 15 years of age. Even in those children with some residual deformity, functional symptoms are rare.

Clubfoot: Equinovarus Deformity. **Clubfoot** describes a range of foot deformities in which the foot turns inward and downward. Technically called **equinovarus,** the heel is positioned varus (inwardly deviated) and equinus (plantar flexed) (Figures 45-7 and 45-8). The clubfoot deformity can be positional (correctable passively), idiopathic, or teratologic equinovarus (as a result of another syndrome, such as spina bifida). These three types are discussed in the following sections. Overall, the true positional equinovarus lends itself to rapid correction by application of serial casts. The idiopathic variety is treated by attempting

FIGURE 45-7 Bilateral Clubfoot. **A,** Infant with bilateral congenital talipes equinovarus. **B,** Ponseti casting. (**A** courtesy of Dr. a.E. Chudley, Section of Genetics and Metabolism, Department of Pediatrics and Child Health, Children's Hospital and University of Manitoba, Winnipeg, Manitoba, Canada. In Moore KL, et al: *The developing human,* ed 9, Philadelphia, 2013, Saunders.)

FIGURE 45-8 Idiopathic Clubfoot. Idiopathic clubfoot displaying forefoot adduction (toward midline of body) and supination (upturning) and hindfoot equinus (pointed downward). Note skin creases along arch and back of heal.

cast correction, followed by surgical intervention of resistant deformities. Teratologic equinovarus nearly always requires surgical correction and/or muscle balancing procedures.

Positional Equinovarus. **Positional equinovarus** is a deformity in which an infant's foot is in equinovarus position but does have flexibility without deep creases at the posterior ankle or midfoot. The Achilles tendon is still flexible. The foot can be passively brought to a plantigrade position and is amenable to casting. In general, 1 to 3 months of serial above-knee casting corrects this foot without the need for surgical intervention or lengthy bracing.

Idiopathic Congenital Equinovarus. The etiology of idiopathic equinovarus (clubfoot) is unknown. In one human fetal study, all clubfeet were associated with identifiable anterior horn cell changes in L5 and S1. Muscle biopsies of both the anterior tibialis long flexors and the peroneus brevis muscles in clubfoot reveal that at least 50% of cases show a decreased number of muscle fibers and/or abnormal fiber histology. The soleus often has an increase in type 1 fibers, whereas the peroneus brevis has a fiber type disproportion. The more abnormal the histopathology, the more severe the deformity, and the greater the chance of recurrent deformity after treatment. The genetic component is unclear and studies are ongoing.

Idiopathic equinovarus occurs in approximately 1 of every 1000 live births, with males being affected twice as often as females. Historically, these deformities were treated by posteromedial release, a surgical procedure that lengthened all tight structures and opened the capsule of all tight joints in the foot. However, since 1998 the casting technique developed by Ignacio Ponseti (see Figure 45-7, *B*) has been used; the technique involves six to eight above-knee casts, left on for 5 to 7 days each, followed by a percutaneous tendoachilles lengthening procedure performed with local anesthesia. The child then uses special braces at night until 3 years of age. Noncompliance with braces leads to increased recurrence and need for additional casting or surgery. Nearly 30% of children may need an anterior tibialis transfer around age 3.[7] Studies comparing operative posteromedial release with Ponseti techniques show better long-term results with less invasive Ponseti method[8] (Box 45-1).

Teratologic Equinovarus. The most common causes of **teratologic equinovarus** are either neuromuscular (such as spina bifida) or syndromic, as in arthrogryposis or osteochondrodysplasia (such as diastrophic dwarfism). The teratologic clubfoot, unlike the idiopathic type, more often fails to be corrected with Ponseti casting and may require operative intervention. The surgery is often more extensive than that for an idiopathic clubfoot, and revision surgery is also more common (Box 45-1).

Pes Planus (Flatfoot) Deformity. **Pes planus (flatfoot)** commonly raises parental concern. Despite medical evidence to the contrary, it can be very difficult to convince families that a flexible flatfoot is often as functional as one with a "normal" arch. The majority of babies are born with flat (or "fat") feet, with the arch becoming more apparent with age. The relatively benign natural history, however, should not overshadow the importance of accurate diagnosis. Significant ankle valgus, vertical talus, tarsal coalition, and skewfoot must be accurately differentiated from flexible pes planus.

BOX 45-1 PONSETI CASTING

Ponseti casting implements toe-to-groin casts changed weekly for 6 weeks. Casting begins as early as possible after birth and culminates in a percutaneous tendoachilles lengthening in the clinic, followed by a final cast worn for 3 weeks. In recalcitrant cases, a full surgical posteromedial release (PMR) still may be required. The need for PMR in idiopathic clubfoot has decreased from 90% to less than 20% of infants when this casting technique is used. Long-term results, presumably because of less scarring and more long-term flexibility, are better with Ponseti casting than the PMR method.

Flexible flatfoot deformity appears to be familial, with occasional association of generalized ligamentous laxity. Careful evaluation of possible occult Achilles contracture is done by holding the hindfoot in varus position and dorsiflexing the ankle. Achilles contracture can signify a more severe flatfoot variant. The flexibility of the hindfoot is evaluated by having the child stand on his or her toes facing away from the examiner. In flexible pes planus, the hindfoot swings into a varus position as the planter fascia tightens in toe raise. In rigid pes planus, the hindfoot stays in valgus and the child has more difficulty going up onto tip-toe.

The surgical or orthotic treatment of *asymptomatic* flexible pes planus is unnecessary. Custom orthotics, Helfet heelcups, and corrective orthopedic shoes have no influence over the natural history (clinically or radiographically) of flat feet. Adult studies on army recruits have shown that soldiers with flat feet perform just as well as their counterparts without "fallen" arches.

There is a small subset of children with painful flexible flat feet. For these children careful attention to the possibility of Achilles contracture or tarsal coalition (congenital union of the hindfoot bones) must be made. This group of children is best treated with inexpensive shoe inserts and then expectantly watched. If pain continues into adolescence, requiring more aggressive treatment, calcaneal lengthening will correct the pes planus without decreasing hindfoot motion. In rigid flat feet, a computed tomographic (CT) scan often will reveal a coalition, a bony or cartilaginous connection between the bones—if painful, this can be resected. Heel cord contractures can be surgically lengthened if stretching alone is inadequate. All surgery carries risk; if a foot is flat but nonpainful, treatment is not required. The painless flatfoot should be viewed as a variation of normal feet.

Abnormal Density or Modeling of the Skeleton

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) (brittle bone disease) is a spectrum of disease caused by genetic mutation in the gene that codes for type I collagen, the main component of bone and blood vessels. The disorder was first described in 1840 as a syndrome in newborns that consisted of osteoporosis with fractures and skeletal deformities. The Sillence classification is based on both models of inheritance and clinical findings (Table 45-2). In the most severe form of this disorder, the child is usually stillborn or dies soon after birth, although some survive into childhood. OI in its more severe forms is evident at birth because fractures and deformity have occurred in utero. The less severe forms may not become evident until the child begins to walk.

TABLE 45-2 SILLENCE CLASSIFICATION OF OSTEOGENESIS IMPERFECTA SYNDROMES

TYPE	TRANSMISSION	MAIN BIOCHEMICAL DEFECT	ORTHOPEDIC	MISCELLANEOUS
IA	AD	Decreased production of type I collagen	Mild to moderate bone fragility, osteoporosis, normal stature	Blue sclera, hearing loss, easy bruising, dentinogenesis imperfecta absent
IB	AD		Short stature	More severe in IA with dentinogenesis imperfecta
II	AD, AR, and mosaic	Substitutions of glycyl residue in X1 or X2 chains in triple helix	Multiple intrauterine fractures, extreme bone fragility	Usually lethal in perinatal period, delayed ossification of skull, intrauterine growth restriction
IIA			Long bones broad, crumpled; ribs broad with continuous beading	
IIB			Long bones broad, crumpled; ribs discontinuous or beading	
IIC			Long bones thin, fractured; ribs thin, beaded	
IID			Severely osteoporotic with generally well-formed skeleton; normal-shaped vertebrae and pelvis	
III	AD and AR	Abnormal type I collagen	Progressive deforming phenotype, severe bone fragility with fractures	Hearing loss, short stature, blue sclerae becoming less blue with age, shortened life expectancy, dentinogenesis imperfecta, relative macrocephaly with triangular facies
IVA	AD	Shortened pro-α (I)-chains	Mild to moderate bone fragility, osteoporosis, bowing of long bones, scoliosis	Light sclerae, normal hearing, normal dentition, dentinogenesis imperfecta absent
IVB	AD			Dentinogenesis imperfecta present

AD, Autosomal dominant; *AR,* autosomal recessive.

Some children with this milder form then experience numerous fractures and can be mistaken for nonaccidental trauma until the diagnosis is made.

The prevalence rate of the most common form is about 1 in 30,000. Inheritance is usually autosomal dominant but can be autosomal recessive. At least four syndromes have been identified that have various clinical manifestations and prognoses (see Table 45-2).

PATHOPHYSIOLOGY. The major errors in OI lie in the synthesis of collagen, a triple helix with two matching alpha chains and one beta chain. Collagen is present in bone, cartilage, eye tissue, skin, and the vascular system. The severity of the OI phenotype and the related anomalies of the eye, dentition, or vascular system are all dependent on the severity of the genetic anomaly and the part of the triple helix that is affected.[9] (Genes are discussed in Chapter 4.)

A number of metabolic abnormalities are associated with OI. Some individuals have increased serum thyroxine levels, suggesting hyperthyroidism. This is consistent with the findings of increased sweating, heat intolerance, increased body temperature, a resting tachycardia, and tachypnea. Studies of leukocyte metabolism suggest an uncoupling of oxidative phosphorylation. Reports of alterations of platelet function with defects in adhesion and clot retraction also exist.

CLINICAL MANIFESTATIONS. The classic clinical manifestations of OI are osteoporosis and increased rate of fractures, possible bony deformation, triangular facies, possible vascular weakness (i.e., aortic aneurysm), possible blue sclerae, and poor dentition. The Sillence classification designated types I through IV on the basis of severity. The most severe, types II and III, are comparable to *osteogenesis imperfecta congenita*. These two types are characterized by autosomal recessive inheritance and early onset of manifestations. Both can cause stillbirth or severe neonatal deformity and a short life expectancy. Less severe are types I and IV, which are comparable to *osteogenesis imperfecta tarda*. Type I is slightly more common than types II and III, and type IV is quite rare. Types I and IV are inherited as autosomal dominant traits and vary in age of onset from birth to adulthood. Type IV, especially when the sclerae are white, is the least deforming type and is often confused with nonaccidental trauma (child abuse).

EVALUATION AND TREATMENT. Evaluation of OI is based primarily on clinical manifestations. Serum alkaline phosphatase level is elevated in all forms of the disease. OI can be diagnosed prenatally by ultrasound or chorionic villi sampling. Quantitative analysis of cultured skin fibroblast collagen by electrophoresis shows a decreased quantity of collagen in 95% of individuals.

Type II OI is often terminal in the perinatal period, and therefore little is known about appropriate treatment for the few children who survive. For other types of OI, careful positioning and handling of the newborn help prevent fractures. Beyond the neonatal period, various orthopedic measures are

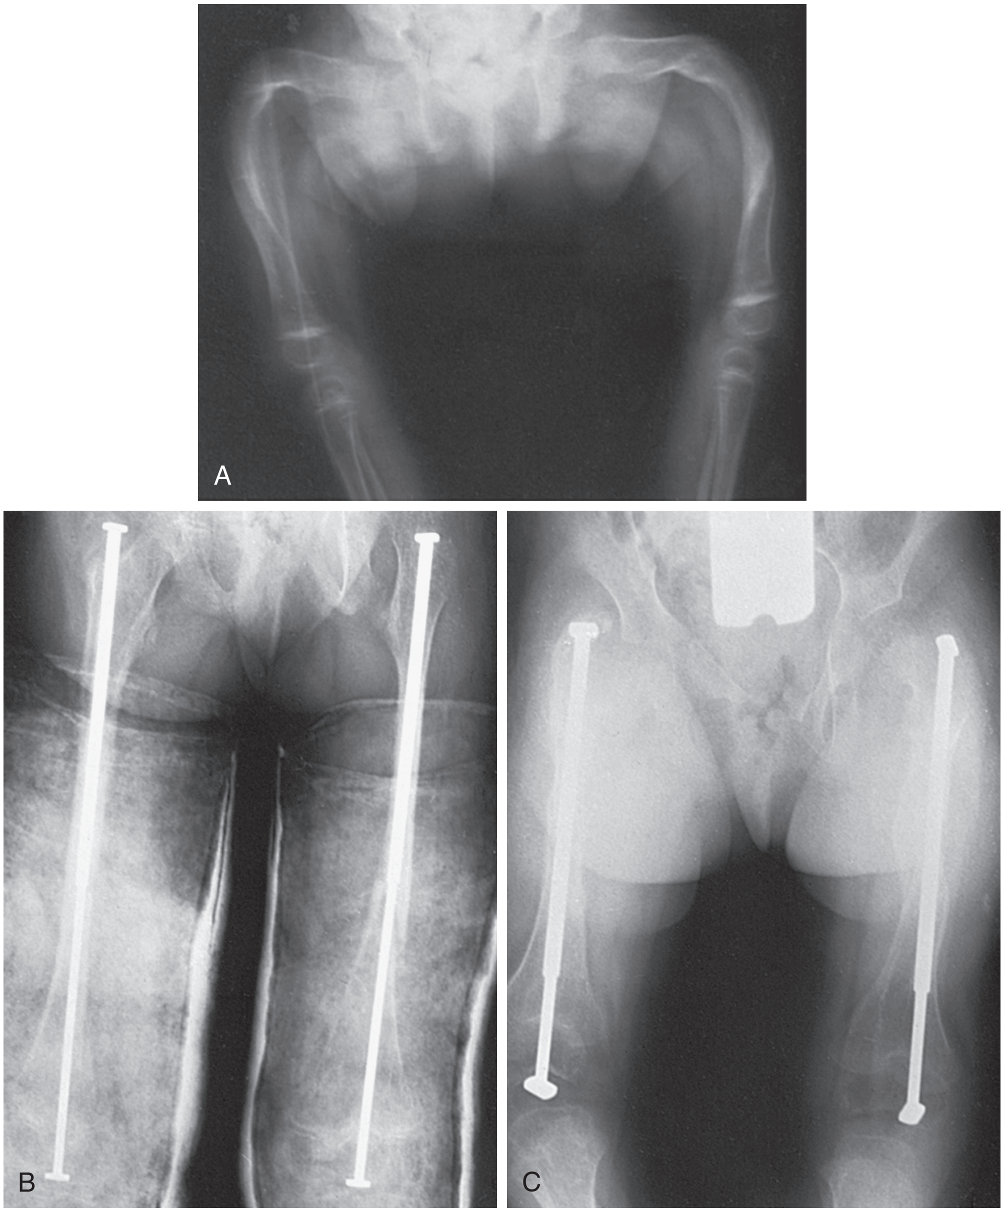

FIGURE 45-9 **Osteogenesis Imperfecta Treated with Osteotomies and Telescoping Medullary Rods. A,** Severe deformity of both femurs. **B,** Same individual after multiple osteotomies with telescoping medullary rod fixation. **C,** Same individual 4 years later demonstrating growth of femurs, no recurrence of deformity, and elongation of rods. (Plaster casts are in place for immobilization of tibial osteotomies.) (From Crenshaw AH, editor: *Campbell's operative orthopaedics,* ed 8, vol 3, St Louis, 1992, Mosby.)

applied, such as prompt splinting of fractures and correction of deformities arising from the progressive bowing or bending of the skeleton by intramedullary rodding of the bones (Figure 45-9). Newer, telescoping rods, which grow with the child, have been shown to reduce the reoperative rate by 30%.[10] Scoliosis is present in up to 50% of Sillence III cases and often requires surgery. A multicenter study of a bisphosphonate therapy showed promising results in type III OI, with marked improvements of bone density (up to 30%). Despite these results, there is concern that the healing of fractures and surgical intervention can be more difficult. More study is needed to address the efficacy and safety of these types of drugs. Genetic counseling for affected families should aim at primary prevention.

Rickets

Rickets is a disorder in which growing bone fails to become mineralized (ossified), resulting in "soft" bones and skeletal deformity (Figure 45-10). Rickets results from either insufficient vitamin D, insensitivity to vitamin D, wasting of vitamin D by the kidney, or inability to absorb vitamin D and calcium in the gut. The most common form is X-linked hypophosphatemic rickets in industrialized nations. In addition to the severe form of metabolic rickets, dietary and lifestyle changes in the United States have led to widespread vitamin D deficiency in children.[11] Although unprotected exposure to ultraviolet rays is not suggested, children still need 15 to 20 minutes per week of true sun exposure to activate vitamin D, the mineral necessary

for absorption and metabolism of calcium and phosphate. In one recent study up to 90% of *normal* American children had a low vitamin D level, especially children of color. This can lead to early fracture or slow bone healing after fracture.[12]

Severe metabolic rickets in the immature skeleton leads to short stature and bowing of the limbs with broad, irregular growth plates. The rows of cells in the growth plate that are intended to ossify fail to do so as they reach the metaphysis since calcification is impeded.

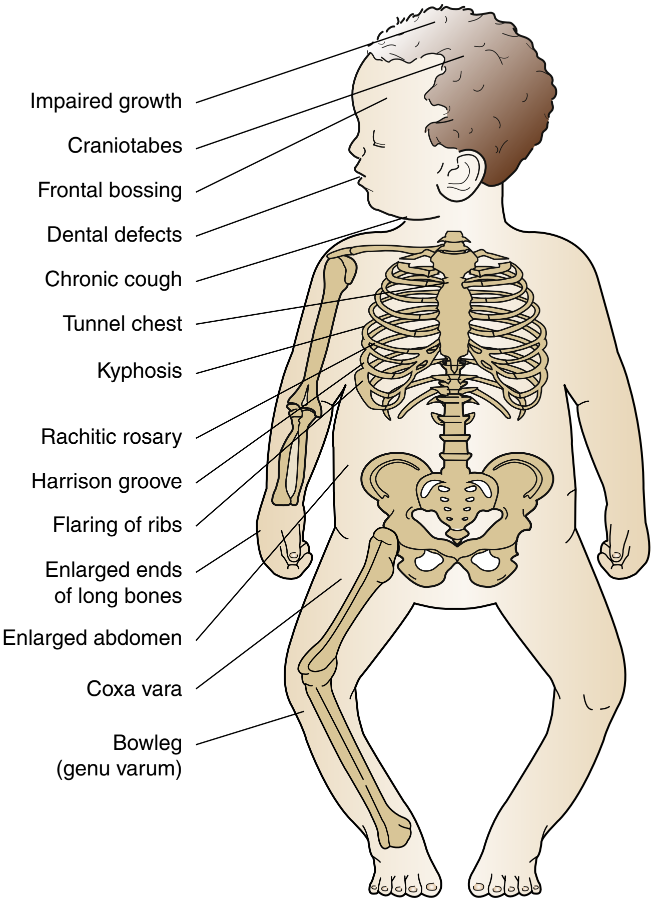

FIGURE 45-10 Rickets.

Children with rickets are often listless and irritable. They have hypotonia and muscle weakness and may be unable to walk without support. Abnormal parietal flattening and frontal bossing occur in the skull. The calvaria become soft, and the sutures may widen. Cartilaginous attachments of the ribs become prominent, and the long bones of the extremities (tibia, femur, radius, ulna) may be bowed. Growth is restricted, and fractures are common.

Like osteogenesis imperfecta, surgical treatment of bony deformity can be required. However, medical management of calcium, phosphorous, and vitamin D levels must be optimized before surgical intervention. Deformity often improves with normalization of bone metabolism.

Scoliosis

Scoliosis is a rotational curvature of the spine most obvious in the anteroposterior plane (Figure 45-11). It can be classified as nonstructural or structural. **Nonstructural scoliosis** results from a cause other than the spine itself, such as posture, leg length discrepancy, or pain. **Structural scoliosis** is curvature of the spine associated with vertebral rotation. Nonstructural scoliosis can become structural if the underlying cause is not found and treated.

Structural scoliosis can be caused by a great variety of conditions. It can result from congenital skeletal abnormalities (15%), neuromuscular diseases (15%), trauma, extraspinal contractures, bone infections that involve the vertebrae, metabolic bone disorders (e.g., rickets, osteoporosis, osteogenesis imperfecta), joint disease, and tumors. Most cases of structural scoliosis, however, have no known cause, although genetic factors are suggested. Structural scoliosis with no known cause, termed **idiopathic scoliosis,** accounts for at least 70% of cases.

Idiopathic scoliosis is classified as infantile, juvenile, or adolescent, depending on the child's age at the time of onset. In infantile scoliosis, spinal curvature develops during the first

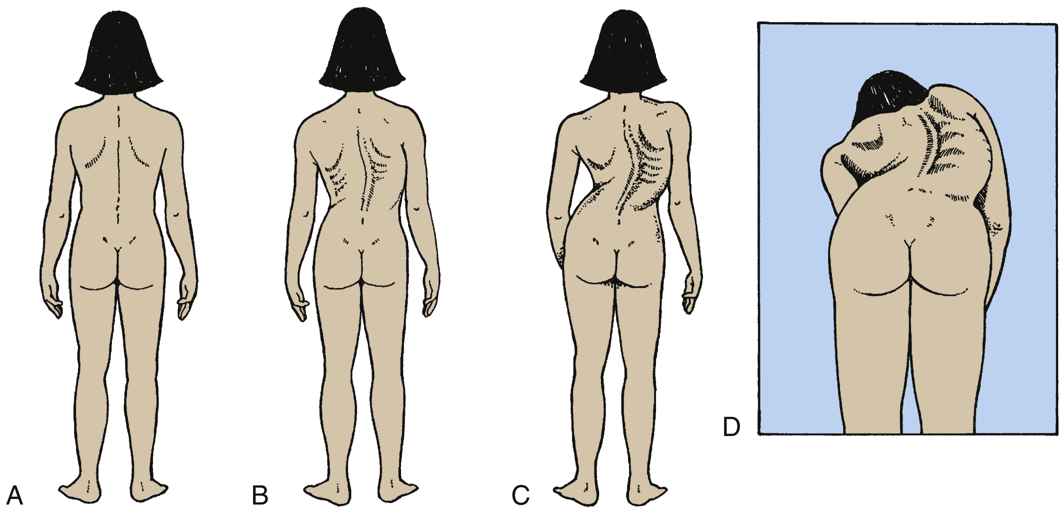

FIGURE 45-11 Scoliosis in Children. Normal spinal alignment and abnormal spinal curvatures associated with scoliosis. **A,** Normal. **B,** Mild. **C,** Severe. **D,** Rotation and curvature of scoliosis.

3 years of life; in juvenile scoliosis, curvature develops between the skeletal age of 4 years and the onset of adolescence; and in adolescent scoliosis, it develops after the skeletal age of 10. Adolescent idiopathic scoliosis is the most common. Scoliosis in its milder forms occurs equally in boys and girls; once curves measure more than 15 degrees, however, girls are five times more likely to have scoliosis than boys.

PATHOPHYSIOLOGY. It has been hypothesized that in individuals with adolescent scoliosis, there is an abnormality of the central nervous system involving the balance mechanism (reticular system) in the midbrain. A genetic component is also suggested because 30% occur within families.

Experimentally it also has been shown that individuals with adolescent idiopathic scoliosis have an abnormality in the function of the posterior columns of the spinal cord. This results in abnormal proprioception and is not evident clinically except in the presence of scoliosis. The exact cause of scoliosis, however, remains elusive.[13]

The earliest pathologic changes, which are probably secondary changes, occur in the soft tissues. The muscles, ligaments, and other soft tissues become shortened on the concave side of the curve. Vertebral deformity occurs as asymmetric forces are applied to the epiphyseal center of the ossification by shortened and tight soft tissues on the concave side of the curve. True curves involve not only bending but also twisting of the torso leading to the "rib hump" seen when the child bends forward.

The curves increase most rapidly during periods of rapid skeletal growth. If the curve is less than 40 degrees at skeletal maturity, the risk of progression is quite small. In curves greater than 50 degrees, the spine is biomechanically unstable, and the curve usually progresses even after the cessation of growth. Curves in the thoracic spine greater than 80 degrees result in decreased pulmonary function, whereas the most common complication of large curves in the lumbar spine is back pain.

CLINICAL MANIFESTATIONS. The clinical manifestations of nonstructural scoliosis are mild spinal curvature with prominence of one hip or rounded shoulders. The curvature disappears with forward flexion of the spine, lying down, or traction of the head. Treatment for nonstructural scoliosis is correction of the underlying disorder. The clinical manifestations of structural scoliosis include asymmetry of hip height, asymmetry of shoulder height, shoulder and scapular (shoulder blade) prominence, and rib prominence.

EVALUATION AND TREATMENT. Spinal curvature is usually visible or palpable, and muscles on one side of the lower back (the convex side) may be prominent or bulging. Most cases of idiopathic scoliosis are noticed during school screening programs. In girls the deformity may be noticed because clothing does not "hang" properly on the body. Diagnosis is made by roentgenographic examinations.

Treatment of curves greater than 20 degrees in the skeletally immature child is with bracing. In most cases a low-profile thoracolumbar brace is used. Low-profile braces are worn for 22 hours per day until skeletal maturity. Bracing will only prevent progression of the curve; it will not correct the curvature. Bracing is not effective in large curves or in skeletally mature individuals; the most effective time for bracing is in growing prepubescents with a small curve.[14] Extensive chiropractic manipulations and electrical stimulation have not been shown to change natural history. Surgical treatment with spinal fusion with instrumentation is recommended for curves greater than 40 to 50 degrees. If surgery is indicated, it is better performed during the adolescent years while there is greater flexibility of the curves and less risk of complications.

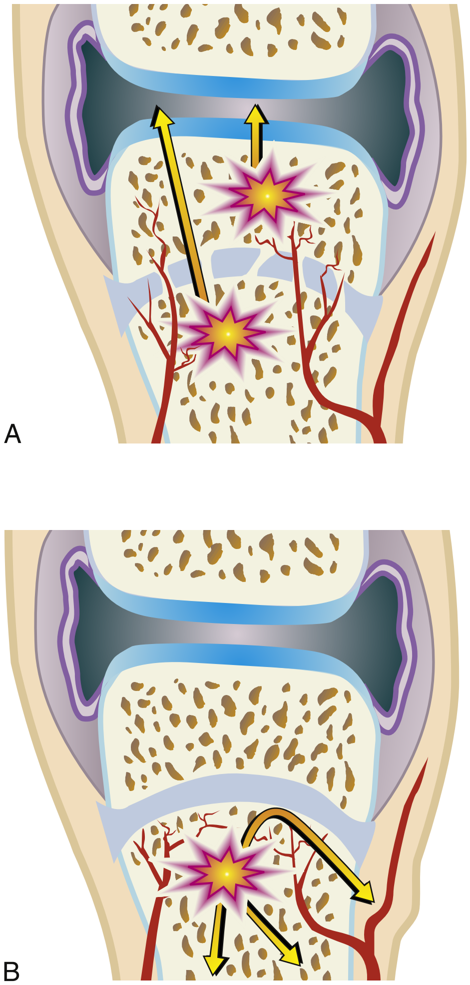

FIGURE 45-12 Pathogenesis of Acute Osteomyelitis Differs with Age. **A,** In infants younger than 1 year the epiphysis is nourished by penetrating arteries through the physis, allowing development of the condition within the epiphysis. **B,** In children up to 15 years of age the infection is restricted to below the physis because of interruption of the vessels.

Bone Infection: Osteomyelitis

Osteomyelitis is an infection of the bone. Occurring twice as often in males as females, acute osteomyelitis may affect infants and children of any age, but it occurs most often between 3 and 12 years of age.

Bacteria enter the bone through the bloodstream and lodge in the medullary cavity, where a rich phagocytic mechanism often prevents most of the bacteria from establishing an infectious state. In some cases, however, the bacteria may lodge at the end of the venous loops beneath the epiphyseal plate, and infection then develops because there are no phagocytic cells present to remove the bacteria[15-17] (Figure 45-12).

BOX 45-2 CAUSATIVE MICROORGANISMS OF OSTEOMYELITIS ACCORDING TO AGE

Newborns
Staphylococcus aureus
Group B streptococcus
Gram-negative enteric rods

Infants
S. aureus (MSSA 70, MRSA 30)
Haemophilus influenzae

Older Children
Staphylococcus aureus
Pseudomonas
Salmonella
Neisseria gonorrhoeae

Adolescents and Adults
Pseudomonas
Mycobacterium tuberculosis

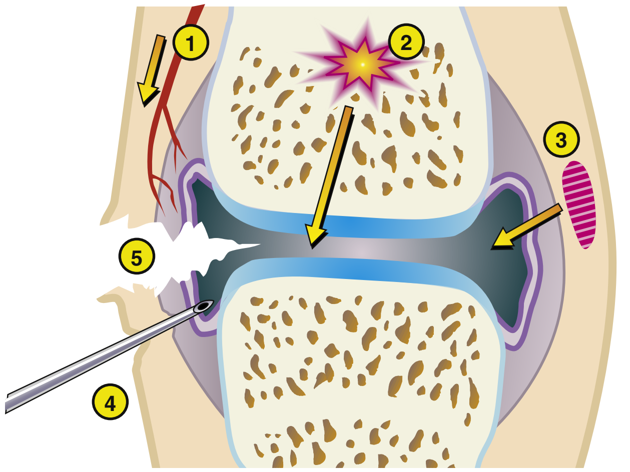

FIGURE 45-13 Routes of Infection to the Joint. **(1)** The hematogenous route; **(2)** dissemination from osteomyelitis; **(3)** spread from an adjacent soft tissue infection; **(4)** diagnostic or therapeutic measures; **(5)** penetrating damage by puncture of cutting.

The microorganism responsible for osteomyelitis varies and is related to the age of the child (Box 45-2). Osteomyelitis in the newborn is caused primarily by *Staphylococcus aureus.* Group B streptococcus and *Escherichia coli* infections are responsible for some cases, especially those of multiple bone involvement and in high-risk infants.[17]

S. aureus is the responsible microorganism in 80% to 90% of osteomyelitis cases in older children. *Haemophilus influenzae,* a previously common cause of osteomyelitis in children less than 5 years of age, has become rare with the improvements in immunization. However, cases of methicillin-resistant *Staphylococcus aureus* (MRSA) have risen alarmingly in the past 5 years. Once an infrequent cause of childhood osteomyelitis, MRSA now causes up to 30% of new cases.[18] Gram-negative microorganisms account for an increasing number of infections of the vertebrae,[19,20] whereas *Salmonella* infections are associated with sickle cell disease.

Factors that predispose an individual to the development of osteomyelitis include impetigo, furunculosis, infected lesions of varicella (chickenpox), infected burns, cerebral abscesses, immunization with bacille Calmette-Guérin (BCG) vaccine, prolonged intravenous or central parenteral alimentation, drug addiction, and direct trauma to the area adjacent to the site of osteomyelitis.

PATHOPHYSIOLOGY. Osteomyelitis usually begins as a bloody abscess in the metaphysis of the bone. The abscess ruptures under the periosteum and spreads along the bone shaft or into the bone marrow cavity if untreated. Infection rarely spreads down the medullary cavity of the bone but rather first gains entrance to the subperiosteal space in the metaphysis. The bone cortex in this area is porous, allowing easier entry for the bacteria than the shaft of the bone.[21] Because of the accumulation of debris caused by the infection, the periosteum may separate and form a shell of new bone around the infected portion of the shaft. Because the periosteum is separated from an adequate blood supply, sections of the bone die; these pieces of dead bone are called **sequestra.** The periosteum that maintains a blood supply generates new bone and is responsible for the appearance of the periosteal new bone, or **involucrum.** The presence of the sequestra and involucrum indicates that the disease is highly aggressive or established.

In cases in which the infection in the metaphysis occurs near the joint, the accumulating pus (bacteria, white blood cells, fluid) creates increasing pressure that may cause a rupture into the joint cavity. If rupture into the joint occurs, the pus causes inflammation and a condition called **secondary septic arthritis.**[19] Studies show that up to 40% of children will have adjacent joint involvement with osteomyelitis. The most common joint to be affected is the knee. Osteomyelitis is most commonly caused by bacteria that reach the metaphysis through the bloodstream but may occur through secondary inoculation of microorganisms caused by trauma or contagious spread of infection from cellulitis in adjacent soft tissue.

Osteomyelitis in infants is often associated with septic arthritis because the infant's bone has blood vessels that perforate the growth plate. Because of the unique nature of the blood supply to an infant's bones, the occurrence of osteomyelitis and septic arthritis in combination is higher than 50%. Normal anatomic variations in infants allow infection to spread directly to the epiphysis, which causes both joint disease and permanent injury to the growth plate. Multiple sites of osteomyelitis are also common in children younger than 2 years of age. Other areas of osteomyelitis and possibly septic arthritis must be evaluated through a bone scan of the entire skeleton.[22]

Children are susceptible to joint involvement for several reasons (Figure 45-13). In the immature infant, there is no epiphyseal plate or an ossific nucleus at the end of the bone and the cartilage precursor of bone is penetrated by vascular channels.

In these infants the infection begins in the vulnerable cartilage precursor of the end bone itself and results in rapid destruction of the joint and arrested growth of the bone. For this reason the early detection and treatment of osteomyelitis are crucial if the infant's joint is to be saved from destruction. As the child matures and the epiphyseal, or growth, plate forms, a temporary barrier is established against infection because the arterioles end beneath the epiphyseal plate.[21]

In children older than 2 years, the epiphyseal plate prevents the spread of a metaphyseal abscess into the epiphysis and the cortex of the metaphysis is thicker. These anatomic differences increase the likelihood that the metaphyseal abscess will extend into the diaphysis, and the blood supply of the bone will be disrupted. The periosteum is also more difficult to perforate in older children; this may lead to a larger subperiosteal abscess that could endanger the periosteal blood supply as well. This process results in extensive sequestrum formation and chronic osteomyelitis.[21]

Osteomyelitis is much less common after the physeal plates are closed, except in the vertebral body. Infection may develop in any part of a bone, and abscesses spread slowly. Destruction of the cortex in a localized area may result in a pathologic fracture.[19,20]

Spread of infection to contiguous joints is related to the child's age. Metaphyseal infection may spread to contiguous joints if the fibrous joint capsule includes the metaphysis and epiphysis. This special situation exists at the hip joint, distal femur, proximal humerus and radius, and lateral ankle. Careful clinical vigilance helps protect children with osteomyelitis from suffering permanent joint injury. Unlike bone, the articular cartilage of joints is unable to repair itself after injury from infection.[22]

CLINICAL MANIFESTATIONS. The clinical manifestations of osteomyelitis are age dependent and are related to the differing vascular patterns found in the skeletal system at various ages. Three distinct groups may be identified: (1) infants younger than 1 year, (2) children from 1 year of age to puberty, and (3) adolescents after cessation of bone growth and adults.

Infants

Osteomyelitis may be an acute illness characterized by fever and failure to move the affected limb (pseudoparalysis). Infantile osteomyelitis is characterized by involvement of multiple sites within the same bone or in multiple bones. If untreated, involvement of the adjacent growth plate can result in growth arrest.

Children

Osteomyelitis in children between the ages of 1 year and puberty is characterized by fever and systemic signs of toxicity. The illness is sometimes subacute, with the child complaining of swelling, fever, tenderness, and decreasing ability to bear weight on or move the affected area. Onset can be abrupt. Osteomyelitis during childhood most often affects the long bones but also may be found in the pelvis and spine. Clinical manifestations are usually accompanied by elevated white blood cell counts and elevated erythrocyte sedimentation rates. When the level of C-reactive protein (CRP) is elevated, it a sensitive sign of osteomyelitis and can rapidly decrease with appropriate treatment. Evidence of infection using roentgenograms can be delayed but bone scan is positive within 48 hours.

Adolescents and Adults

In addition to the sites previously mentioned, osteomyelitis in adolescents and adults may involve the vertebrae. Back pain, with a duration of several weeks, may be the only clinical complaint. This age group is less often affected than younger populations.

EVALUATION AND TREATMENT. White blood cell counts and erythrocyte sedimentation rates are sometimes elevated, but this is not a consistent finding. Monitoring of erythrocyte sedimentation rates is an indication of response to management but can be delayed. CRP is more quickly responsive to appropriate treatment. Blood cultures (positive in 30% to 40%) and aspiration of the soft tissue or bone, or both, should be done to identify the causative microorganism. Appropriate antibiotics should be prescribed *after* culture and sensitivity studies have been completed. A tuberculin test also is administered because *Mycobacterium tuberculosis* is sometimes responsible and has had a slight resurgence in incidence. Bone scans can be quite helpful with diagnosis and in children younger than 1 year are absolutely required to define whether multiple sites are involved.

Treatment includes intravenous (IV) antibiotics or, in highly reliable children and families, a combination of IV and oral antibiotics for 6 weeks. Drainage and margination of bone is required if changes are present on radiographs signifying abscess. Immobilization may help with pain control. If a joint is also infected (termed "septic arthritis"), the situation becomes a *surgical emergency;* surgery on the affected joint can help prevent damage to the articular cartilage by lysozymes released from the involved neutrophils.

Death is rare, but serious sequelae may occur. The course of the disease and prognosis depend on the age of the child, the rapidity with which the diagnosis is established, the initiation of early treatment, and maintenance of treatment for an adequate time. The most serious complications are growth arrest, osseous necrosis, and recurrence. Recurrence with presently available antibiotic regimens is less than 10%.

Juvenile Idiopathic Arthritis

The rheumatic diseases are a group of diverse conditions having in common the inflammation of connective tissues. They include juvenile idiopathic arthritis (JIA, formerly known as juvenile rheumatoid arthritis), systemic lupus erythematosus, dermatomyositis, and progressive systemic sclerosis (formerly called scleroderma). The incidence of these disorders in children is estimated in Table 45-3.

Juvenile idiopathic arthritis (JIA) is the childhood form of rheumatoid arthritis (RA) (see Chapter 43). Like adult-onset RA, JIA is a syndrome that is often accompanied by systemic manifestations. Approximately 5% of all cases of RA begin in childhood. An estimated 250,000 children in the United States have JIA.

TABLE 45-3 INCIDENCE OF CONNECTIVE TISSUE DISEASES IN CHILDREN

DISEASE	ANNUAL RATE/10^5	GENDER RATIO (FEMALE/MALE)	RACE RATIO (WHITE/BLACK)	PEAK AGE GROUP AT RISK (yr)	CHILDHOOD ONSET (%)
Rheumatoid arthritis	40	3:1	Equal	Increases with age (20-50)	5
Systemic lupus erythematosus	6	8:1	1:4	15-45	18
Dermatomyositis	0.8	2:1	1:3	45-65	20
Progressive systemic sclerosis	0.4	3:1	Equal	Increases with age (30-50)	3
Polyarteritis	0.2	1:3	Equal	Midadult	Rare

Data from Hollingworth P. In Klippel JH, Dieppe PA, editors: *Rheumatology,* St Louis, 1994, Mosby.

The basic pathophysiology of JIA is the same as that of adult RA. The clinical manifestations of JIA may differ, however, beginning with mode of onset. Unlike adult RA, which begins insidiously with systemic signs of inflammation and generalized aches, JIA has three distinct modes of onset: arthritis in fewer than five joints (pauciarticular arthritis), arthritis in more than five joints (polyarticular arthritis), and systemic or Still disease. JIA differs from the adult form in the following respects[23,24]:

1. Predominantly the large joints are affected.
2. Subluxation and ankylosis of the cervical spine are common if the disease progresses.
3. Joint pain may not be severe, as in the adult type.
4. Serologic tests often detect antinuclear antibody (ANA).
5. Chronic uveitis is common, especially if ANA positive.
6. Serologic tests seldom detect rheumatoid factor.
7. Rheumatoid nodules are not limited to subcutaneous tissue but are found in the heart, lungs, eyes, and other organs.
8. Cyclic citrullinated peptide antibody is often positive.

Treatment for children with JIA is supportive but not curative. Many children with pauciarticular arthritis who are seronegative for ANA will resolve their symptoms over time. However, with systemic onset (Still disease) or seropositivity, JIA may progress to true adult RA. The aims of treatment are to control inflammation and other clinical manifestations of the disease and to minimize deformity.

Avascular Diseases of the Bone: Osteochondrosis

The avascular diseases of the bone, collectively termed **osteochondroses,** are caused by insufficient blood supply to growing bones. Disturbances of blood supply to primary and secondary centers of ossification during periods of rapid bone growth result in a variety of skeletal abnormalities.

The cause of the osteochondroses remains obscure. In the past, infection, nutritional deficiencies, and hormonal imbalances were blamed, but these causes have been largely disproved. Currently, vascular impairment and trauma, coupled with an underlying developmental or genetic predisposition, have been identified as probable causes of osteochondroses. The most common osteochondroses are Osgood-Schlatter disease (tibial tubercle), Sinding-Larsen-Johansson syndrome (distal patellar pole), Panner disease (radial head), Kohler disease (the navicular bone of the foot), and Sever disease (calcaneus). All are associated with activity-related pain of the affected region that improves with rest. All are more common in boys than girls and in athletes more than nonathletes.

The osteochondroses involve areas of significant tensile or compressing stress that undergo partial osseous necrosis, progressive bony weakness, and then microfracture. Most of these are associated with trauma and overuse and improve with rest. Use of anti-inflammatories, modification of activities, and even immobilization of the affected area are used during active stages of the disease. Reparative correction by revascularization is the rule, although this may be a lengthy process.

Legg-Calvé-Perthes Disease

Legg-Calvé-Perthes (LCP) disease, commonly called Perthes disease, is classically thought to be an osteochondrosis like those previously described. This self-limited disease of the hip is presumably produced by recurrent interruption of the blood supply to the femoral head. The ossification center first becomes necrotic and collapses and then is gradually remodeled by live bone.

LCP disease is relatively common (1 in 5000 children), usually occurring in children between 3 and 10 years of age, with a peak incidence at 6 years. It is more common in boys than in girls by a ratio of about 5:1. The condition is bilateral in approximately 10% of affected children; however, bilateral cases are temporally separated. If LCP disease appears at identical stages and the femoral heads show matched radiographic involvement, then another diagnosis, such as an epiphyseal dysplasia, should be considered.

The cause of decreased blood supply to the head of the femur is unknown. Several theories have been proposed, including trauma, infection, and protein C and S deficiencies, which cause a hypercoagulable state or vascular anomolies.[25] A plausible theory is that acute synovitis (infection of the synovial membrane) and increased hydrostatic pressure in the hip joint compress blood vessels that supply the femoral head.

Constitutional factors definitely play a role. Skeletal maturation is delayed an average of 2 years in children with LCP disease, and affected children are between 2.5 and 7 cm shorter than unaffected children of the same age. Familial occurrence is 30% to 40%. The disease is rare in blacks, and it is frequent in children of Japanese and central European ancestry.

PATHOPHYSIOLOGY. LCP disease runs its natural course in 2 to 5 years. In the initial stage the soft tissues of the hip (synovial membrane and joint capsule) are swollen, edematous, and hyperemic, often with fluid present in the joint (Figure 45-14). The joint space widens, and the joint capsule bulges. The first stage lasts only a few weeks. In the second stage, called

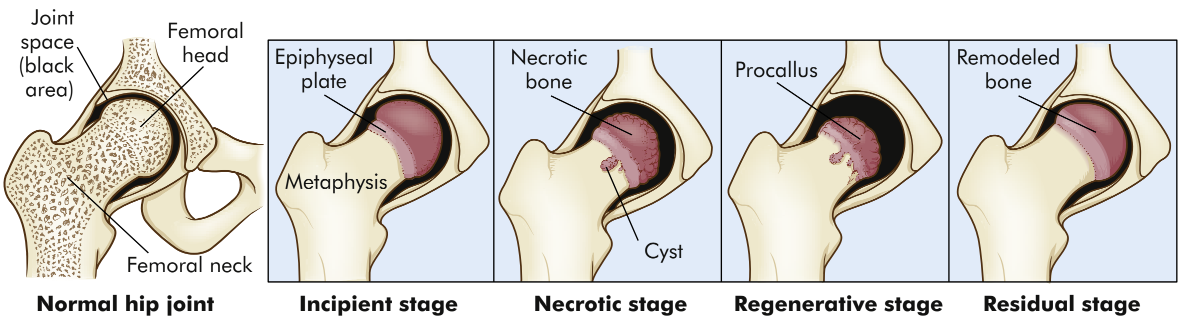

FIGURE 45-14 Stages of Legg-Calvé-Perthes Disease, a Form of Osteochondrosis.

fragmentation, the entire epiphysis or the anterior half of the epiphysis of the femoral head loses blood supply and the metaphyseal bone at the junction of the femoral neck and capital epiphyseal plate is softened because of decalcification. Soon granulation tissue (procallus) and blood vessels invade the dead bone. This stage lasts several months to 1 year.

The third (or regenerative healing) stage ordinarily lasts 2 to 3 years. The dead femoral head is replaced by procallus, and new bone is laid down. Collapse and flattening of the femoral head occur, and the femoral neck becomes short and wide (see Figure 45-14).

In the fourth (or healed) stage, remodeling takes place and the newly formed bone is organized into a live spongy bone. Children less than 6 years of age at onset have more time to remodel the damage LCP has caused and have the best outcome. Recent multicenter studies, using the Herring "lateral pillar" classification,[26] have shown that hips younger than 6 years with *no* involvement of the lateral femoral head (type A) do better than those with involvement of the lateral femoral head. Those children with complete collapse of the lateral femoral head (type C) have the worst prognosis. Long-term studies of type C hips show that 70% to 90% progress to osteoarthritis by 40 years of age.[27]

CLINICAL MANIFESTATIONS. Injury or trauma precedes the onset of clinical manifestations in approximately one third of children with LCP disease. Onset of symptoms is insidious unless trauma aggravates the disease process. The pain often is referred to the knee and can lead to misdiagnosis as a knee injury. The inner thigh and groin also can be painful. In some children, pain may be absent or minimal. If pain is present, it is usually aggravated by activity and relieved by rest.

The typical physical findings include spasm on inward rotation of the hip and a limitation of internal rotation flexion and abduction. If the child is walking, an abnormal gait, termed a Trendelenburg gait or abductor lurch, is apparent. The child dips the trunk toward the affected side with stance to compensate for weak abductor musculature. If the hip pain or limp has been present for a prolonged period, muscles of the hip and thigh atrophy. A limb length inequity may be present if the proximal femoral physis is involved.

EVALUATION AND TREATMENT. Diagnosis is confirmed by radiographic examination. Principles of treatment are *containment* (keeping the ball completely in the socket) and *motion* to maintain the articular cartilage. In the past, children were treated with bed rest and a variety of braces. Most children can be managed with anti-inflammatory medications and crutches for episodes of synovitis and with activity modification (avoidance of jumping activities that place increased stress on the hip) during the active phase of the disease. Serial roentgenograms monitor the progress of the disease and ensure that the hip remains congruent. Surgery may be necessary if the femoral head becomes subluxated or incongruent with the acetabulum before the reparative process. The ball must be congruent to take on the shape of the socket as remodeling occurs. Newer treatments, such as intra-articular injection of bisphosphonates (that reduce the function of osteoclasts), are being studied.[28]

Factors affecting the outcome of LCP disease are the age of the child at onset, the extent of necrosis, and the congruence of the joint at skeletal maturity. Recent studies have shown that girls, despite earlier skeletal maturity, do as well as boys. Outcome is 70% satisfactory with Herring stage A; for Herring stages B and C or age greater than 8 years, outcome is guarded. Present prospective studies are evaluating more aggressive early treatment (i.e., osteotomy of the femur or pelvis) on the more involved hips to change long-term outcome.

Osgood-Schlatter Disease

Osgood-Schlatter disease consists of tendinitis of the anterior patellar tendon, within which the patella (kneecap) is embedded, and associated osteochondrosis of the tubercle of the tibia. Osgood-Schlatter disease occurs most often in preadolescents and adolescents who participate in sports. The incidence is higher in boys than in girls, many of whom have increased outward tibial fusion compared to controls.[29]

PATHOPHYSIOLOGY. The severity of the lesion varies from mild tendinitis to a complete separation of the anterior extension of the tibial epiphysis, which is the part of the epiphysis that contributes to growth of the tibial tubercle. The underlying pathologic alterations also vary. The mildest form of Osgood-Schlatter disease causes ischemic (avascular) necrosis in the region of the bony tibial tubercle, with hypertrophic cartilage formation during the stages of repair. In more severe cases the abnormality involves a true epiphyseal separation of the tibial tubercle.

CLINICAL MANIFESTATIONS. The child experiences pain and swelling in the region of the patellar tendon and tibial tubercle, which becomes prominent and is tender to direct pressure. The pain is most severe after physical activity that involves vigorous

TABLE 45-4 MAJOR MUSCULAR DYSTROPHY SYNDROMES

DISEASE	MODE OF INHERITANCE	AGE AT CLINICAL ONSET	USUAL DISTRIBUTION	RATE OF PROGRESSION	MENTAL RETARDATION	DISTINGUISHING FINDINGS
Duchenne muscular dystrophy (DMD)	X-linked recessive	About 3 years	Hips and shoulders, quadriceps femoris, gastrocnemius (pseudohypertrophy)	Rapid	Frequent	Elevated serum enzymes (CPK, LDH, SGOT, aldolase)
Facioscapulohumeral dystrophy	Autosomal dominant	In first or second decade	Shoulder girdle, neck, face, pelvic girdle (late)	Moderate	Occasional	Several distinct muscle pathologic findings
Limb girdle (LG) dystrophy	Poorly defined or recessive	Variable	Pelvic and shoulder girdles	Variable	Variable	Collection of several diseases
Myotonic dystrophy (MyD)	Autosomal dominant	Variable—birth to fifth decades	Distal extensor muscle, eyelids, face, neck, hands, pharynx	Slow, related to age at clinical onset, faster with younger patients	Frequent	Percussion myotonia, cataracts, diabetic GTT despite increased insulin, testicular atrophy, decreased IgG

quadriceps contraction or direct local trauma to the tibial tubercle area. Often the child experiences sudden acute discomfort referable to the affected region. Sudden onset of pain can represent a pathologic fracture through an area of ischemic necrosis.

EVALUATION AND TREATMENT. Diagnosis is confirmed by roentgenographic examination. The goal of treatment for Osgood-Schlatter disease is to decrease the stress at the tubercle. Often a period of 4 to 8 weeks of restriction from strenuous physical activity is sufficient. If pain relief is not achieved, a cast or brace is required to immobilize the knee, a situation that is particularly difficult if the condition is bilateral.

Gradual resumption of activity is permitted after 8 weeks, but return to unrestricted athletic participation requires an additional 8 weeks to allow for revascularization, healing, and ossification of the tibial tubercle. All types of osteochondroses resolve once skeletal maturity is reached.

Cerebral Palsy

Cerebral palsy (CP) is a general term that refers to nonprogressive disorders of movement and posture resulting from injury or malformation of the developing central nervous system. The resulting disability may be mild, manifesting as a stiff-legged gait; or severe, where the child is in a wheelchair and needs lifelong help eating, ambulating, and communicating. There often are associated conditions, such as intellectual disability, seizures, scoliosis, and hearing or vision, or both, defects, especially in children with more severe forms. The overall incidence is 3% to 5%; this number has stayed approximately the same although changes in prenatal and newborn care have been associated with shifts in the etiologies of CP.[30,31]

EVALUATION AND DIAGNOSIS. The diagnosis of CP is often made when gross motor milestones are not met by predicted ages. In some infants, diagnosis is made at birth because the child has an underlying diagnosis, such as a major brain malformation, that is known to be associated with CP, or as early as 4 months in children with more severe forms.[32] There are classic patterns: hemiplegia involves one side of the body, diplegia usually involves the lower extremities only, and quadriplegia involves all four extremities. All children with CP should receive speech/language therapy with trials of augmentative communication devices so that underlying cognitive abilities, which may not be apparent because of motor problems, are given a chance to manifest.

TREATMENT. Treatment of CP is multifaceted and undergoing constant evolution. Physical and occupational treatments, orthotics, spasticity reduction (by selected dorsal rhizotomy, oral, or intrathecal baclofen), botulinum-A (Botox) toxin injections, and surgery are often used to maximize a child's function. In many centers, a multispecialty approach at "CP clinics" occurs so that a family may, within one clinic visit, see neurology, pediatrics, orthotics, orthopedic surgery, and rehabilitation clinicians.

Children with CP should be carefully followed and given all possible opportunities to flourish. Although CP is a static disorder, progressive deformity because of increased muscle tone can occur. Monitoring these children as they grow with a multispecialty approach is essential to their optimal outcome.

Muscular Dystrophy

The **muscular dystrophies** are a group of inherited disorders that cause progressive muscle fiber loss leading to weakness, mostly of the voluntary muscles. The muscular dystrophies are the most prevalent of the muscle diseases in childhood with increasing disability and deformity, although severity depends on the type of dystrophy (Table 45-4).

Although previous classification of the muscular dystrophies was based on age of onset, rate of progression, distribution of muscular involvement, and patterns of inheritance, increasingly the molecular mechanism or gene, or both, for the condition is used for diagnosis. Examples include Duchenne/Becker muscular dystrophy, both caused by mutations in the gene for the muscle protein dystrophin; myotonic muscular dystrophy, because of a genetic mutation in a protein kinase gene; and

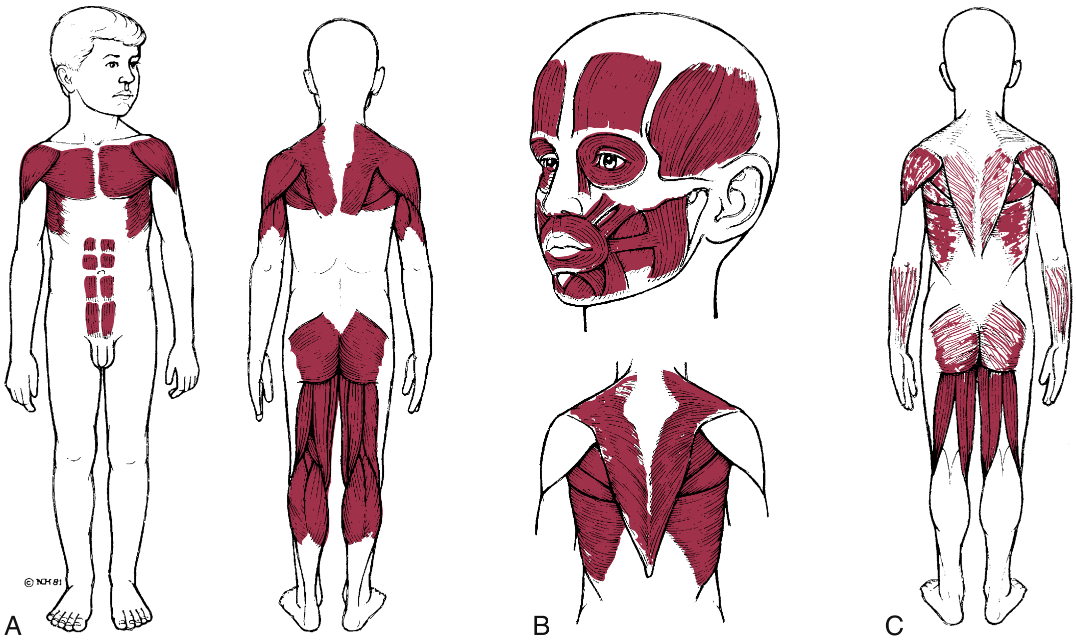

FIGURE 45-15 Initial Muscle Groups Involved in Three Types of Muscular Dystrophy. **A,** Pseudohypertrophic. **B,** Facioscapulohumeral. **C,** Limb girdle. (From Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children,* ed 9, St Louis, 2011, Mosby.)

facioscapulohumeral muscular dystrophy, for which the mutation is still not well understood, although we know that the responsible gene is on chromosome 4 (Figure 45-15).

Duchenne Muscular Dystrophy

In 1868 the French neurologist G.B.A. Duchenne described progressive weakness associated with large calf muscles said to be **pseudohypertrophic,** because they consisted of fat and connective tissue rather than muscle. Today this form of muscular dystrophy, called **Duchenne muscular dystrophy,** is the most common of the muscular dystrophies. Its incidence is approximately 1 in 3500 male births.[33] Classic Duchenne muscular dystrophy occurs only in boys and has a history of X-linked inheritance in half of the cases.

PATHOPHYSIOLOGY. The X-linked inherited type of Duchenne muscular dystrophy is thought to be caused by deletion of a segment of deoxyribonucleic acid (DNA)[33] or a single-gene defect on the short arm of the X chromosome. A protein encoded by the Duchenne muscular dystrophy gene, called **dystrophin,** has been identified.

Dystrophin is present in normal muscle cells and absent in Duchenne muscular dystrophy (it is present in reduced amounts in Becker dystrophy). Dystrophin mediates anchorage of the actin cytoskeleton of skeletal muscle fibers to the basement membrane through a membrane glycoprotein complex. The complete lack of dystrophin in severe Duchenne dystrophy means that poorly anchored fibers tear themselves apart under the repeated stress of contraction. Free calcium then enters the muscle cells, causing cell death and fiber necrosis[34] (Figure 45-16).

Over time, as muscles degenerate, there is increased endomysial connective tissue and fat; loss of striations; and concomitant hyaline, granular, and fatty degeneration of fibers. Disorganization of tendinous insertions is associated with fat accumulation in these areas. Although fibers regenerate in the younger child, regeneration is not able to keep up with muscle cell death.

CLINICAL MANIFESTATIONS. Duchenne muscular dystrophy is usually identified in children at approximately 3 years of age, when the parents first notice slow motor development with progressive weakness and muscle wasting. Sitting, standing, and walking are delayed, and the child is clumsy, falls frequently, and has difficulty climbing stairs.

Muscular weakness begins in the pelvic girdle, causing a "waddling" gait. Hypertrophy of the calf muscles is apparent in 80% of cases. The method of rising from the floor by "climbing up the legs" (Gower sign) is characteristic and is caused by weakness of the lumbar and gluteal muscles. The foot assumes an equinovarus position (see Figure 45-7), and the child tends to walk on the toes because of weakness of the anterior tibial and peroneal muscles. Within 3 to 5 years, muscles of the shoulder girdle become involved. Contractures and wasting of the muscles contribute to muscular atrophy and deformity of the skeleton.

Duchenne muscular dystrophy has serious complications, although these are decreased by treatment with oral corticosteroids at diagnosis. The recent addition of oral corticosteroids early in the disease has dramatically improved outcome. Children are able to walk an additional 2 to 5 years and life expectancy has increased.[35] Complications, such as compromised pulmonary function and kyphoscoliosis ("humped" upper spine combined with scoliosis), are delayed. Full-scale IQ is 85, which is significantly lower than the average IQ of 100, although studies suggest this decrease may be caused by specific learning

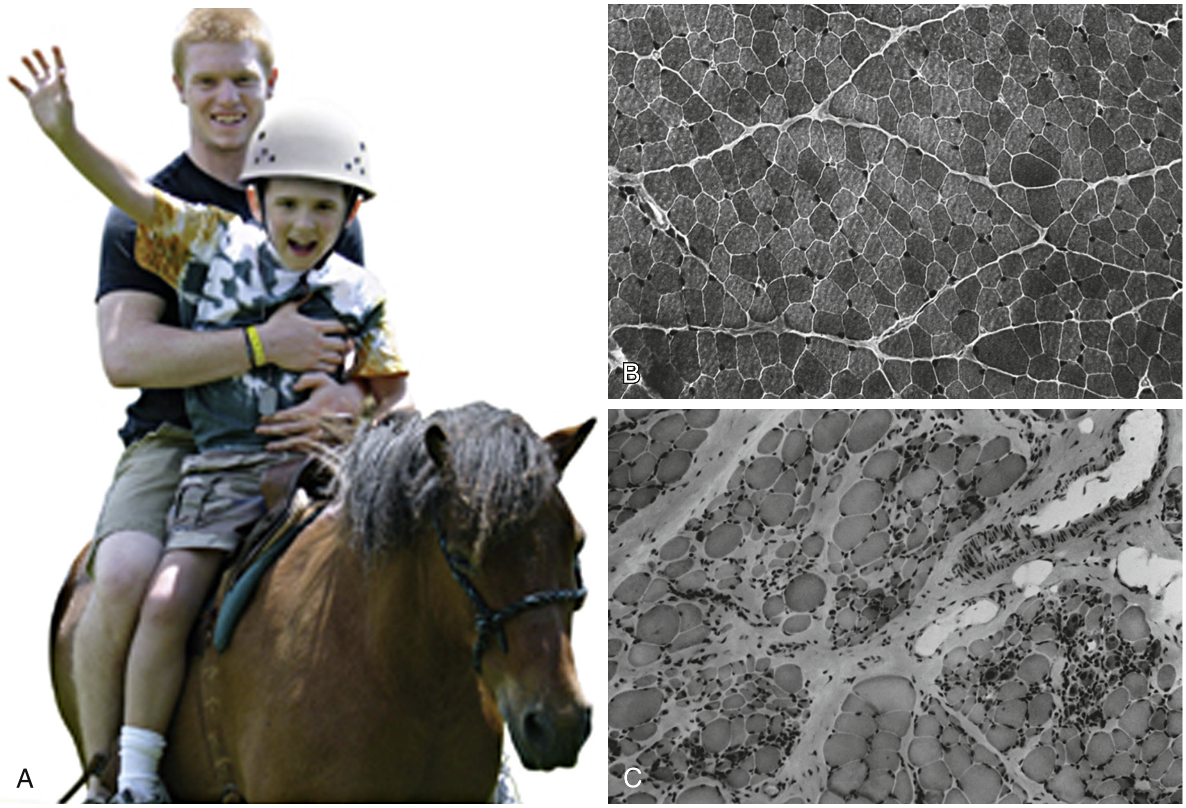

FIGURE 45-16 Duchenne Muscular Dystrophy. **A,** Young boy with Duchenne muscular dystrophy but on horseback. **B,** Transverse section of gastrocnemius muscle from a healthy boy. **C,** Transverse section of gastrocnemius muscle from a boy with Duchenne muscular dystrophy. disabilities rather than a true decreased intelligence. As the condition develops, constipation and incontinence of urine and stool may develop, possibly because of smooth muscle involvement. Although the life expectancy of boys with Duchenne continues to increase, death usually occurs from respiratory tract infection and a compromised respiratory system, with the majority living into their middle twenties. Some individuals who have chosen ventilatory support live a decade or more longer.

EVALUATION AND TREATMENT. Diagnosis is confirmed by genetic testing, which is informative in 95% of cases. Levels of serum enzymes, especially creatine phosphokinase (CPK), are increased to more than 10 times normal, even during infancy and before the onset of weakness. This test may be done as a screening test before gene testing. Electrodiagnostic testing and biopsy are rarely necessary.

Genetic counseling is recommended for all families who have children with DMD. With X-linked inheritance, male siblings of an affected child have a 50% chance of being affected and female siblings have a 50% chance of being carriers. Prenatal diagnosis is now possible and female carriers can be identified, especially if there is a known genetic defect in a son with muscular dystrophy. However, a negative carrier test cannot exclude the female being a carrier since the female's germ cells (her eggs) may be of two different types: one with Duchenne and one without (mosaicism). About one third of the time, the mutation in a boy with DMD is sporadic; that is, the boy is the first person in the family to develop the mutation causing DMD. Various strategies to develop gene therapy are currently in development for children with DMD.

Maintaining function in unaffected muscle groups for as long as possible is the primary goal. Although activity fosters maintenance of muscle function, very strenuous exercise may hasten the breakdown of muscle fibers. Range-of-motion exercises, bracing, and surgical release of contracture deformities are used to maintain normal function as long as possible. To prolong respiratory function or walking ability, or both, surgery for scoliosis is suggested when curves reach greater than 20 degrees. Children with DMD require a multidisciplinary approach to care, including attention to heart and breathing problems, weight loss/gain, constipation, rehabilitative/developmental problems, psychosocial needs, neurologic issues, and orthopedic problems (Figure 45-17).

Becker Muscular Dystrophy

Becker muscular dystrophy is caused by the same mutation in the gene coding for the muscle structural protein dystrophin; therefore, it shares the X-linked inheritance pattern and has similar but milder clinical features. Clinical symptoms often begin between 5 and 15 years of age. Children with Becker muscular dystrophy remain ambulatory into their teens and early twenties Heart failure is infrequent but can be a cause of premature death and disability.

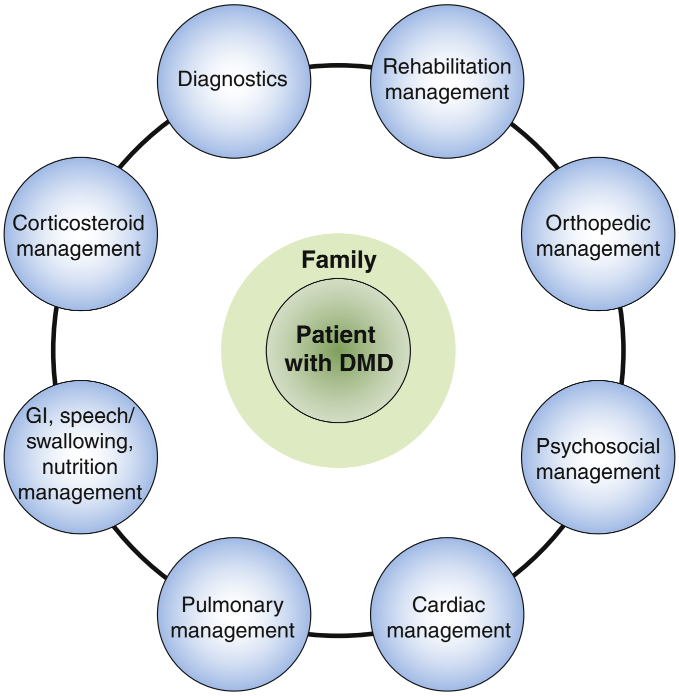

FIGURE 45-17 Multisystem Approach for Evaluation and Treatment of Duchenne Muscular Dystrophy. (Adapted from Bushby K: *Diagnosis and management of Duchenne muscular dystrophy part 1: diagnosis and pharmacological and psychosocial management,* 2009; Bushby K: *Diagnosis and management of Duchenne muscular dystrophy part 2: implementation of multidisciplinary care,* 2009. Available at www.thelancet.com/neurology. Published online November 30, 2009. [doi: 10.1016/S1474-4422(0970271].)

Maintaining ambulation and ensuring careful follow-up examinations for evidence of cardiopulmonary complications are essential for long-term care. If the affected individual marries and has children, all daughters will be carriers of this X-linked recessive disorder; however, male children will be unaffected. Genetic counseling should be offered to the mother, female siblings, offspring, and any maternal relatives.

Facioscapulohumeral Muscular Dystrophy

Facioscapulohumeral muscular dystrophy (FSHD) is a mild form of progressive, autosomal dominant muscular dystrophy. Age at onset varies from early childhood to adulthood, and the disease affects males and females equally. As the name implies, clinical manifestations begin with weakness and atrophy of facial and shoulder girdle (scapulohumeral) muscles. The illness progresses slowly. Inability to close the eyes completely may be noted from early childhood. The face is expressionless, and pouting of the lips makes whistling impossible. The first symptoms usually include drooping of the shoulders with difficulty in raising the arms above the head. Onset of weakness in the lower limbs often is delayed for 20 to 30 years, and pseudohypertrophy of muscles is rare. Contractures and skeletal deformities develop less often and are less prominent than in Duchenne muscular dystrophy. FSHD is rare compared to the other dystrophies in that it often manifests asymmetrically.

Treatment includes supportive physiotherapy to prevent contractures and prolong ambulation. Lightweight plastic ankle-foot orthoses (AFOs) for footdrop are extremely helpful. Shoulder pain is often present and figure-of-eight bracing or surgery to stabilize the shoulder is sometimes advised.

Musculoskeletal Tumors in Children

Bone Tumors

Bone tumors are uncommon childhood tumors and comprise less than 5% of all childhood malignancies. Of the malignant tumors, osteosarcoma and Ewing sarcoma are the most common. Fortunately, the majority of pediatric tumors are benign, most commonly nonossifying fibroma, osteochondroma, simple bone cyst, aneurysmal bone cyst, osteoid osteoma, and fibrous dysplasia.

Benign Bone Tumors

Nonossifying Fibroma. **Nonossifying fibromas** are sharply demarcated, cortically based lesions of fibrocytes that have replaced normal bone. These fibromas constitute about 50% of benign bone tumors. Most fibrous cortical defects are metaphyseal and resolve spontaneously or are obliterated by reparative ossification or remodeling. In some cases, however, the nonossifying fibroma persists and proliferates, affecting the structural integrity of the bone.

Nonossifying fibromas are usually asymptomatic and found incidentally on radiographs. In the 1950s, when fluoride was added to drinking water, random skeletal surveys were done on hundreds of children. Nonossifying fibromas were discovered in 20% to 30% of children and were distributed in nearly every bone of the body.

Nonossifying fibroma is not treated until it occupies more than 50% of the diameter of the bone or extends more than 3 to 4 cm into the cortex. When the tumor grows to this size, a pathologic fracture may occur, and curettage and bone grafting of the defect is undertaken. Quantitative CT scans help define a large lesion clearly and are used for preoperative planning.

Osteochondroma. **Osteochondroma** (or **exostosis**) is a very common benign tumor that results in a bony protuberance of bone growing near the growth plate. They can occur as a solitary lesion or as an inherited syndrome of **hereditary multiple exostoses (HMEs).** Osteochondromas are covered with a cartilage cap that, very rarely, can degenerate into malignant chondrosarcoma. Osteochondromas can occur on any bone and mature while a child is growing. They are the most commonly removed bony tumor.

Hereditary multiple exostosis (HME) occurs in about 1 of every 50,000 live births and results in multiple osteochondroma. It is autosomal dominant and caused by inactivation of EXT1 and EXT2 mutations on chromosomes 8 and 11, respectively. Multiple surgeries are common in affected individuals because the lesions lead to angulation of the bones, pain from pressure on nerves or tendons, and growth abnormalities. The malignant transformation rate is higher, reaching 5%. All affected children should be screened with a spinal MRI to discover if the cord is at risk of injury by spinal exostosis. Involvement of the spine in children with multiple hereditary exostoses is common.[36]

Simple Bone Cyst. **Simple bone cysts (SBCs)** are cystic lesions of the central region of the metaphyseal area in children.

With growth these lesions may appear within the diaphysis. Affected children are usually asymptomatic until pathologic fracture or incidental discovery occurs. Lesions often heal after a fracture, but large lesions may require treatment. A large prospective, randomized study compared steroid injection (the classic treatment for these lesions) with bone marrow injection for treatment. Both treatment modalities were found to have comparable healing rates if the pseudolining of the lesion was scraped from the cyst wall.[37] Very large lesions in weightbearing areas may require internal fixation and bone grafting.

Aneurysmal Bone Cyst. **Aneurysmal bone cysts (ABCs)** are typically eccentric, metaphyseal lesions that occur in a slightly older population than SBCs. The etiology remains controversial; many consider ABC a lesion secondary to another process, such as giant cell tumor. This lesion must be differentiated from malignant telangiectatic osteosarcoma; thus biopsy is necessary. Recent findings of genetic aberration in chromosome band 17p13 suggest a neoplastic basis for ABC.[38] Once diagnosed, curettage with complete removal of the "pseudolining" must be done with chemical cautery or electrocautery to minimize recurrence. Bone graft is placed in the defect. Even with modern techniques, recurrence can be as high as 21%.[39]

Osteoid Osteoma. **Osteoid osteoma,** or the larger counterpart osteoblastoma, presents as painful lesions of the diaphysis or metadiaphysis of long bones. Involvement of the posterior elements of the spine—with resultant "splinting" scoliosis—can occur. Night pain is common, as is relief from symptoms with nonsteroidal anti-inflammatory drugs (NSAIDs), because these tumors release prostaglandins. When pain is too extreme to be controlled medically, resection of the "nidus," or central portion, of the lesion is uniformly successful. CT guidance to the lesion is often used and, if possible, CT-guided laser ablation can be done. When present in the spine, surgical resection must be used since the heat of laser ablation can injure the spinal cord.

Fibrous Dysplasia. **Fibrous dysplasia (FD)** is a disease that causes thinning of the bone or the formation of growths or lesions that can occur in one bone (monostotic) or in multiple bones (polyostotic). **Albright syndrome** is a triad of polyostotic FD, precocious puberty, and cutaneous pigmentation. Although any bone can be affected, the long bones, ribs, and skull are the most common. A radiographic "ground glass" appearance is present primarily in the metaphyseal or metadiaphyseal areas. Deformity can be marked and necessitate operative intervention. When Albright syndrome is present, endocrine abnormalities also must be addressed.

Malignant Bone Tumors

Osteosarcoma. **Osteosarcoma** is the most common malignant bone tumor that occurs during childhood; it originates from bone-producing mesenchymal cells. It accounts for 60% of all malignant bone tumors and strikes between the ages of 10 and 18.

Molecular analysis has demonstrated deletion of genetic material on the long arm of chromosome 13, leading to the identification of a tumor-suppressor gene as part of the mechanism for tumor development. The oncogene *src* also has been associated with osteosarcoma.

PATHOPHYSIOLOGY. Osteosarcoma occurs mainly in the metaphyses of long bones. Most tumors arise in bones involved with the knee joint at the distal end of the femur or proximal end of the tibia. As a tumor of mesenchymal cells, osteosarcoma makes osteoid tissue.

Osteosarcoma is a bulky tumor that extends beyond the bone into the soft tissues. It may encircle the bone and destroy the trabeculae of the diseased bone. Osteosarcoma disseminates through the bloodstream, usually to the lung. As many as 25% of children diagnosed with osteosarcoma exhibit lung metastases at diagnosis. Other sites of metastatic spread include other bones and visceral organs.

CLINICAL MANIFESTATIONS. The most common presenting complaint is pain. There may be swelling, warmth, and redness caused by the vascularity of the tumor. Symptoms also may include cough, dyspnea, and chest pain if lung metastasis is present. If a lower extremity is involved, a limp or even pathologic fracture may be present.

Initial evaluation includes roentgenographic examination that shows the osteosarcoma's characteristic osteoblastic and osteolytic changes. "Staging" studies to determine not only the local extent of the tumor but also possible metastatic spread must be done. These include bone scan (to assess bony spread), magnetic resonance imaging (MRI) of the lesion (to plan surgical resection and to compare with postchemotherapy studies), and chest roentgenograms or CT, or both. The chest roentgenogram must be done *before* biopsy because the general anesthetic required for biopsy can give false-positive results on the roentgenogram.

EVALUATION AND TREATMENT. Tissue biopsy confirms the diagnosis, although needle biopsy is often sufficient to establish the diagnosis. There are five histologic types of osteosarcoma, each determined by the predominant cell type. The tumor is then graded according to degree of malignancy; the higher the number, the worse the prognosis.

Surgery and multiagent chemotherapy are the primary treatments for osteosarcoma. Radiation is occasionally used. The 5-year survival rate with modern protocols is 70% to 80%.[40]

Chemotherapy is used preoperatively to shrink the size of the tumor and minimize metastatic growth. Following chemotherapy, the child is given a short "rest period" to regain strength for surgery. Following adjunctive chemotherapy, the majority of children undergo "limb salvage" rather than amputation procedures. The long-term survival rate of children treated with limb salvage and chemotherapy is now nearly equal to amputation in 5- and 10-year survival.[41]

Ewing Sarcoma. **Ewing sarcoma** is a malignant round cell tumor of bone and soft tissue that has a poor prognosis. It is the second most common and most lethal malignant bone tumor that can occur during childhood. The peak incidence is 10 to 20 years. Like osteosarcoma, Ewing sarcoma is slightly more common in males than females and is linked with periods of rapid bone growth. The incidence of Ewing sarcoma is less than 2% in blacks.[42]

PATHOPHYSIOLOGY. Ewing sarcoma commonly occurs in the diaphysis of long bones or in flat bones. The most common sites include the pelvis, femur, and tibia (Figure 45-18). The femur

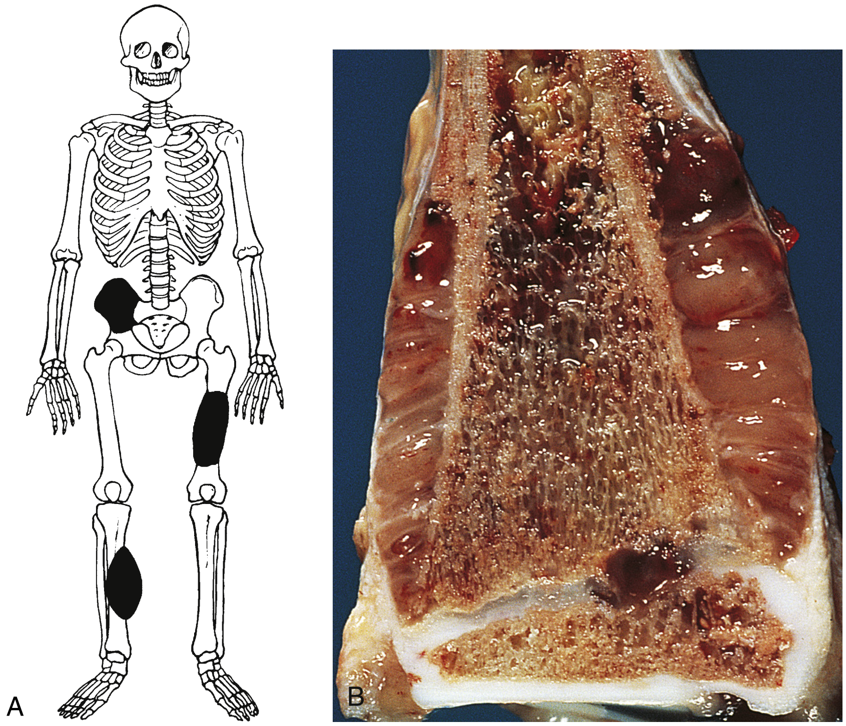

FIGURE 45-18 Ewing Sarcoma. **A,** Most common anatomic sites. **B,** Close-up view of Ewing sarcoma of the distal end of the tibia. Tumor extends into the soft tissue. (From Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

is involved in most cases, with the pelvis being the second most common site. It can occur in any bone.

Arising from bone marrow, Ewing sarcoma can break through the cortex of the bone to form a soft tissue mass. It does not form bone, but abundant reactive bone may be present in an attempt to contain this quickly growing lesion. Metastasis occurs early and is usually apparent at diagnosis or within 1 year. The most common sites are the lung, other bones, lymph nodes, bone marrow, liver, spleen, and central nervous system, although invasion of any organ is possible.

CLINICAL MANIFESTATIONS. Like osteosarcoma, the most common complaint is pain. A soft tissue mass is often present. Additional symptoms may include fever, malaise, and anorexia. Known as "the great imitator," Ewing sarcoma can appear radiographically identical to infection or even benign lesions such as Langerhans cell granulomatosis. Any pervasive diaphyseal or rib lesion must be regarded with a high index of suspicion.

EVALUATION AND TREATMENT. In addition to plain roentgenogram, CT and MRI are needed to help establish the diagnosis and extent of the tumor. Bone scan, chest roentgenogram, and chest CT scan are also used to detect metastases. No specific laboratory test is diagnostic; however, the sedimentation rate will be elevated and lactic dehydrogenase (LDH) level often is elevated. An elevated LDH level is a poor prognostic sign. Biopsy is used to conclusively establish the diagnosis. The identification of an 11:22 chromosomal translocation within the tumor cells confirms the diagnosis of Ewing sarcoma.

The use of multidrug chemotherapy has improved survival rates. Treatment protocols call for preoperative chemotherapy followed by radiation or surgical resection or both, with continuation of chemotherapy for 12 to 18 months afterward. Surgical resection is essential.

Historically, Ewing sarcoma had a dismal prognosis with 5-year survival rates no better than 5% to 10%. Combinations of aggressive radiation, chemotherapy, and surgical resection have improved the survival rate for extremity disease to 65% to 75%.[43] Disease of the trunk or pelvis continues to have a 5-year survival of only 40%. The major predictor of prognosis appears to be the location of the primary tumor and the presence of metastases at diagnosis.

Muscle Tumors

Most soft tissue tumors in children are benign. Only two malignant soft tissue tumors occur with any frequency—rhabdomyosarcoma in the younger child and synovial cell sarcoma in the teenager. Both of these occur rarely. The annual incidence is 8 cases per million for white children and 7.7 per million for black children. About 230 U.S. children are diagnosed with a soft tissue tumor each year. Soft tissue tumors originate from the primitive mesenchymal cells that normally give rise to muscle, tendons, blood vessels, lymphatic structures, fibrous and connective tissue, and bursa and fascia. Table 45-5 identifies the classification of soft tissue tumors according to origin. All malignant soft tissue tumors are characterized as highly aggressive tumors that invade surrounding structures and metastasize early.

Rhabdomyosarcoma (RMS) is the most common soft tissue sarcoma of childhood and accounts for more than 50% of soft tissue tumors but less than 3% of all childhood cancers. RMS arises from embryonal rhabdomyoblasts that normally differentiate into mature striated muscle.

TABLE 45-5 CLASSIFICATION OF TUMORS BY ORIGIN

TISSUE	TUMOR
Muscle	
Striated	Rhabdomyosarcoma
Smooth	Leiomyosarcoma
Adipose	Liposarcoma
Fibrous	Fibrosarcoma
Synovial mesothelium	Synovial sarcoma
Lymphatic structures	Lymphangiosarcoma
Blood vessels	Hemangiopericytoma
Nerve sheath	Neurogenic sarcoma

RMS can develop anywhere striated muscle is located. The primary locations and percentage range of incidence are the head and neck (including the orbit), 36% to 61%; the trunk, 8% to 33%; the extremities, 14% to 24%; and the genitourinary tract, 10% to 17%. Two age ranges (2 to 6 years and 15 to 19 years) are associated with RMS. More than two thirds of children with RMS are diagnosed by 10 years of age, and RMS is slightly more common in males than females.

Recent studies demonstrate an association between *TP53* (a tumor-suppressor gene) mutations and sporadic rhabdomyosarcoma.[44] Three oncogenes *(src, ras,* and *c-myb)* have been associated with this tumor.[45]

PATHOPHYSIOLOGY. RMS generally appears as a firm, fleshy, grayish white mass. RMS has various appearances, depending on the phase of differentiation of the rhabdomyoblast. The cells may be round, spindle shaped, tadpole shaped, or multinucleated giant cells.

At least 20% of children with RMS have metastatic disease at diagnosis. The preferred sites of metastases include the lungs, lymph nodes, bone marrow, liver, brain, and bone. Another 30% have disease that is unresectable, although not widely spread.

CLINICAL MANIFESTATIONS. The signs and symptoms of RMS depend on the anatomic location of the primary tumor and the presence of symptomatic metastases. The tumors are usually painless, and early detection of RMS is facilitated by the presence of a palpable or visible mass. Deep-seated tumors may cause functional impairment but can be silent until they are very large. The clinical manifestations of RMS are outlined in Table 45-6.

TABLE 45-6 CLINICAL MANIFESTATIONS OF RHABDOMYOSARCOMA

LOCATION	MANIFESTATION
Head and Neck	
Orbit	Ptosis
	Exophthalmos
	Proptosis
Paranasal sinuses	Nasal obstruction
	Epistaxis
	Swelling
	Chronic sinusitis
Nasopharynx	Hypernasal speech
	Nasal discharge
	Visible polypoid mass
Oropharyngeal	Dysphagia
	Painful mastication
Middle ear	Chronic serous otitis media
	Discharge from affected ear
	Facial nerve palsy
	Conduction hearing loss
	Visible polypoid mass
Extremities	
All locations	Deep-seated, fixed palpable mass
Retroperitoneal	
All locations	Usually asymptomatic
	May have vague abdominal pain
	Bowel or genitourinary obstruction (late)
	Possible palpable mass
Genitourinary	
Vaginal	Abnormal vaginal bleeding
	Protruding polypoid mass
Prostate	Urinary tract obstruction
Bladder	Urinary retention
	Straining to void
	Hematuria
Paratesticular	Mass in scrotum that may be painful

EVALUATION AND TREATMENT. Diagnostic studies during the pretreatment phase are used to determine the extent of the primary tumor and metastases. Specific diagnostic studies depend on the primary site, but a combination of radiographic, nuclear, and CT scanning or MRI technology and blood studies is used. A biopsy of the primary tumor is necessary to confirm the diagnosis.

RMS is treated by a combination of surgery, radiation, and chemotherapy. Complete surgical resection combined with multiagent chemotherapy has increased the overall survival rate to 70%. If surgical resection leads to serious disfigurement or functional disability (e.g., enucleation for orbital tumors or cystectomy for bladder tumors), chemotherapy and radiation serve as the primary treatment, and surgery is avoided or minimized.

The primary prognostic factor in RMS is the degree of residual disease after surgical resection. Children with localized disease (stages I and II) have long-term survival rates of 70% to 80%. With widespread disease, long-term survival rates drop to 20%. Orbital tumors have an overall favorable prognosis, probably because of the lack of lymphatics in the area and early physical signs of disease.

NONACCIDENTAL TRAUMA

Abuse is estimated to occur in more than 1.5 million U.S. children per year. The maltreatment may be psychologic, sexual, or physical. Of children who suffer physical abuse, 30% are initially seen by an orthopedist. Accurate and appropriate referrals to child protection services are not only legally mandated but

also essential for the well-being of the child; an abused child who returns unmonitored to an abusive situation has a 15% chance of mortality.

ETIOLOGY. Children who are not yet ambulatory and present with a long bone fracture have a greater than 75% chance of that fracture being caused by nonaccidental trauma. **"Corner" metaphyseal fractures,** caused by a twisting force, are *nearly pathognomonic* of abuse but occur only 25% of the time (Figure 45-19). Fractures at multiple stages of healing are also suggestive; however, osteogenesis imperfecta must be ruled out. The most common presentation is a transverse tibia fracture.[46] After walking age, only 2% of long bone fractures are the result of nonaccidental trauma.[47]

EVALUATION. If suspected, nonaccidental trauma necessitates early consultation with child protective services. The child should undergo skeletal radiographic survey, especially if less than 2 years of age, and have a complete physical examination to evaluate for patterned bruising, burns, or multiple soft tissue injuries. Ophthalmologic examination and brain CT should be used to evaluate for retinal or brain hemorrhage caused by shaking. A thorough history must be obtained for all identified injuries. Bone scan can be helpful in diagnosing subtle injuries, especially rib fractures. Posterior rib fractures are especially likely to be caused by abuse. It is important to remember that social isolation can lead to increased likelihood of abuse, but no social stratum is immune.

TREATMENT. A nonjudgmental attitude on the part of the treating healthcare provider is essential. The child and family involved in nonaccidental trauma are delicate and require not only physical but also emotional care. Social workers need to be involved early to ensure appropriate medical care to the child. Fortunately, fractures heal quickly in young children; neurologic injury and social disease, however, are much more difficult to cure.

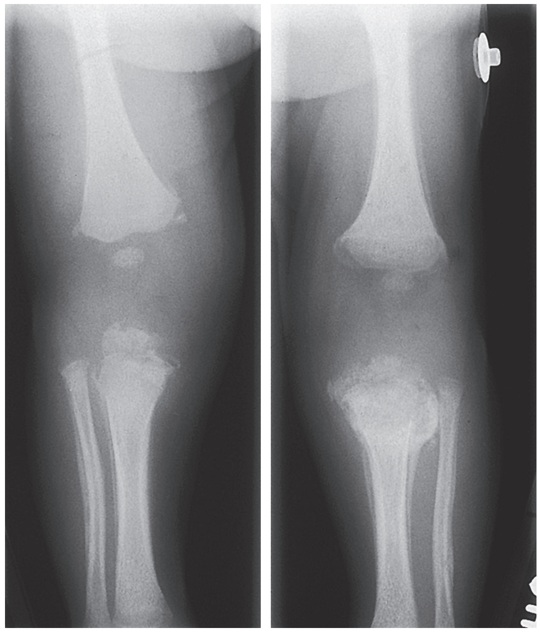

FIGURE 45-19 Corner Fracture. Bilateral knee radiograph showing healing corner fractures of bilateral proximal tibias and distal femurs. Note the varying amount of callus formation signifying fractures at different stages of healing.

SUMMARY REVIEW

Musculoskeletal Development in Children

1. Skeletal growth and development consists of two phases: (a) delivery of bone cell precursors to sites of bone formation, and (b) the aggregation of these cells at primary centers of ossification where they mature to secrete osteoid.
2. Ossification takes place in two centers in long bones: (a) the primary center, or the diaphysis (the long, central portion of the bone); and (b) the secondary center, or the epiphysis (the end portions of the bone).
3. Peak bone mass is achieved by the middle to late twenties.
4. By 1 year of age 50% of the total growth of the spine has occurred, and most children have achieved 50% of their adult height by 2 years of age.
5. The appendicular skeleton (extremities) grows faster during childhood than does the axial skeleton.
6. Muscle fibers reach their maximal size in females at 10 years of age and at 14 years of age in males.

Musculoskeletal Alterations in Children

1. The most common congenital defect of the upper extremities is syndactyly (webbing of the fingers).
2. Developmental dysplasia of the hip (DDH) is an abnormality in the development of the femoral head, acetabulum, or both. It is a serious and disabling condition in children if not diagnosed and treated early, preferably in infancy.
3. Clubfoot (equinovarus) is a common deformity in which the foot is twisted out of its normal shape or position. Clubfoot can be positional, idiopathic, or teratologic.
4. Congenital muscle disorders (myopathies) include absence of muscles, hypoplasia, hyperplasia, and faulty intrinsic development.
5. Osteogenesis imperfecta (brittle bone disease) is a genetic disorder of collagen that affects primarily bones and results in fractures of many bones.
6. Rickets is a condition caused by deficiencies in vitamin D, calcium, and usually phosphorus that is characterized by the failure of bones to become mineralized (ossified) and results in skeletal deformity.
7. Scoliosis is a lateral curvature of the spinal column that can be caused by congenital malformations of the spine, neuromuscular disease, trauma, extraspinal contractures, bone infections, metabolic bone disorders, joint disease, and tumors.
8. Osteomyelitis is a local or generalized bacterial infection of bone and bone marrow. Bacteria are usually introduced by direct extension from a nearby infection, through the bloodstream, or by trauma. Septic arthritis (bacteria within

SUMMARY REVIEW—cont'd

the joint) may be associated with osteomyelitis and is a surgical emergency.

9. Juvenile idiopathic arthritis is an inflammatory joint disorder characterized by pain and swelling. Large joints are most commonly affected.
10. Avascular diseases of the bone are collectively referred to as osteochondroses and are caused by an insufficient blood supply to growing bones.
11. Legg-Calvé-Perthes disease is one of the most common osteochondroses. This disorder is characterized by epiphyseal necrosis or degeneration of the head of the femur followed by regeneration or recalcification.
12. Osgood-Schlatter disease is characterized by inflammation or partial separation of the tibial tubercle caused by chronic irritation, usually as a result of overuse of the quadriceps muscles. The condition is seen primarily in muscular, athletic adolescent males.
13. The muscular dystrophies are a group of genetically transmitted diseases characterized by progressive atrophy of symmetric groups of skeletal muscles without evidence of involvement or degeneration of neural tissue. There is an insidious loss of strength in all forms of the disorder with increasing disability and deformity.
14. The two most common forms of benign bone tumors include nonossifying fibroma and osteochondroma. Other benign bone tumors include simple bone cysts, aneurysmal bone cysts, osteoid osteoma, and fibrous dysplasia.
15. The two main types of malignant childhood bone tumors are osteosarcoma and Ewing sarcoma.
16. Osteosarcoma, the most common malignant childhood bone tumor, originates in bone-producing mesenchymal cells and is most often located in the distal end of the femur or proximal end of the tibia.
17. Most childhood osteosarcoma tumors occur between the ages of 10 and 18 years.
18. Ewing sarcoma originates from cells within the bone marrow space and is located most often in the midshaft of long bones, in ribs, or in flat bones.
19. Ewing sarcoma is more common in males and is diagnosed most often between the ages of 5 and 15 years.
20. Pain is the usual presenting symptom for either osteosarcoma or Ewing sarcoma.
21. The primary treatments for osteosarcoma are surgery and chemotherapy. The primary treatment for Ewing sarcoma is a combination of chemotherapy, radiation, and surgery.
22. The most common type of childhood soft tissue tumor is rhabdomyosarcoma.
23. Rhabdomyosarcoma originates from embryonal rhabdomyoblasts that normally differentiate into mature striated muscle.
24. Clinical manifestations of rhabdomyosarcoma depend on the anatomic location; superficial tumors exhibit a painless palpable mass, whereas deep-seated tumors cause functional impairment.
25. Rhabdomyosarcoma is treated with a combination of surgery, radiation, and chemotherapy.

Nonaccidental Trauma

1. Nonaccidental trauma must be considered with any long bone injury in a preambulatory child.
2. Evidence of soft tissue injury, corner fractures, and fractures at different stages of healing are extremely helpful in making a diagnosis of nonaccidental trauma.
3. When nonaccidental trauma is suspected, a child must be evaluated radiographically for other fractures, head trauma, and retinal hemorrhage.
4. All social strata are at risk.
5. The healthcare provider is legally responsible to report suspected nonaccidental trauma.

CHAPTER OUTLINE

The skin covers the entire body and is the body's largest organ, accounting for approximately 20% of the body's weight. Combined with the accessory structures of hair, nails, and glands, it forms the *integumentary system.* The primary function of the skin is to protect the body from the environment by serving as a barrier against microorganisms, ultraviolet (UV) radiation, loss of body fluids, and the stress of mechanical forces. The skin also regulates body temperature within a very narrow range, and is involved in immune surveillance and the activation of vitamin D. Touch and pressure receptors provide important protective functions and pleasurable sensations. The commensal (normal) microorganisms of the skin protect against pathologic bacteria.

STRUCTURE AND FUNCTION OF THE SKIN

Layers of the Skin

The skin is formed of two major layers: (1) a superficial or outer layer of **epidermis,** and (2) a deeper layer of **dermis** (the true skin) (Figure 46-1). The subcutaneous layer (**hypodermis**) is the lowest lying layer of connective tissue that contains macrophages, fibroblasts, fat cells, nerves, fine muscles, blood vessels, lymphatics, and hair follicle roots. Each skin layer contains cells that represent progressive stages of skin cell differentiation and function as the skin grows. These are summarized in Table 46-1.

Epidermis

The **epidermis** is a defensive barrier that continually renews itself by shedding the superficial layer of **stratum corneum.** It is formed primarily of keratinocytes embedded in a lipid matrix. These cells are named for the substances they produce. **Keratinocytes** produce **keratin,** a scleroprotein that provides protection from mechanical stress. Keratin is the main constituent of skin, hair, and nail cells. The thickness of the epidermis varies from 0.3 mm on the eyelids to 1.5 mm on the palms of the hands and soles of the feet. New cells (keratinocytes) formed in the **basal layer (stratum basale)** move upward and differentiate, forming

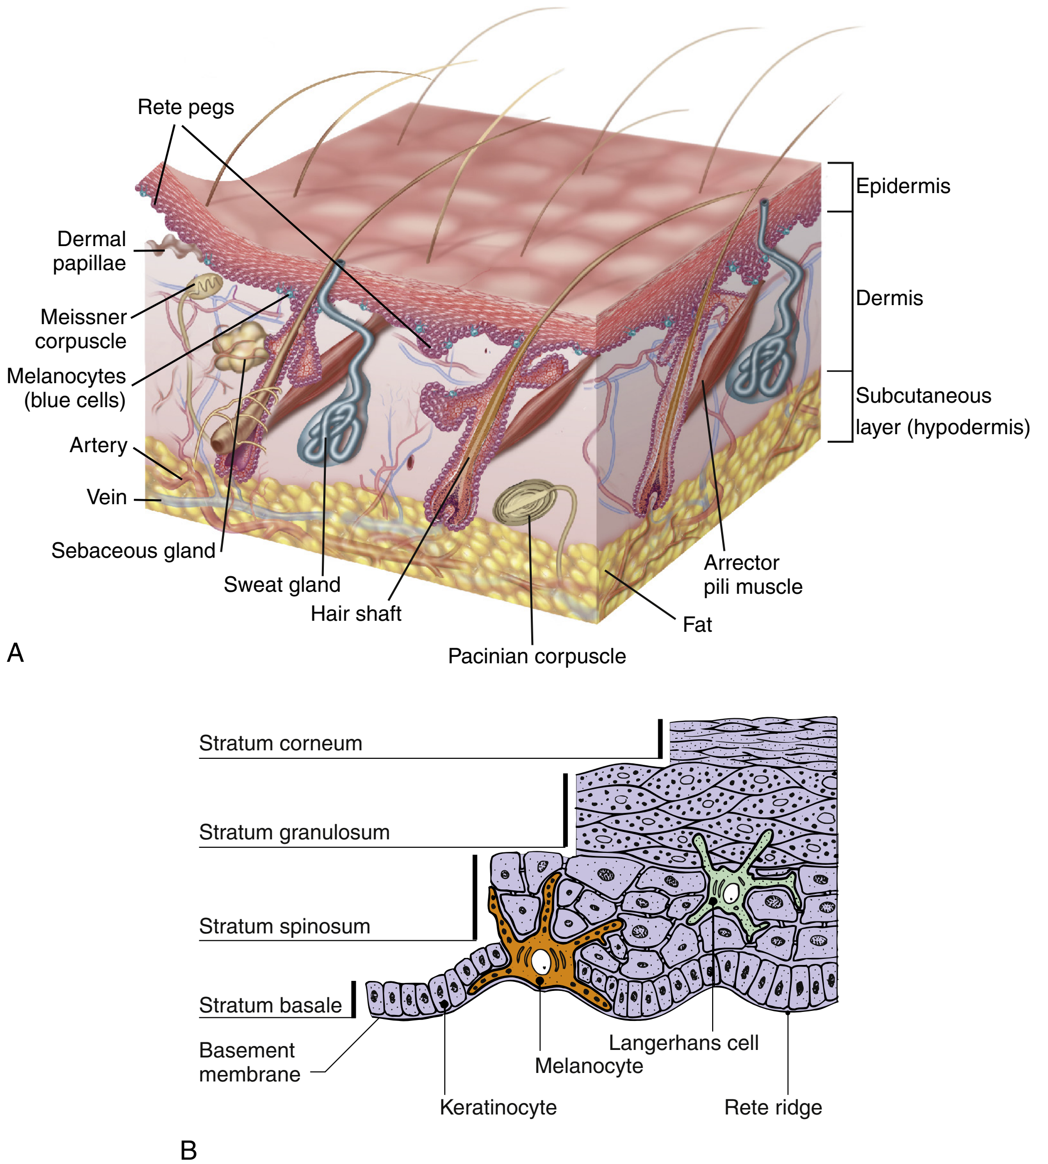

FIGURE 46-1 Structure of the Skin. **A,** Cross section showing major skin structures. **B,** Layers of the epidermis. (**A** from Kumar V et al: *Robbins & Cotran pathologic basis of disease,* ed 8, St Louis, 2009, Saunders; **B** from Gawkrodger D, Ardern-Jones MR: *Dermatology,* ed 5, Philadelphia, 2012, Churchill Livingstone.)

the **spinous layer (stratum spinosum).** Together they form the **germinative layer (stratum germinativum)** and ensure continual renewal of the skin. The cells enlarge and then become flattened, stacked, and cornified (stratum corneum) as they ascend to the skin surface. Cornification, or keratinization, prevents dehydration of deeper skin layers and loss of body water. The average turnover of the epidermis is about 30 days.

The epidermis has three additional types of cells that facilitate its functional characteristics: melanocytes, Langerhans cells, and Merkel cells. The **melanocytes** are usually located near the base of the epidermis. They synthesize and secrete the pigment melanin with exposure to UV light in response to melanocyte-stimulating hormone (MSH). Melanin in the epidermis provides a shield against UV radiation and determines skin color. **Vitiligo** is an autoimmune-related loss of melanocytes resulting in the depigmentation of patches of skin (see "Patch" in Table 44-3, p. 1547). **Langerhans cells** migrate to the epidermis from the bone marrow. Langerhans cells (a type of dendritic cell) and dermal dendritic cells initiate an immune response by presenting processed antigen to T cells, thus providing a defense against environmental antigens.[1] **Merkel cells** are associated with touch receptors and function as slowly adapting mechanoreceptors when stimulated by deformation of the epidermis.

Dermis

The **dermis** is 1 to 4 mm thick and is composed of three types of connective tissue: (1) collagen, (2) elastin and reticulin, and (3) a gel-like ground substance. The haphazard arrangement of connective tissue allows the skin to be mobile and to stretch and contract with body movement. Hair follicles, sebaceous glands, sweat glands, blood vessels, lymphatic vessels, and nerves are

TABLE 46-1 LAYERS OF THE SKIN

LAYER	CELL TYPES	CHARACTERISTICS
Epidermis		Most important layer of skin; normally very thin (0.12 mm) but can thicken and form corns or calluses with constant pressure or friction; includes rete pegs that extend into papillary layer of dermis
Stratum corneum	Keratinocytes	Tough superficial sheets of cornified cells
Stratum lucidum	Keratinocytes	Clear layers of cells containing eleidin, which becomes keratin as cells move up to the corneum layer; *found only in palmoplantar skin*
Stratum granulosum	Keratinocytes	Lose their nuclei
		Keratohyalin gives a granular appearance to this layer
Stratum spinosum	Keratinocytes	Polygonal-shaped with spinous processes projecting between adjacent keratinocytes
	Langerhans cells	Cells with dendritic processes and immune function
Stratum basale (germinativum)	Keratinocytes	Basal layer where keratinocytes divide and move upward to replace cells shed from the surface
	Melanocytes	Originate in neural crest and migrate to stratum basale and produce melanin
	Merkel cells	The function of Merkel cells is not clearly known—have role in light touch
Dermis	Macrophages	Irregular connective tissue layer with rich blood, lymphatic, and nerve supply; contains sensory receptors and sweat glands (apocrine, eccrine, sebaceous); macrophages (phagocytic and important for wound healing) and mast cells (release histamine) have immune functions (see Chapter 7)
Papillary layer (thin)	Mast cells	
Reticular layer (thick)	Histiocytes	Histiocytes are wandering macrophages that collect pigments and inflammatory debris
	Fibroblasts	Generate connective tissue; imported for wound healing
Subcutaneous (Hypodermis)		Subcutaneous tissue or superficial fascia of varying thickness that connects the overlying dermis to underlying muscle; contains macrophages, fibroblasts, fat cells, nerves, blood vessels, lymphatics, and hair follicle roots

contained in the dermis. The conelike projections of the papillary dermis interface with the epidermis. The papillae provide texture to the surface of the skin by forming *rete pegs.*

The cells of the dermis include fibroblasts, mast cells, and macrophages. Fibroblasts secrete the connective tissue matrix and collagen. Mast cells release histamine and play a role in hypersensitivity reactions in the skin. Macrophages are phagocytic and participate in immune responses. Histiocytes are macrophages that reside in loose connective tissue and phagocytize pigments and the debris of inflammation.

Subcutaneous Layer

The third layer of the skin is subcutaneous tissue and consists of fat cells or adipocytes. The lobules are separated by fibrous walls (septa) of collagen and large blood vessels. Dermal collagen is continuous with the collagen found in the subcutaneous tissue.

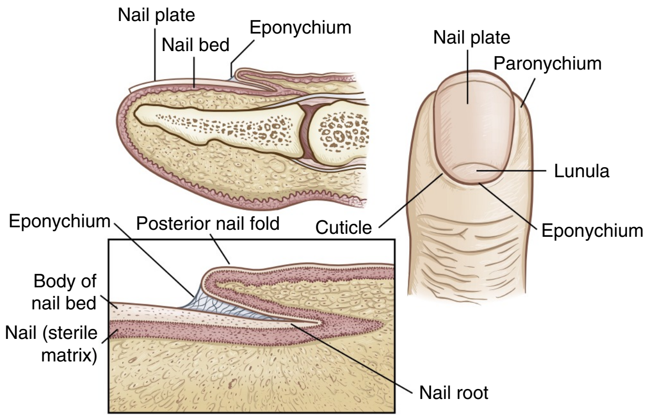

FIGURE 46-2 Structures of the Nail. (Redrawn from Thompson JM et al: *Mosby's clinical nursing,* ed 5, St Louis, 2002, Mosby.)

Dermal Appendages

The **dermal appendages** include the nails, hair, sebaceous glands, and the eccrine and apocrine sweat glands. The **nails** are protective keratinized plates composed of four structural units: (1) the proximal nail fold, (2) the matrix from which the nail grows, (3) the hyponychium (nail bed), and (4) the nail plate (Figure 46-2). Nail growth is continuous throughout life at a rate of 1 mm or less per day.

Hair follicles and sebaceous glands are integrated units (see Figure 46-1). Hair color, density, grain, and pattern of distribution have considerable variability and depend on age, gender, and race. **Hair follicles** arise from the matrix (or bulb) located deep in the dermis. They extend from the dermis at an angle and have an erector pili muscle attached near the mid-dermis that straightens the follicle when contracted, causing the hair to stand up. Hair growth begins in the bulb, with cellular differentiation of stem cells occurring as the hair progresses up the follicle.[2] Hair color is determined by melanin-secreting follicular melanocytes. Hair is fully hardened, or cornified, by the time it emerges at the skin surface. Hair growth is cyclic, with periods of growth and rest that vary over different body surfaces.

The **sebaceous glands** open onto the surface of the skin through a canal. They are found in greatest numbers on the face, chest, and back; modified glands are found on the eyelids, lips, nipple, glans penis, and prepuce. Sebaceous glands secrete sebum, composed primarily of lipids, that oils the skin and hair and prevents drying. Growth of sebaceous glands is stimulated by androgens, and their enlargement is one of the early signs of puberty.

The **eccrine sweat glands** are distributed over the body, with the greatest numbers in the palms of the hands, soles of the feet, and forehead. These secretions are important in thermoregulation and cooling of the body through evaporation. The **apocrine sweat glands** are fewer in number and are located in the axillae, scalp, face, abdomen, and genital area and have very limited proven function.

TABLE 46-2 SUMMARY OF SKIN DIAGNOSTIC PROCEDURES

TEST	PURPOSE
Dermoscopy	Magnified illumination of the skin using a liquid medium and transparent plate to examine skin lesions
Skin biopsy	Histologic examination of tissue to determine differential diagnosis of cellular structure (i.e., benign growths vs. carcinoma, chronic infections, blistering diseases, and vasculitis)
Microscopic immunofluorescence	Identification of antibodies, immunoglobulins, and complement components for diseases such as pemphigus, vasculitis, and discoid lupus erythematosus using fluorescent light on slide-mounted biopsy specimens
Gram stain	Differentiation of gram-positive from gram-negative bacteria according to stain absorption
Culture	Identification of chronic bacterial and fungal infections by incubating skin specimens in culture media
Wood lamp examination	Examination of skin or hair to identify fungus that fluoresces bright yellow-green under ultraviolet light
Patch and scratch tests	Application of suspected allergens to skin by patch or scratch for evaluation of immune system responses to known allergens and evaluation of cell-mediated immune function (*Candida albicans*, skin fungus, chemicals, aeroallergens, and foods)
Skin scrapings	Application of potassium hydroxide and low heat to skin scrapings on a glass slide to identify dermatophytes and *C. albicans*
Side lighting	Indirect lighting of the skin using light to the side of the lesions to evaluate patterns of depression and elevation of skin lesions
Diascopy	Use of glass or clear plastic pressed on the skin to differentiate erythema caused by dilated capillaries (blanching) from extravasation of blood (no blanching)
Tzanck smear	A microscopic examination of cellular material from skin lesions to help diagnose vesicular diseases, including herpes simplex virus and varicella-zoster virus

Blood Supply and Innervation

The blood supply to the skin is limited to the **papillary capillaries,** or plexus, of the dermis. These capillary loops arise from a subpapillary plexus that is supplied by a deeper horizontal cutaneous arterial plexus. Branches from the deep plexus supply hair follicles and sweat glands. A subpapillary network of veins drains the capillary loops. Arteriovenous anastomoses in the dermis facilitate the regulation of body temperature. Heat loss can be regulated by varying blood flow through the skin by opening and closing the arteriovenous anastomoses in conjunction with evaporative heat loss of sweat. The sympathetic nervous system regulates vasoconstriction and vasodilation through α-adrenergic receptors. The lymphatic vessels arise in the papillary dermis and drain into larger subcutaneous trunks, removing cells, proteins, and immunologic mediators.

AGING AND SKIN INTEGRITY

Many age-associated changes in the skin are generalized and readily observable. Genetics and cumulative environmental factors, including UV radiation from sun exposure (photoaging), inflammatory responses, tobacco smoke, and gravity contribute to cutaneous changes with aging.[3,4] Structurally the skin becomes thinner, less elastic, drier, and wrinkled with a change in pigmentation. The cellular alterations contributing to the changes include a flattening of the dermoepidermal junction with a shortening and decrease in the number of capillary loops. There are fewer melanocytes, resulting in decreased protection against UV radiation. A significant decrease in the number of Langerhans cells reduces the skin's immune response with aging. The thickness of the dermis also decreases and accounts for the translucent, paper-thin quality of the skin. Loss of the rete pegs gives the skin a smooth, shiny appearance.[5]

The decreased vasculature and lymphatic drainage contribute to loss of barrier protection and the atrophy of eccrine, apocrine, and sebaceous glands, all of which promote dry skin. Loss of elastin fibers is associated with wrinkling. Collagen fibers become fragmented, and fibroblasts decrease in number, resulting in a decreased ability of the skin to stretch and regain shape. Decreased cell proliferation, diminished blood supply, and depressed immune responses also delay wound healing in aging skin. Changes in hair color and distribution also occur. Graying is caused by loss of melanocytes from hair bulbs, and thinning occurs from a gradual decline in the number of hair follicles and growth of finer hair.[6]

Epidermal cells change shape, and the barrier function of the stratum corneum is reduced. There is increased permeability and decreased clearance of toxic oxidative substances from the dermis. The accumulation of such substances is related to decreased vascularity and can cause skin irritation. Temperature regulation is compromised in older adults, with an increased risk for heat stroke and hypothermia. Loss of cutaneous vasomotion and subcutaneous fat, reduced vascularity, and decreased eccrine sweat production are contributing factors.[7] The pressure and touch receptors and free nerve endings decrease in number and reduce sensory perception. With aging many of the protective functions of the skin decrease, whereas the likelihood of infection and delay in wound healing increase.[8]

Tests of Skin Function

Diagnostic evaluations of skin disorders often can be completed by gathering historical information, performing a physical examination, and observing the distribution and characteristics of the presenting lesions. Additional diagnostic studies are summarized in Table 46-2.

Clinical Manifestations of Skin Dysfunction

Lesions

Lesions of the skin are readily observable and easily assessed for distribution and structure. Identification of the morphologic structure, including a differentiation between the primary and secondary lesions, and the general appearance of the skin is critical. The physical exam, in combination with a thorough health history, is essential to identify the underlying pathophysiology. Table 46-3 describes and illustrates the primary lesions of the skin and Table 46-4 describes and illustrates the

Text continued on p. 1625

TABLE 46-3 PRIMARY SKIN LESIONS

LESIONS	EXAMPLES		
Macule A flat, circumscribed area that is a change in the color of the skin; less than 1 cm in diameter	Freckles, flat moles (nevi), petechiae, measles, scarlet fever		 Macules[a]
Papule An elevated, firm, circumscribed area less than 1 cm in diameter	Wart (verruca), elevated moles, lichen planus, fibroma, insect bite		 Lichen planus[b]
Patch A flat, nonpalpable, irregular-shaped macule more than 1 cm in diameter	Vitiligo, port-wine stains, mongolian spots, café-au-lait spots		 Vitiligo[c]
Plaque Elevated, firm, and rough lesion with flat top surface greater than 1 cm in diameter	Psoriasis, seborrheic and actinic keratoses		 Plaque[d]

TABLE 46-3 PRIMARY SKIN LESIONS—cont'd

LESIONS	EXAMPLES		
Wheal Elevated, irregular-shaped area of cutaneous edema; solid, transient; variable diameter	Insect bites, urticaria, allergic reaction		 Wheal[e]
Nodule Elevated, firm, circumscribed lesion; deeper in dermis than a papule; 1-2 cm in diameter	Erythema nodosum, lipomas		 Lipoma[f]
Tumor Elevated, solid lesion; may be clearly demarcated; deeper in dermis; greater than 2 cm in diameter	Neoplasms, benign tumor, lipoma, neurofibroma, hemangioma		 Neurofibroma[f]
Vesicle Elevated, circumscribed, superficial, does not extend into dermis; filled with serous fluid; less than 1 cm in diameter	Varicella (chickenpox), herpes zoster (shingles), herpes simplex		 Vesicles[g]

Continued

TABLE 46-3 PRIMARY SKIN LESIONS—cont'd

LESIONS	EXAMPLES		
Bulla Vesicle greater than 1 cm in diameter	Blister, pemphigus vulgaris		 Bullae[h]
Pustule Elevated, superficial lesion; similar to a vesicle but filled with purulent fluid	Impetigo, acne		 Acne[c]
Cyst Elevated, circumscribed, encapsulated lesion; in dermis or subcutaneous layer; filled with liquid or semisolid material	Sebaceous cyst, cystic acne		 Sebaceous cyst[c]
Telangiectasia Fine (0.5-1.0 mm), irregular red lines produced by capillary dilation; can be associated with acne rosacea (face), venous hypertension (spider veins in legs), systemic sclerosis, or developmental abnormalities (port-wine birthmarks)	Telangiectasia in rosacea		 Telangiectasia[e]

TABLE 46-5 SPECIAL SKIN LESIONS

TYPE	CLINICAL MANIFESTATIONS
Comedone	A plug of sebaceous and keratin material lodged in the opening of a hair follicle; an open comedone has a dilated orifice (blackhead), and a closed comedone has a narrow opening (whitehead)
Burrow	A narrow, raised, irregular channel caused by a parasite
Petechiae	A circumscribed area of blood less than 0.5 cm in diameter
Purpura	A circumscribed area of blood greater than 0.5 cm in diameter

secondary lesions of the skin. Special skin lesions are described in Table 46-5.

Pressure Ulcers. Pressure ulcers are ischemic ulcers resulting from unrelieved pressure, shearing forces, friction, and moisture. Pressure that consistently interrupts arterial and venous blood flow to and from the skin or deeper tissue is the most significant cause.[9] The term *decubitus ulcer* refers to an ulcer or pressure sore that results when an individual lies or sits in one position for a long time. The more general terms of *pressure sore* or *ulcer* are used here. Risk factors for pressure ulcers are summarized in Box 46-1.

Most individuals with darkly pigmented skin are at greater risk for developing pressure ulcers because early signs of skin damage may not be clearly visible.[10] Pressure sores usually develop over bony prominences: the sacrum, heels, ischia, and greater trochanters are the most common sites. Continuous pressure on tissue between the bony prominence and a resistant outside surface distort capillaries and occlude the blood flow and oxygen supply. Several scales are available for predicting pressure sore risk; the Braden Scale is one of those most frequently used.[11-13] One classification of pressure ulcer grades or stages is summarized as follows[14]:

I. Nonblanchable erythema of intact skin usually over bony prominence; darkly pigmented skin may not have visible blanching
II. Partial-thickness skin loss (erosion or blistering) involving epidermis or dermis presenting as a shallow open ulcer with a red-pink wound bed, without slough
III. Full-thickness skin loss involving damage or necrosis of subcutaneous tissue that may extend to, but not through, underlying fascia
IV. Full-thickness tissue loss with exposure of muscle, bone, or supporting structures (tendons or joint capsules); can include undermining and tunneling

Suspected deep tissue injury is localized in an area of purple or maroon discolored intact skin or blood-filled blister caused by underlying soft tissue damage from pressure and/or shear.

Unstageable is full-thickness tissue loss with base of ulcer covered by slough or eschar, or both, in the wound bed.

Superficial damage results in a layer of dead tissue that appears as a blister, erosion, or nonblanchable red/darkened skin or as a reddish blue discoloration when there is deeper tissue damage. Superficial sores are more common on the sacrum as a result of shearing or friction forces (forces parallel to the skin). Deep sores develop closer to the bone as a result of tissue distortion and vascular occlusion from pressure that is perpendicular to the tissue (over the heels, trochanter, and ischia) (Figure 46-3).

The primary goal for those at risk for pressure ulcers is prevention, including frequent skin assessment with repositioning and turning; use of pressure reduction surfaces and specialty beds; elimination of incontinence, moisture, and drainage; and maintenance of fluid, protein, and caloric intakes.[15,16]

BOX 46-1 PRESSURE ULCER RISK FACTORS

Prolonged Pressure/Immobilization

Lying in bed or sitting in chair or wheelchair without changing position or relieving pressure over an extended period

- Lying for hours on hard x-ray and operating tables
- Neurologic disorders (coma, spinal cord injuries, cognitive impairment, or cerebrovascular disease)
- Fractures or contractures
- Debilitation: elderly persons in hospitals and nursing homes
- Pain
- Sedation

Shearing forces

- Turning by dragging on coarse bed sheets

Disease/Tissue Factors

Impaired perfusion; ischemia
Fecal or urinary incontinence; prolonged exposure to moisture
Malnutrition, dehydration
Chronic diseases accompanied by anemia, edema, renal failure, malnutrition, peripheral vascular disease, or sepsis
Previous history of pressure ulcers

Additional Risk Factors for the Critically Ill

Norepinephrine infusion
Acute Physiology and Chronic Health Evaluation (APACHE II) score
Anemia
Age greater than 40 years
Multiple organ system disease or comorbid complications
Length of hospital stay

Data from Alderden J et al: *Crit Care Nurse* 31(4):30–43, 2011; Coleman S et al: *Int J Nurs Stud* 50(7):974–1003, 2013; Cowan LJ et al: *Wound Repair Regen* 20(2):137–148, 2012; Guihan M, Bombardier CH: *J Spinal Cord Med* 35(4):240–250, 2012; Jaul E: *Drugs Aging* 27(4):311–325, 2010; Thomas DR: *J Am Med Dir Assoc* 11(6):397–405, 2010; White-Chu EF et al: *Clin Geriatr Med* 27(2):241–258, 2011.

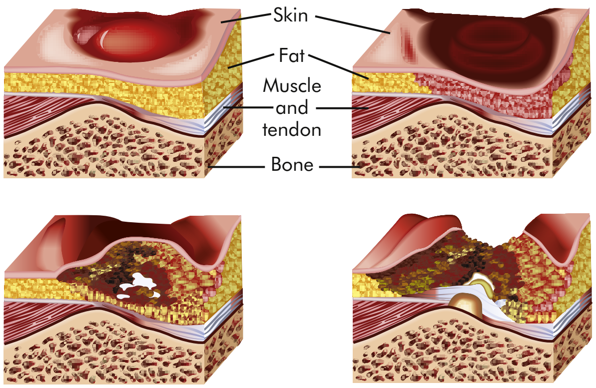

FIGURE 46-3 Progression of Decubitus Ulcer. Sustained pressure over a bony prominence compresses the tissue and reduces blood flow, resulting in progressive ischemia and necrosis of tissue.

Superficial ulcers should be covered with flat, moisture-retaining dressings that cannot wrinkle and cause increased pressure or friction; multiple options are available.[17] Successful healing requires continued adequate relief of pressure; débridement of dead tissue; use of specialty wound care products (dressings, foams, gels, cleansers); and repair with skin flaps for large, deep ulcers. Negative pressure wound healing is a useful technology in the treatment of stage III/IV pressure ulcers.[18,19] Infection requires treatment with antibiotics and pain should be controlled.[20] Randomized controlled trials are needed to determine the best methods for treating pressure ulcers.[21,22]

Keloids and Hypertrophic Scars. **Keloids** are rounded, firm, elevated scars with irregular clawlike margins that extend beyond the original site of injury. **Hypertrophic scars** are elevated erythematous fibrous lesions that do not expand beyond the border of injury. Both lesions are genetically influenced and caused by abnormal wound healing with excessive fibroblast activity and collagen formation during dermal connective tissue repair.[23,24] A familial tendency for keloid formation has been found and both autosomal recessive and autosomal dominant inheritance patterns have been reported.[25] Genes regulating fibroblasts may be up- or down-regulated in keloid tissue.[26]

Keloids are most common in darkly pigmented skin types and burn scars (see Chapter 48). Excessive or poorly aligned tension on a wound, introduction of foreign material into the skin, and the occurrence of certain types of trauma (e.g., burns) are provocative factors. At risk are the shoulders, back, chin, ears, and lower legs. Keloids can appear within weeks to months after a stable scar has formed. Individuals 10 to 30 years of age develop lesions much more commonly than do children before puberty or older adults. Hypertrophic scars usually regress within a year.

The amount of type III collagen is increased with keloids. The increased synthesis of collagen is associated with interleukin-6 (IL-6) signaling and dermal fibroblasts that have high metabolic and mitotic rates. There is aberrant expression of transforming growth factor-beta (TGF-β) and platelet-derived growth factor (PDGF).[27]

Myofibroblasts, cells with characteristics of fibroblasts and smooth muscle cells, are the principal cells in keloids. Collagenase activity in keloids is normal or increased, but the collagen may be protected from degradation by **proteoglycan,** a glycoprotein present in connective tissue that serves as a binding (cementing) material, and by specific inhibitors of proteolytic enzymes.[28] Keloids first appear as pink or red, firm, well-defined rubbery plaques that persist for several months after trauma. Later, uncontrolled overgrowth causes extension beyond the site of the original wound and the tumor becomes smoother, irregularly shaped, hyperpigmented, and harder with **clawlike prolongations** (Figure 46-4).

Keloids are the most extreme example of cutaneous scarring and the most difficult to treat. Preventive measures such as avoidance of unnecessary elective surgeries, recognition of familial tendency, and early detection are of paramount

FIGURE 46-4 Keloid. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

importance. Standard management of keloids and hypertrophic scars includes intralesional corticosteroids, cryotherapy, radiotherapy, and surgical/laser procedures whereas intralesional injections of interferon, bleomycin, and 5-fluorouracil (5-FU) are emerging treatments.[29] There remains a need for research to improve treatment outcome.[30,31]

Pruritus

Pruritus, or itching, is the most common symptom associated with many primary skin disorders, such as eczema, psoriasis, or lice infestations, or it can be a manifestation of systemic disease (e.g., xerosis, chronic renal failure, cholestatic liver disease, thyroid disorders, iron deficiency, neuropathies, or malignancy) or drug reactions. Pruritus may be acute (e.g., mosquito bite) or chronic, and may be localized or generalized and migratory.

Multiple stimuli can produce itching and there is interaction between itch and pain sensations. Peripheral pruritogenic (itch) mediators include histamine, neuropeptides, serotonin, prostaglandins, bradykinin, substance P, opioids, acetylcholine, interleukin-31, and nerve growth factor. Itch sensation is thought to be carried by specific unmyelinated C nerve fibers and thinly myelinated Aδ nerve fibers. Specific spinal pathways carry itch sensations through the spinal cord to the brain.[32] These nerve fibers also may interact with dermal eosinophils, lymphocytes, and mast cells.[33]

Central nervous system mechanisms also can modulate itching, which is less perceptible when the mind is distracted by other stimuli. How the central nervous system influences the itch sensation is unclear. *Neuropathic itch* (itch without pruritogenic stimuli) is related to pathology along an afferent pathway (i.e., postherpetic neuropathy).[34] *Psychogenic itch* is associated with psychologic disorders (e.g., depression and obsessive-compulsive disorder).[35]

Chronic itching is an unpleasant sensation that may or may not be relieved by scratching—often done so intensely that trauma to the skin occurs, resulting in infection, skin thickening (lichenification), and scarring. Both central and peripheral sensitization occurs.[35] Some individuals become so distraught with the constant irritation that they apply heat and/or ice with enough intensity and duration to produce skin injury. Management of itching is challenging and depends on the cause; the primary condition must be treated. Both topical and systemic therapies are used.[36,37]

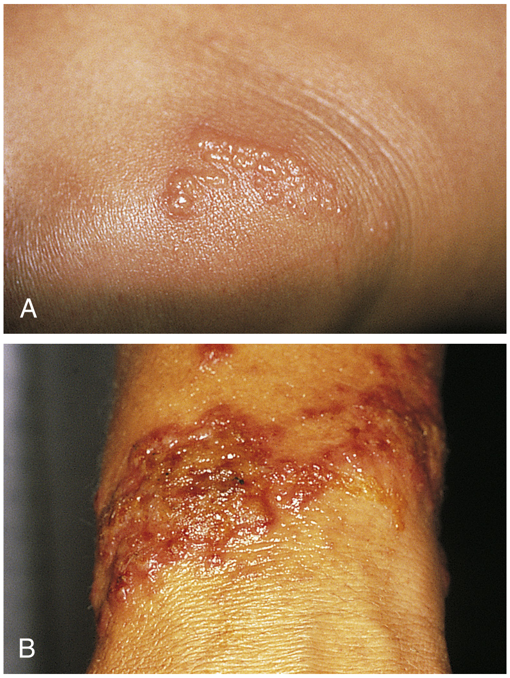

FIGURE 46-5 Poison Ivy. **A,** Poison ivy on knee. **B,** Poison ivy dermatitis. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

DISORDERS OF THE SKIN

Disruptions in skin integrity may be precipitated by trauma, abnormal cellular function, infection and inflammation, and systemic diseases. Many skin disorders are benign and self-limiting, whereas others are severe and life threatening.

Inflammatory Disorders

The most common inflammatory disorder of the skin is **eczema,** or dermatitis. Eczema and dermatitis are general terms that describe a particular type of inflammatory response in the skin—the terms can be used interchangeably. Eczematous disorders are generally characterized by pruritus, lesions with indistinct borders, and epidermal changes. These lesions either can appear as erythema, papules, or scales or can present in an acute, subacute, or chronic phase. Edema, serous discharge, and crusting occur with continued irritation and scratching. In chronic eczema the skin becomes thickened, leathery, and hyperpigmented from recurrent irritation and scratching. The location of eczema is related to the underlying cause. Eczematous inflammations need to be differentiated from other dermatoses, particularly psoriasis.

Allergic Contact Dermatitis

Allergic contact dermatitis is a common form of T-cell–mediated or delayed hypersensitivity (type IV).[38] (See Chapter 9 for various types of allergic responses.) Genetic susceptibility involves several genes including loss-of-function mutations in the gene encoding the epidermal protein filaggrin.[39] Allergens (e.g., microorganisms, chemicals, foreign proteins, drugs, metals, latex) can form the sensitizing antigen; contact with poison ivy is a common example (Figure 46-5). The response is a

reaction to irritants with release of cytokines, chemokines, and cytotoxins from keratinocytes, dendritic cells (Langerhans cells), and natural killer cells. When the allergen comes into contact with the skin the allergen is bound to a carrier protein, forming a hapten-specific sensitizing antigen. Langerhans cells process the antigen and carry it to T cells that then become sensitized to the antigen, releasing cytokines and chemokines and leading to leukocyte infiltration and inflammation.[40] Latex allergy can be either a type IV hypersensitivity reaction to chemicals used in latex rubber processing or a type I immediate hypersensitivity reaction with IgE antibodies formed in response to latex rubber protein.[41]

In delayed hypersensitivity, several hours pass before an immunologic response is apparent. The T cells play an important role because they differentiate and secrete lymphokines that affect macrophage movement and aggregation, coagulation, and other inflammatory responses (see Chapter 9). Sensitization usually develops with first exposure to the antigen, and symptoms of dermatitis occur with reexposure.

The manifestations of allergic contact dermatitis include erythema and swelling with pruritic (itching) vesicular lesions in the areas of allergen contact. The pattern of distribution provides clues to the source of the antigen (e.g., hands exposed to chemical solutions or boundaries from rings and bracelets). Patch tests with specific antigens may assist with diagnosis. Removal of the allergen is necessary for resolution of the inflammatory response and tissue repair. Topical or systemic steroids, as well as other symptomatic treatment, may be required depending on the severity of the lesion.[42]

Irritant Contact Dermatitis

Irritant contact dermatitis is a common nonimmunologically-mediated inflammation of the skin. The intensity of the inflammation is related to the concentration of the irritant, exposure time, disruption of the skin barrier, and age.[43] Irritation can occur from almost anything, especially if the epidermal barrier is compromised in any way (Box 46-2). The skin lesions are similar in appearance to allergic contact dermatitis. Removing the source of irritation and using topical agents (i.e., corticosteroids and petroleum-based emollients) and nonirritating soaps constitute effective treatment.

Atopic Dermatitis

Atopic dermatitis (allergic dermatitis) is more common in infancy and childhood; however, some individuals are affected throughout life. See Chapter 47 for details.[44]

Stasis Dermatitis

Stasis dermatitis usually occurs on the legs as a result of venous stasis and edema. The disorder is associated with varicosities (incompetent venous valves), phlebitis, and vascular trauma. Pooling of venous blood traps leukocytes that may release proteolytic enzymes. Increased venous pressure widens interendothelial pores with deposition of red blood cells, fibrin, and other macromolecules, making them unavailable for repair and promoting inflammation.[45] Edema evolves to erythema and pruritus with progression to scaling, petechiae, and hyperpigmentation.

BOX 46-2 SUBSTANCES KNOWN TO CAUSE CONTACT DERMATITIS*

- Alkalis
  - Soaps
  - Detergents
  - Ammonia preparations
  - Lye
  - Drainpipe cleaners
  - Toilet bowl cleaners
  - Oven cleaners
- Acids
- Metal salts
  - Cyanides of calcium, copper, mercury, nickel, silver, zinc
  - Chlorides of calcium and zinc
- Bromine, chlorine, iodine, fluorine
- Insecticides
- Herbicides
- Dusts of lime, zinc, arsenic
- Dyes and fragrances
- Wood dust from teak, cinchona bark, quinine, pyrethrum
- Tobacco dust from cigars
- Explosive powders
- Hydrocarbons
  - Crude petroleum, lubricating oil, cutting oil
  - Paraffins, mineral oils
  - Asphalt, other tar products
- Soot, peat
- Preservatives

*For chemicals that cause occupational allergic contact dermatitis see National Library of Medicine: Haz-map Table 1: Chemicals that cause occupational allergic contact dermatitis, Bethesda, MD, last updated April 2013. Available at www.hax-map.com/allergic.htm.

FIGURE 46-6 Stasis Ulcer. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Progressive lesions become ulcerated (stasis ulcers), particularly around the ankles and tibia (Figure 46-6).

Treatment includes elevating the legs as often as possible, refraining from wearing tight clothes around the legs, and avoiding standing for long periods. Defined infections are treated with antibiotics. Chronic lesions with ulceration are treated with moist dressings, external compression garments, and vein ablation surgery.[46]

FIGURE 46-7 Seborrheic Dermatitis. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Seborrheic Dermatitis

Seborrheic dermatitis is a common chronic inflammation of the skin involving the scalp, eyebrows, eyelids, ear canals, nasolabial folds, axillae, chest, and back (Figure 46-7). In infants it is known as *cradle cap.* The cause is unknown, but genetic predisposition, the production of specific phospholipases from the presence of *Malassezia yeasts, and immune responses* are implicated.[47,48] The lesions appear from infancy to old age, with periods of remission and exacerbation. The lesions appear as greasy, scaly, white, or yellowish inflammatory plaques in sebaceous areas with mild pruritus. Mild cases are treated with shampoos containing sulfur, salicylic acid, or tar. Ketoconazole has antifungal and anti-inflammatory effects and has been used with success along with topical calcineurin inhibitors. Corticosteroid applications are useful for suppression of severe symptoms but should not be used for maintenance therapy.[49]

Papulosquamous Disorders

Psoriasis, pityriasis rosea, and lichen planus are inflammatory disorders characterized by papules, scales, plaques, and erythema. Collectively they are described as **papulosquamous disorders.**

Psoriasis

Psoriasis is a chronic, relapsing, proliferative, inflammatory disorder that involves the skin, scalp, and nails and can occur at any age. The disease affects about 1% to 8% of the world population and is more common in countries north of the equator.[50] The onset is generally established by 20 years of age. A family history of psoriasis is common. The genetic mechanisms are complex and the human leukocyte antigen (HLA)-Cw6 allele *(PSORS1)* is a major susceptibility gene that affects skin barrier function and innate immune responses.[51] Psoriasis is a T helper (Th) cell–mediated autoimmune disease. The interleukin (IL)-23/T helper (Th) 17 cell axis plays an important role in the pathogenesis of psoriasis.[52] Inflammatory cytokines involved include tumor necrosis factor-alpha (TNF-α), interferon-gamma (IFN-γ), IL-6, IL-12, IL-15, IL-17, IL-20, IL-21, and IL-22 derived from activated T cells, B cells, dendritic cells, and macrophages.[53]

The dermis and epidermis are thickened with keratinocyte hyperproliferation, altered keratinocyte differentiation, expanded dermal vasculature, infiltration of neutrophils and lymphocytes, and inflammation.[54] The turnover time for shedding the epidermis is decreased from the normal 26 to 30 days to 3 to 4 days. There are increased numbers of germinative cells and an increase in transit time of cells through the dermis. The rapid cellular proliferation does not allow time for cell maturation and keratinization to occur, resulting in a thickened epidermis and plaque formation. The loosely cohesive keratin gives the lesion a silvery, scaly appearance. There is often capillary dilation and increased vascularization to accommodate the increased cell metabolism. The increased vascularity causes erythema.

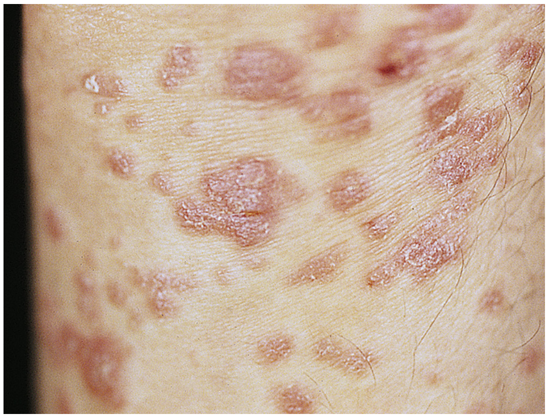

FIGURE 46-8 Psoriasis. Typical oval plaques with well-defined borders and silvery scale. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

The types of psoriasis include plaque (psoriasis vulgaris), inverse, guttate, pustular, and erythrodermic. **Plaque psoriasis** is the most common and affects 80% to 90% of individuals with psoriasis. The disease can be mild, moderate, or severe, depending on the size, distribution, and inflammation of the lesions. Early onset psoriasis is an inflammatory lesion with epidermal hyperproliferation and the presence of activated T lymphocytes. The typical lesion of plaque psoriasis is a well-demarcated, thick, silvery, scaly, erythematous plaque surrounded by normal skin (Figure 46-8). Initial lesions usually develop insidiously as small erythematous papules that enlarge and coalesce into larger inflammatory lesions that can be painful. The lesions are commonly located on the scalp, elbows, and knees and at sites of trauma. The scales are usually loosely adherent and may cause small bleeding points when removed. **Inverse psoriasis** is rare and involves lesions that develop in skinfolds (i.e., axilla or groin). They are large, smooth, dry, and deep red. The clinical course of psoriasis is characterized by remissions and exacerbations. Psoriasis may be triggered by drugs including antimalarials, lithium, nonsteroidal anti-inflammatories, and beta-blockers.[55]

In **guttate psoriasis,** small papules (1 to 10 mm) appear suddenly on the trunk and extremities (Figure 46-9). The lesions may appear a few weeks after a streptococcal respiratory tract infection and are more common in children. Guttate psoriasis may resolve spontaneously in weeks or months. **Pustular psoriasis** appears as blisters of noninfectious pus (collections of neutrophils) that develop over areas of plaque psoriasis.

FIGURE 46-9 Guttate Psoriasis after Streptococcal Infection. Numerous uniformly small lesions may abruptly occur after streptococcal pharyngitis. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

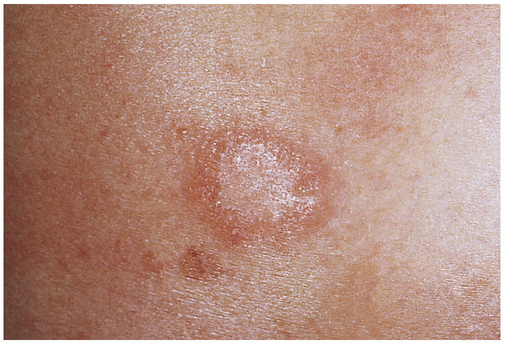

FIGURE 46-10 Pityriasis Rosea Herald Patch. A collarette pattern has formed around the margins. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Erythrodermic (exfoliative) psoriasis is characterized by widespread red, scaling lesions that cover a large body surface area (BSA) and is often accompanied by itching or pain associated with constitutional symptoms (fever, chills, fatigue) and skin infections.

Psoriatic arthritis (PsA) and ankylosing spondylitis are associated with the proinflammatory cytokines that cause psoriatic skin lesions. Joints of the hands, feet, knees, and ankles are involved, and 5% to 50% of individuals with psoriasis have seronegative joint involvement. Psoriatic arthritis mutilans involves pronounced bone destruction and there is greater risk of cardiovascular disease with PsA.[56,57] **Psoriatic nail disease** can occur in all psoriasis subtypes with pitting, onycholysis, subungual hyperkeratosis, and nail plate dystrophy. Psoriasis also is a risk factor for a number of comorbidities including inflammatory bowel disease; metabolic syndrome, including hypertension insulin resistance, dyslipidemias, and abdominal obesity; and increased risk for atherosclerosis and cardiovascular disease that is independent of traditional risk factors for these diseases.[58,59]

Treatment is individualized and related to maintaining skin moisture, reducing epidermal cell turnover and itching, and improving immunomodulation. Mild lesions are usually treated with emollients, keratolytic agents, and corticosteroids. Moderate lesions may respond to UVB light, tar preparations, or a combination of both, and to methotrexate, cyclosporine A, and acitretin. Moderate to severe disease is responsive to the photosensitizing agent oral psoralen in combination with UVA light (PUVA), although skin cancer risk (melanoma and squamous cell) with cumulative dose remains a valid concern.[60] Vitamin D_3 (calcitriol) is used to reduce epidermal proliferation. Moderate to severe disease is the indication for biologic treatment including TNF-α blockers (adalimumab, etanercept, infliximab) and interleukin (IL)-12/-23 inhibitors (ustekinumab). Clinical trials are evaluating new agents.[61,62]

Pityriasis Rosea

Pityriasis rosea is a benign self-limiting inflammatory disorder that occurs more often in young adults, with seasonal peaks in the spring and fall. This is a benign disorder except when contracted during pregnancy, when risks are increased for miscarriage and premature delivery.[63] The cause is unknown but is thought to be associated with a virus (e.g., human herpesvirus 6 [HHV-6] and HHV-7) because of the timing and clustering of the outbreaks.[64] Pityriasis rosea begins as a single lesion known as a **herald patch** (Figure 46-10) that is circular, demarcated, and salmon-pink; is approximately 3 to 4 cm in diameter; and is usually located on the trunk. Early lesions are macular and papular; secondary lesions develop within 14 to 21 days and extend over the trunk and upper part of the extremities. Lesions are rarely located on the face. They emerge as small erythematous papules that expand into characteristic oval lesions. There may be few or hundreds of lesions. The pattern of distribution follows the skin lines around the trunk and resembles a drooping pine tree. As scales flake off from the margin of the lesions, a collarette pattern is formed. Itching is the most common symptom. Headache, fatigue, or sore throat may precede the development of the lesions.

The diagnosis of pityriasis rosea is made by the clinical appearance of the lesion. Secondary syphilis, psoriasis, drug eruption, nummular eczema, and seborrheic dermatitis are among the differential diagnosis considerations. The disorder is usually self-limiting and resolves in a few months with symptomatic treatment for pruritus or cosmetic concerns. UV light (with some risk for hyperpigmentation), antihistamines, or topical corticosteroids may be used to control itching. Erythromycin and acyclovir also may be used for treatment.[65]

Lichen Planus

Lichen planus (LP) is a benign, autoimmune inflammatory disorder of the skin and mucous membranes with multiple clinical variations. The cause is unknown, but T cells, adhesion molecules, inflammatory cytokines, perforin, and antigen-presenting cells are involved.[66] The infiltrate of T cells mediates immunoreactivity against basal layer keratinocytes, which have altered surface antigens and adhesion molecules.[67] LP is also linked to hepatitis C virus. Some individuals develop lichenoid lesions after exposure to drugs or film-processing chemicals. The age of onset is usually between 30 and 70 years. The disorder begins with flat purple, polygonal, pruritic, nonscaling papules 2 to 4 mm in size, usually located on the wrists, ankles, lower legs, and genitalia (Figure 46-11). New lesions are pale pink and evolve into a dark violet. Persistent lesions may be thickened and red, forming hypertrophic LP. Oral lesions

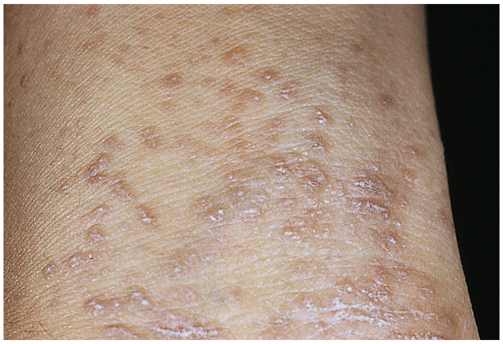

FIGURE 46-11 Hypertrophic Lichen Planus on Arms. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

(oral lichen planus) appear as lacy white rings that must be differentiated from leukoplakia or oral candidiasis and they may be precancerous lesions.[68] Fine white lines, known as Wickham striae, can be seen throughout the oral lesions on magnification. These lesions also can develop on the penis and vulvovaginal area. More commonly, oral lesions do not ulcerate, but localized or extensive painful ulcerations do, and frequently, occur. Chronic ulcerated lesions become malignant in 1% of individuals with the disease. Thinning and splitting of nails are common, and part or all of the nail may be shed.

Pruritus is the most distressing symptom. The lesions are self-limiting and may last for months or years, with an average duration of 6 to 18 months. Postinflammatory hyperpigmentation is a common consequence of the lesion. Approximately 20% of individuals have a recurrence. Diagnosis is commonly made by the clinical appearance of the lesion; however, histopathologic diagnosis is recommended. For cutaneous LP, treatment is individualized and includes topical, intralesional, or systemic corticosteroids (second line for resistant LP), and systemic acitretin with/without adjuvant light therapy. Antihistamines are given for itching, and topical or systemic corticosteroids may be used to control inflammation. Short-term systemic glucocorticoids are indicated if oral lesions are severe or for LP involving three or more nails. Mucous membrane lesions are treated with potent topical steroids, topical retinoids, and systemic glucocorticoids.[69-71]

Acne Vulgaris

Acne vulgaris is an inflammatory disorder of the pilosebaceous follicle (the sebaceous gland contiguous with a hair follicle). It occurs most commonly during adolescence. Details of this disorder are presented in Chapter 47. Hidradenitis suppurativa (inverse acne) is summarized in What's New? Hidradenitis Suppurativa (Inverse Acne).

Acne Rosacea

Acne rosacea is a chronic, readily exacerbated, inflammatory skin disease with varied presentations and extent of involvement that develops primarily in middle-age adults. There are four types of lesions: erythematotelangiectatic, papulopustular, phymatous, and ocular.[72] They occur in the middle third of the face, including the forehead, nose, cheeks, and chin (Figure 46-12). The cause is unknown, but immune-mediated inflammation may be a factor. The lesions are associated with chronic,

WHAT'S NEW?

Hidradenitis Suppurativa (Inverse Acne)

Hidradenitis suppurativa (inverse acne) is a chronic, inflammatory, recurring, scarring disease of the pilosebaceous follicular ducts involving areas of skin where there are folds, hair follicles, and apocrine (sweat) glands (i.e., axillary, inguinal, inframammary, genital, buttocks, and perineal areas of the body) (see figure). The incidence is unknown but estimated at 1% to 4% of the population and is more common in females. The pathogenesis of the disease is complex and includes a combination of genetic, hormonal, immune, and environmental factors. Aggravating factors include tight clothing, heat and perspiration, obesity, stress, and smoking. Follicular hyperkeratosis and occlusion obstructs the pilosebaceous unit, causing perifolliculitis, abscess formation, sinus tracts, and scarring. Bacterial infection is a secondary event. The lesions present as deep, firm, painful subcutaneous nodules that track and rupture horizontally under the skin. They are differentiated from "boils" (carbuncles) because boils extend vertically and discharge onto the skin. Diagnosis can be difficult, delaying effective treatment. Treatment can include administering systemic medications, performing incision and drainage of nodules, obtaining a culture of the exudate, and giving antibiotics, with concern about the presence of methicillin-resistant *Staphylococcus aureus* (MRSA), topical or intralesional corticosteroids, and retinoids. Lesions often require surgical excision and skin grafting. Complete, spontaneous resolution is rare. Deterrence includes avoiding heat and perspiration, losing weight if obese, wearing loose clothing, refraining from shaving affected areas, stopping smoking, and using zinc gluconate supplements to reduce inflammation. The disease can recur for years with negative effects on quality of life. Clinical trials are needed to identify the best treatment options.

inappropriate vasodilation resulting in flushing and sensitivity to the sun. Sebaceous hypertrophy, fibrosis, and telangiectasia may be severe enough to produce an irreversible bulbous appearance of the nose, known as *rhinophyma.* The vascular abnormalities induce local production of transforming growth factor-β1 (TGF-β1) capable of creating fibrosis and, therefore, cutaneous thickening.[73] *Demodex folliculorum* (mites) infection may be a contributing factor.[74] Disorders of the eye often accompany rosacea, particularly conjunctivitis and, more rarely, keratitis, which can result in visual impairment.[75] Facial application of fluorinated topical steroids may precipitate rosacea-like lesions that are difficult to treat.

Hot drinks or alcohol should be taken cautiously because the heat and vasodilation accentuate erythema. Daily use of photoprotection, including sunscreens, is recommended; both topical (metronidazole, azelaic acid) and oral drugs (tetracyclines) may be effective.[76] Surgical excision of excessive tissue may be required for rhinophyma.

Lupus Erythematosus

Lupus erythematosus is an inflammatory, autoimmune, systemic disease with cutaneous manifestations. Discoid (or cutaneous) lupus erythematosus (DLE) is limited to the skin and can progress to systemic lupus erythematosus (SLE). DLE may be described as a subset of SLE, with cutaneous manifestations as the only symptom[77] (Figure 46-13). (SLE, a diffuse, multisystem disease that also has cutaneous manifestations, is discussed in Chapter 9.)

Discoid (Cutaneous) Lupus Erythematosus. **Discoid (cutaneous) lupus erythematosus (DLE)** usually occurs in genetically susceptible adults, particularly in women in their late thirties or early forties. There are three forms of the disease: acute, subacute, and chronic. The lesions may be single or multiple and of various sizes. Often the lesions are located on light-exposed areas of the skin, and photosensitivity is common. The face is the most common site of lesion involvement. The characteristic manifestations of the different categories of DLE are summarized in Table 46-6.

The cause is unknown but thought to be related to genetic and environmental factors and an altered immune response to

FIGURE 46-13 Subacute Cutaneous Lupus (Discoid Lupus Erythematosus). (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

an unknown antigen or response to UV wavelengths with the development of self-reactive T and B cells, decreased number of regulatory T cells, and increased proinflammatory cytokines. Autoantibodies and immune complexes cause tissue damage.[78]

Diagnosis of DLE is made from the presenting symptoms, biopsy of skin lesions with direct immunofluorescence, as well as histologic results. Skin biopsy with immunofluorescent observation reveals lumpy deposits of immunoglobulins, especially IgM and C3.[79] DLE can progress to systemic lupus erythematosus and individuals with SLE should be regularly screened for this progression.[80]

Individuals with DLE must use sunscreen and sun protection because direct sun exposure initiates or exacerbates lesions. Treatment options include topical steroids, calcineurin inhibitors, antimalarial drugs (e.g., hydroxychloroquine sulfate), and immunosuppressors. These medications must be used with caution to prevent serious side effects.[81]

Vesiculobullous Disorders

Vesiculobullous skin diseases share a common characteristic of vesicle, or blister, formation. Two such diseases are pemphigus and erythema multiforme.

Pemphigus

Pemphigus (meaning to blister or bubble) is a rare autoimmune blistering disease of the skin and oral mucous membranes caused by circulating autoantibodies directed against the cell surface adhesion molecule desmoglein at the desmosomal cell junction in the suprabasal layer of the epidermis. Pemphigus

TABLE 46-6 **CATEGORIES AND MANIFESTATIONS OF DISCOID LUPUS ERYTHEMATOSUS (DLE)**

CATEGORY OF DLE	CLINICAL MANIFESTATIONS
Acute	
Localized	Butterfly pattern of erythema over bridge of nose and malar areas of face (malar rash); may have fine surface scales and underlying edema; scalp areas may develop alopecia; lasts for hours to days
Generalized	Diffuse or papular erythema of face, upper trunk, or extremities; develops quickly and lasts hours to days
Subacute	Erythematous macules and papules that evolve into *papulosquamous* or *annular* plaques developing on sun-exposed areas of the upper body (V area of neck, upper chest, back, shoulders, extensor surface of arms and hands); can be associated with reaction to drugs; may be accompanied by mild systemic disease
Chronic	Classic discoid lupus erythematosus is the most common form; lesions are red to purple macules or papules with a superficial brownish scale; scale can penetrate hair follicle leaving a carpet-tack appearance when removed; may have residual scarring, dermal atrophy hypopigmentation, alopecia, and telangiectasia; Raynaud phenomenon occurs in some individuals

Data from Kuhn A, Biji M: *Lupus* 17(5):389–393, 2008; Rothfield N, Sontheimer RD, Bernstein M: *Clin Dermatol* 24(5):348–362, 2006; Uva L et al: *Autoimmune Dis* 2012:834291, 2012.

can occur in all age groups but is more prevalent between 40 and 50 years of age. There is a genetic predisposition as well as environmental triggers, most of which are unknown.[82] Pemphigus presents in varying forms:

- **Pemphigus vulgaris** is the most common form with acantholysis at the suprabasal level. Immunoglobulin G (IgG) autoantibodies and C3 complement bind to the desmoglein adhesion molecules, resulting in the destruction of cell-to-cell adhesion (acantholysis) in the epidermis with fluid accumulation and the resulting symptom of blister formation.[83] Oral lesions precede the onset of skin blistering, which is more prominent on the face, scalp, and axilla. The blisters rupture easily because of the thin, fragile overlying portion of epidermis, resulting in painful erosions. *Pemphigus vegetans* is a rare variant of pemphigus vulgaris with large blisters that progress to hypertrophic granulomas with tissue erosion and pustules (vegetating plaques). They usually occur in tissue folds.
- **Pemphigus foliaceus** is a milder form of the disease and involves acantholysis at the subcorneal level with blistering, erosions, scaling, crusting, and erythema usually of the face and chest. Oral mucous membranes are rarely involved. *Pemphigus erythematosus* is a subset of pemphigus foliaceus often associated with systemic lupus erythematosus with positive antinuclear antibodies. The lesions are generally less widely distributed.
- **Paraneoplastic pemphigus** is the most severe form of pemphigus and is associated with lymphoproliferative neoplasms. Internal organs, including lungs, thyroid, kidney, smooth muscle, and the gastrointestinal tract, also are involved, leading to the term *paraneoplastic autoimmune multiorgan syndrome*. In contrast to pemphigus vulgaris, the lesions develop from inflammatory papules or macules rather than normal skin.[84]
- **IgA pemphigus** is the most benign form of pemphigus characterized by tissue-bound and circulating IgA antibodies targeting desmosomal or nondesmosomal cell surface components in the basement membrane of the epidermis. Acantholysis is not as severe as that in pemphigus vulgaris but there is still blister formation.[85]

The diagnosis of pemphigus is made from the clinical manifestations and histologic examination of the skin. Immunofluorescence demonstrates the presence of antibodies at the site of blister formation. The clinical course of the disease may range from rapidly fatal to relatively benign. The primary treatment for pemphigus is systemic corticosteroids in combination with adjuvant immunosuppressants and, in difficult cases, adjuvant protein A immunoadsorption intravenous immunoglobulins, plasmapheresis, and anti-CD20 monoclonal antibody therapy. Newer methods of treatment and a clearer understanding of the pathogenesis have improved the prognosis and decreased mortality.[86]

Bullous Pemphigoid

Bullous pemphigoid (BP) is a more benign autoimmune disease than pemphigus vulgaris, with blistering of the subepidermal skin layer. Autoantibodies (IgG and IgE) to hemidesmosomal proteins designated BP 180 and BP 230 have been found. There are numerous triggers, including drugs and skin trauma. The autoantibodies activate complement with inflammatory infiltration of neutrophils, eosinophils, and lymphocytes. Loss of dermal-epidermal adhesion is caused by inflammatory cytokines.[87,88] The lesions of pemphigoid begin with localized erythema or as pruritic plaques that extend and become edematous. The plaques turn reddish purple by 2 to 3 weeks, with vesicles and bullae emerging on the surface (Figure 46-14). Oral lesions can occur. The bullae do not extend with pressure. The blisters rupture within 1 week and heal rapidly. BP occurs more commonly after 60 years of age.

Diagnosis is by skin biopsy and immunofluorescent examination. The presence of subepidermal blistering and eosinophils distinguishes pemphigoid from pemphigus. Treatment usually includes hydroxyzine (Atarax) for itching and topical or systemic corticosteroids. Adjuvant immunosuppressive drugs may be prescribed. Relapse may occur with discontinuation of treatment.[89,90]

Erythema Multiforme

Erythema multiforme is not a single disease but rather a syndrome characterized by inflammation of skin and mucous

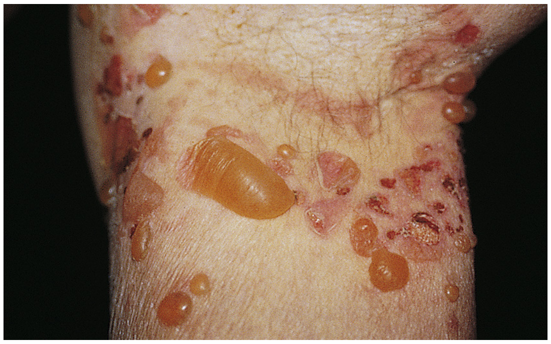

FIGURE 46-14 **Bullous Pemphigoid.** Generalized eruption with blisters arising from an edematous, erythematous annular base. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

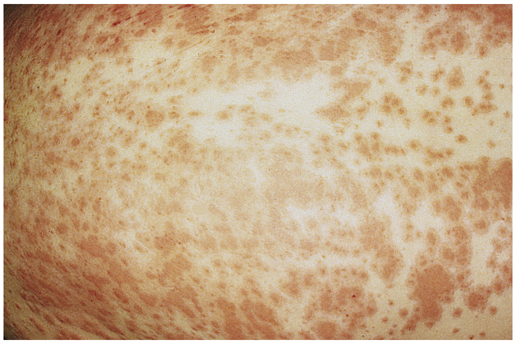

FIGURE 46-15 **Erythema Multiforme Caused by Doxepin.** (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

membranes. It often is associated with a T-cell–mediated immunologic reaction to microorganisms (e.g., herpes simplex virus, *Mycoplasma pneumoniae*) or a toxic reaction to drugs in which TNF-α causes tissue damage.[91] Overall, it is relatively rare and can occur at any age but is more common between 20 and 40 years of age. Immune complex formation and deposition of complement (C3), IgM, and fibrinogen around the superficial dermal blood vessels, basement membrane, and keratinocytes are found in most individuals with erythema multiforme. Edema develops in the superficial dermis, leading to the formation of vesicles and bullae. The lesions vary in clinical presentation and may involve the skin or mucous membranes, or both. The characteristic "bull's-eye" or "target" lesions occur on the skin surface with a central dusky region surrounded by concentric rings or alternating edema and inflammation.[92,93] The lesions usually occur suddenly in groups over 2 to 3 weeks. Urticarial plaques, 1 to 2 cm in diameter, can develop without the target lesion. A vesiculobullous form is characterized by mucous membrane lesions and erythematous plaques over elbows and knees. Single or multiple vesicles or bullae may arise on a part of the plaque, accompanied by pruritus and burning. In the minor form, there may be tens to hundreds of lesions.[94] The lesions heal within 3 to 4 weeks (Figure 46-15).

Prodromal symptoms of erythema multiform include fever, headache, malaise, sore throat, and cough in approximately one third of cases. The bullous lesions form erosions and crusts when ruptured. The mouth, air passages, esophagus, urethra, and conjunctiva may be involved when mucous membranes are affected. Blindness can result from corneal ulcerations. Difficulty with eating, breathing, and urinating may develop with severe manifestations. Severe forms of the disease can be fatal.

Diagnosis is made by medication history, by recognition of the target lesion, or by skin biopsy to establish the diagnosis. Mild, acute forms of the disease last 10 to 14 days, are usually self-limiting, and require no treatment. Any ongoing drug therapy should be withdrawn or reevaluated and underlying infections treated. Treatment is individualized according to severity.[93] Antiviral prophylaxis may be required. Fluid and electrolyte balance should be monitored in severe forms of the disease, and mucous membranes must be carefully managed with a bland diet, warm saline eyewashes, topical anesthetics, or corticosteroids to maintain comfort and prevent infection. Use of systemic steroids is controversial. Cutaneous blisters can be treated with wet compresses of nanocrystalline silver. Ophthalmic, kidney, and lung involvement requires special care. Resolution occurs in 8 to 10 days, usually without scarring. Mucosal lesions may take 6 weeks to heal.[93]

Infections

Cutaneous infections are common forms of skin disease. They generally remain localized; however, serious complications can develop with systemic involvement. The types of skin infection include bacterial, viral, and fungal. Most infections occur superficially; however, systemic signs and symptoms occasionally develop and rarely become life threatening. Aerobes, yeast, and anaerobes comprise the normal flora of the skin and often provide protection against pathogens that cause skin infections, including *Staphylococcus* and *Streptococcus.*

Bacterial Infections

Most bacterial infections of the skin are caused by local invasion of pathogens. Coagulase-positive *Staphylococcus aureus* and, less often, beta-hemolytic *Streptococci* are the common causative microorganisms. Community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) is also a cause of serious skin infection (Box 46-3).

Folliculitis. **Folliculitis** is an infection of the hair follicle and can be caused by bacteria, viruses, or fungi. *S. aureus* is a common causative microorganism.[95] The infection develops from proliferation of the microorganism around the opening of the follicle and then spreads into the follicle. Inflammation is caused by the release of chemotactic factors and enzymes from the bacteria. The lesions appear as pustules with a surrounding area of erythema. They are most prominent on the scalp and extremities and rarely cause systemic symptoms. Prolonged skin moisture, occlusive clothing, topical agents, skin trauma (e.g., shaving facial hair), and poor hygiene are associated contributing factors to the development of folliculitis. Cleaning with soap and water and topical application of antibiotics are effective forms of treatment.

Furuncles and Carbuncles. A **furuncle,** or "boil," is an inflammation of the hair follicles that may develop from a preceding folliculitis and spread through the follicular wall into the surrounding dermis. The invading microorganism is

BOX 46-3 COMMUNITY-ACQUIRED METHICILLIN-RESISTANT *Staphylococcus aureus* (CA-MRSA)

CA-MRSA is a serious skin and soft tissue infection that includes abscesses, cellulitis, and necrotizing fasciitis, and can serve as a source for bloodstream infections. Infections are documented among healthy individuals who have no known risk factors, that is, no recent hospitalization, surgical procedures, or prolonged antibiotic treatment. Outbreaks have been documented among athletic teams, among prisoners, and in daycare centers. CA-MRSA strains are epidemiologically and clonally different from hospital- or nursing home–acquired MRSA. The most common tests involve genotyping for the staphylococcal chromosomal cassette mec (SCCmec) type IV and Panton-Valentine leukocidin genes. The USA300-0114 strain has been epidemic in the United States. It also has caused life-threatening pneumonia, osteomyelitis, and septic arthritis and is spreading internationally. CA-MRSAs are more sensitive to antibiotic treatment and there is a wider choice of antibiotic treatment options for CA-MRSA compared with hospital-acquired MRSA. CA-MRSA is usually susceptible to a variety of oral non–beta-lactam antibiotics, including trimethoprim-sulfamethoxazole, clindamycin, tetracyclines, and linezolid. Parenteral therapy with vancomycin or daptomycin also can be considered. Ceftaroline has been effective for both skin and systemic infections. Mupirocin may be used to clear MRSA from nasal secretions if cultures show contamination in the nose. New drugs are under investigation. Preventive measures include practicing good hand hygiene, applying antiseptics and covering cuts and abrasions, using antibacterial soaps for showers after contact sports, avoiding sharing towels and razors, and frequently washing towels.

Data from Casapao AM et al: *Expert Opin Pharmacother* 13(8):1177–1186, 2010; Nimmo GR: *Clin Microbiol Infect* 18(8):725–734, 2012; Tattevin P et al: *Clin Infect Dis* 55(6):781–788, 2012; Tonn K, Ryan TJ: *J Environ Health* 75(6):44–49, 2013; Watkins RR, David MZ, Salata RA: *J Med Microbiol* 61(Pt 9):1179–1193, 2012.

FIGURE 46-16 **Furuncle on the Forearm.** (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

usually *S. aureus*, including community-associated methicillin-resistant *S. aureus* (CA-MSRA). The infecting strain may spread to the skin from the anterior nares. Any skin area with hair can be infected, and one or several lesions may be present. The precipitating events are similar to those for folliculitis. The initial lesion is a deep, firm, red, painful nodule 1 to 5 cm in diameter (Figure 46-16). Within a few days the initial erythematous nodule changes to a large fluctuant and tender cystic nodule that may be accompanied by cellulitis. No systemic symptoms are present, and the lesion may drain large amounts of pus and necrotic tissue.[96]

A **carbuncle** is a collection of infected hair follicles occurring most often on the back of the neck, the upper back, and the lateral thighs. The lesion begins in the subcutaneous tissue and lower dermis as a firm mass that evolves into an erythematous, painful, swollen mass that drains through many openings. Abscesses may develop. Chills, fever, and malaise are systemic symptoms that can occur during the early stages of lesion development.

Furuncles and carbuncles are treated with warm compresses to provide comfort and promote localization and spontaneous drainage. Abscess formation requires incision and drainage and recurrent infections, extensive lesions, or those associated with cellulitis or systemic symptoms are treated with systemic antibiotics.

Cellulitis. **Cellulitis** is an infection of the dermis and subcutaneous tissue usually caused by *Staphylococcus*, CA-MRSA, or group B streptococci. Cellulitis can occur as an extension of a skin wound, of an ulcer, or from furuncles or carbuncles. It can be associated with chronic venous insufficiency and stasis dermatitis. Risk factors include diabetes mellitus, edema, peripheral vascular disease, tinea pedis, insect bites, and immune suppression. The infected area is erythematous, warm, swollen, and painful and can extend to lymph nodes and the blood. Initial systemic treatment with antibiotics should cover both *Staphylococci* and *Streptococci*, and Burrow soaks can be used to relieve pain. Corticosteroids are used for adjuvant therapy.[97]

Cellulitis must be differentiated from **necrotizing fasciitis.** Necrotizing fasciitis is a rare, rapidly spreading inflammation starting in the fascia, muscles, and subcutaneous fat with subsequent necrosis of the overlying skin; it is treated with antibiotics and often requires surgical débridement.[98]

Erysipelas. **Erysipelas** is an acute superficial infection of the upper dermis (a superficial form of cellulitis) most often caused by *Streptococcus pyogenes*, beta-hemolytic streptococci, and *Staphylococcus aureus*. The face, ears, and lower legs are common sites of involvement, and the site of initial infection may not be identified. Chills, fever, and malaise precede the onset of lesions by 4 hours to 20 days. The initial lesions appear as firm, red spots that enlarge and coalesce to form a clearly circumscribed, advancing edge, bright red, hot lesion with a raised border. Vesicles may appear over the lesion and at the border, producing a bullous form of the disease. Itching, burning, and tenderness accompany the development of the lesion. Cold compresses provide symptomatic relief, and systemic antibiotics are required to arrest the infection.[99]

Impetigo. **Impetigo,** most common in children, is a superficial lesion of the skin caused by coagulase-positive *Staphylococcus aureus* or alpha-hemolytic streptococci[100] (see Chapter 47).

FIGURE 46-17 **Herpes Simplex.** Typical presentation with tense vesicles involving the nasal mucosa and extending onto the skin. (From Habif TP: *Clinical dermatology: a color guide to diagnosis and therapy,* ed 4, Philadelphia, 2004, Mosby.)

FIGURE 46-18 **Herpes Zoster.** Diffuse involvement of a dermatome. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Viral Infections

Herpes Simplex Virus. Skin infections with **herpes simplex virus (HSV)** are commonly caused by two types: HSV-1 and HSV-2. Either type can occur in different parts of the body, including oral and genital locations. Their differences are distinguished by laboratory tests. HSV-1 is generally associated with oral infections (cold sore or fever blister) or infection of the cornea (herpes keratitis) but it also can cause genital herpes.[101] HSV-1 is usually transmitted by contact with infected saliva. With primary infection, the virus infects epithelial cells and moves by retrograde axonal transport to the dorsal root ganglion, where the virus develops lifelong latency. The incubation period ranges from 2 to 14 days. During the secondary phase, the lesions occur at the same site from reactivation of the virus. The virus travels down the peripheral nerve to the site of the original infection, where it is shed. Exposure to ultraviolet light, skin irritation, fever, fatigue, or stress may cause reactivation.

The lesions for HSV-1 appear as a rash or clusters of inflamed and painful vesicles (e.g., within the mouth, over the tongue, on the lips, within and/or around the nose) (Figure 46-17). Increased sensitivity, paresthesias, and mild burning often occur before onset of the lesions. The vesicles rupture, forming a crust. Lesions may last from 2 to 6 weeks. Treatment is symptomatic and includes topical antiviral agents; lesions usually resolve within 2 weeks. Oral antivirals may be indicated at the time of acute infection or through daily suppressive dosing to prevent acute infections.[102]

Genital infections are more commonly caused by HSV-2. The virus is spread by skin-to-skin mucous membrane contact during viral shedding. Risk of infection is high after sexual contact with infected individuals and for those who are immunosuppressed and there is increased risk for human immunodeficiency virus (HIV) infection. Vertical transmission from mother to neonate is associated with significant neonatal neurologic morbidity and mortality.[103] The primary infection is asymptomatic. With recurrent exposure, the lesions begin as small vesicles that progress to ulceration within 3 to 4 days with pain, itching, and weeping. Treatment is symptomatic and includes topical or oral antiviral agents. Efforts are in progress to develop prophylactic vaccines.[104]

Herpes Zoster and Varicella. **Herpes zoster** (shingles) and **herpes varicella** (chickenpox, see Chapter 47) are caused by the same herpes virus—varicella-zoster virus (VZV). VZV is the primary infection followed years later by herpes zoster (shingles) from reactivation of the virus, particularly among those who are immunosuppressed.[105] It can cause severe disease in nonimmune pregnant women. Following the primary infection the virus remains latent in trigeminal and dorsal root ganglia.

Herpes zoster has initial symptoms of pain and paresthesia localized to the affected dermatome (the cutaneous area innervated by a single spinal nerve; see Chapter 15), followed by vesicular eruptions along a facial, cervical, or thoracic lumbar dermatome (Figure 46-18). Some individuals have vesicles scattered outside the area of the dermatome but lesions do not usually cross the midline. Local symptoms are alleviated with compresses, calamine lotion, or baking soda. Persistent pain may last for weeks or months and is a debilitating complication, particularly in older adults, and requires treatment. Approximately 15% to 20% of individuals experience postherpetic neuralgias.[106] There is no cure for herpes zoster. Antiviral drugs are useful if used within the first 72 hours.[107] Treatment includes a topical lidocaine patch, anticonvulsant medication, controlled-release narcotics, tricyclic antidepressants, and topical capsaicin.[108] Because older adults are at increased risk due to declining immunocompetence, the live-attenuated varicella vaccine is recommended for those older than age 60 as it is well tolerated and effective and may boost humoral and cellular immunity.[109,110]

Warts. **Warts** (verrucae) are benign lesions of the skin caused by the many different types of **human papillomavirus (HPV)** that infect the stratified epithelium of skin and mucous

FIGURE 46-19 Verruca Vulgaris. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

membranes. Specific viruses are associated with specific kinds and locations of lesions.[111] The lesions are round and elevated with a rough, grayish surface; can occur anywhere on the skin; and are transmitted by touch. *Common warts* (verrucae vulgaris) occur most often in children and are usually on the fingers, although they may be located on any skin surface or mucous membrane. Warts vary in shape, size (flat, round, or fusiform), and location (Figure 46-19). Plantar warts are usually located at pressure points on the bottom of the feet.

Diagnosis of warts is by visualization. Treatment considers age of the individual and size and location of the lesion. Warts can be removed by freezing with liquid nitrogen, electrocauterization, vaporization with lasers, application of keratolytics, or application of irritants and corrosives such as salicylic acid, formaldehyde, interferons, or podophyllum.[112] Recalcitrant warts may benefit from application of topicals such as imiquimod 5% cream (immunomodulatory) or 5-fluorouracil, by intralesional injections of bleomycin or *Candida* (immunoreactive antigen), or by more aggressive surgical procedures.[113] Many warts resolve spontaneously but often recur.

Condylomata acuminata (venereal warts) are highly contagious and sexually transmitted. The cauliflower-like lesions occur in moist areas along the glans of the penis, vulva, and anus (see Chapter 26). Oncogenic HPV (e.g., types 16 and 18) is a primary cause of cervical cancer (see Chapter 24).

Fungal Infections

The fungi causing superficial skin infections are called *dermatophytes,* and they thrive on keratin (stratum corneum, hair, nails). Fungal disorders are known as *mycoses;* when caused by dermatophytes, the mycoses are termed *tinea* (dermatophytosis or ringworm).

Tinea Infections. **Tinea infections** are fungal infections of the skin and are classified according to their location on the body.[114] The most common sites are summarized in Table 46-7. These infections are common in children (see Chapter 47). **Tinea unguium (onychomycosis)** is a fungal infection of the nails and is discussed on p. 1647. **Tinea pedis** is a chronic, superficial fungal infection of the skin of the foot common in adults (Figure 46-20). In prepubertal children, most scaling disorders of the toes and feet are eczema. **Tinea corporis** **(ringworm)** and **tinea capitis** (a fungal infection of the scalp) are much more common in children than adults. (See Chapter 47 for a discussion of fungal infections in children.)

TABLE 46-7 COMMON SITES OF TINEA INFECTIONS

SITE	CLINICAL MANIFESTATIONS
Tinea capitis (scalp)	Scaly, pruritic scalp with bald areas; hair breaks easily
Tinea corporis (skin areas, excluding scalp, face, hands, feet, groin)	Circular, clearly circumscribed, mildly erythematous scaly patches with a slightly elevated ringlike border; some forms are dry and macular, and other forms are moist and vesicular
Tinea cruris (groin, also known as "jock itch")	Small erythematous and scaling vesicular patches with a well-defined border that spreads over the inner and upper surfaces of the thighs; occurs with heat and high humidity
Tinea pedis (foot, also known as "athlete's foot")	Occurs between the toes and may spread to the soles of the feet, nails, and skin of toes; slight scaling, macerated painful skin, occasionally with fissures and vesiculation
Tinea manus (hand)	Dry, scaly, erythematous lesions, or moist vesicular lesions that begin with clusters of intensely itching, clear vesicles; often associated with fungal infection of the feet
Tinea unguium or onychomycosis (nails)	A superficial or deep inflammation of the nail that develops yellow-brown accumulations of brittle keratin over all or portions of the nail

FIGURE 46-20 Tinea Pedis. Inflammation has extended from the web area onto the dorsum of the foot. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Tinea is diagnosed by culture, microscopic examination of skin scrapings prepared with potassium hydroxide wet mount, or observation of the skin with a UV light (Wood lamp).

TABLE 46-8 SITES OF CANDIDIASIS

SITE	RISK FACTORS	CLINICAL MANIFESTATIONS	TREATMENT
Vagina (vulvovaginitis)	Heat, moisture, occlusive clothing Pregnancy Systemic antibiotic therapy Diabetes mellitus Sexual intercourse with infected male	Vaginal itching; white, watery, or creamy discharge Red and swollen vaginal and labial membranes with erosions Lesions may spread to anus and groin	Miconazole cream Clotrimazole tablets or cream Nystatin tablets Ketoconazole cream Loose cotton clothing
Penis (balanitis)	Uncircumcised Sexual intercourse with infected female	Pinpoint, red, tender papules and pustules on glans and shaft of penis	Any of creams listed above Topical steroids for severe inflammation
Mouth	Diabetes mellitus Immunosuppressive therapy Inhaled steroids	Red, swollen, painful tongue and oral mucous membranes Localized erosions and plaques appear with chronic infection	Nystatin oral suspension Clotrimazole troches Ketoconazole Fluconazole
Skinfolds	Heat and moisture Diabetes mellitus Immunosuppressive therapy	Pruritic red rash progressing to vesicles and papules that enlarge and rupture	Topical antifungals (e.g., clotrimazole, econazole, ciclopirox, miconazole, ketoconazole, nystatin)

Cultures establish the particular type of fungus and are necessary for hair and nail infections. Fungi have characteristic spores and filaments known as **hyphae** that are more prominent when prepared in potassium hydroxide. The spores fluoresce blue-green when exposed to UV light. Treatment is related to the type of fungi and includes both topical and systemic antifungal medications.

Candidiasis. **Candidiasis** is caused by the yeastlike fungus *Candida albicans* and normally can be found on mucous membranes, on the skin, in the gastrointestinal tract, and in the vagina. *C. albicans* can, under certain circumstances, change from a commensal microorganism to a pathogen, particularly in the critically ill and those who are immunosuppressed.[115] Factors that predispose to infection include: (1) a local environment of moisture, warmth, maceration, or occlusion; (2) the systemic administration of antibiotics; (3) pregnancy; (4) diabetes mellitus; (5) Cushing disease; (6) debilitated states; (7) age younger than 6 months (more likely to get an infection because of decreased immune reactivity); (8) immunosuppression; and (9) certain neoplastic diseases of the blood and monocyte-macrophage system. The resident bacteria on the skin, mainly cocci, inhibit proliferation of *C. albicans.* Cell-mediated immunity plays a major role in the defense against monilial infections. *C. albicans* can activate the complement system by the alternative pathway and can include small abscesses. Candidiasis affects only the outer layers of mucous membranes and skin and occurs in the mouth, vagina, uncircumcised penis, nail folds, interdigital areas, and large skinfolds (inframammary area, intertriginous area, perianal region, and abdominal creases). Table 46-8 lists selected sites of candidiasis. Innate and adaptive immune responses are required for elimination of *C. albicans.*[116]

The initial lesion is a thin-walled pustule that extends under the stratum corneum with an inflammatory base that may burn or itch. The accumulation of inflammatory cells and scale produces a whitish yellow curdlike substance over the infected area. The lesion ceases to spread when it reaches dry skin.[117] Topical antifungal medication is most commonly used for treatment.

Vascular Disorders

Vascular abnormalities are commonly associated with skin diseases, or they may be present as congenital vascular malformations (see Chapter 47) or as vascular responses to local or systemic vasoactive substances. Blood vessels may increase in number, dilate, constrict, or become obliterated by disease processes.

Cutaneous Vasculitis

Cutaneous vasculitis (angiitis) is an inflammation of the blood vessels of the skin. The vasculitis is often idiopathic or can be triggered by infection, decreased blood flow (i.e., venous stasis), drugs, or autoimmune disorders. The initiating site of inflammation may be the blood, the vessel wall, or the adjacent tissue. Small vessels are usually affected. Immune complexes, which initiate an uncontrolled inflammatory response, are often the cause of damage, and the lesions are often polymorphic.

Cutaneous vasculitis develops from the deposit of immune complexes in small blood vessels as a toxic response to drugs (phenothiazines, barbiturates, sulfonamides) or allergens, as a response to streptococcal or viral infection, or as a component of systemic vasculitic syndromes. The precise mechanism is not known, but the deposit of immune complex activates complement, which is chemotactic for polymorphonuclear leukocytes and other mediators of inflammation that disrupt adhesion molecules and the vessel wall. The cutaneous form usually resolves in a few weeks and is treated with steroids.

A systemic form (cutaneous systemic vasculitis) can involve other organs, including the kidneys, lungs, and gastrointestinal tract (e.g., Wegener granulomatosis). The extremities are the chief sites affected, primarily the lower legs and feet. The lesions appear as palpable purpuras (from the leakage of blood from damaged vessels) and progress to hemorrhagic bullae with necrosis and ulceration from occlusion of the vessel (Figure 46-21). Lesions appear in clusters and remain from 1 to 4 weeks. Recurrences are common.

Serum analysis and biopsy provide the most accurate differential diagnosis. Identifying the primary disease or removing

FIGURE 46-21 **Vasculitis of the Leg.** (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

FIGURE 46-22 **Urticaria.** (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

the antigen (chemical, drug, or source of infection) is the first step of treatment. Corticosteroids and immunosuppressants are used when symptoms are severe.[118,119]

Urticaria

Urticaria (hives) is a pruritic circumscribed area of raised erythema with central pallor occurring in the superficial dermis; they are often generalized in distribution. The erythema blanches with pressure. **Urticarial lesions** are most commonly associated with type I hypersensitivity reactions to drugs (e.g., penicillin, aspirin), certain foods (e.g., strawberries, shellfish), systemic diseases (e.g., intestinal parasites, lupus erythematosus), physical agents (e.g., heat, cold), or complement-mediated reactions (see Chapter 9). They may occur with angioedema (edema of the dermis and subcutaneous tissue). The lesions are usually mediated by IgE-stimulated release of histamine, bradykinin, or kallikrein from mast cells or basophils, or both, which causes the endothelial cells of skin blood vessels to contract, increasing permeability. IgG antibody directed against the IgE receptor and other inflammatory mediators, such as serotonin, leukotrienes, prostaglandins, and kinins, also may be mediators of urticaria. Fluid leakage from vessels appears as wheals, welts, or hives; there may be a few leaks or many leaks distributed over the entire body (Figure 46-22). Most lesions resolve spontaneously within 24 hours, but new lesions may appear. All possible causes should be removed. Nonsedating, second-generation antihistamines (H1 antagonists) usually reduce hives and itching but may be combined with histamine H2 blockers,

FIGURE 46-23 **Scleroderma.** Note inflammation and shiny skin. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

first-generation antihistamines, or leukotriene receptor agonists to improve outcomes.[120] Epinephrine or corticosteroids and α-adrenergic agonists may be required for treatment of severe attacks (i.e., angioedema). Chronic urticaria (recurrent wheals for more than 6 weeks) is either an autoimmune or an idiopathic disease.[121]

Localized Scleroderma

Localized scleroderma (morphea) means sclerosis of the skin. The disease is rare and the cause is unknown. It is more prominent in white females, usually with childhood onset. Genetic predisposition, autoimmunity, and an immune reaction to a toxic substance are possible initiating mechanisms of the disease. T helper cells (Th1 and Th17) and their cytokines are associated with fibroblast proliferation and fibrosis. Several autoantibodies also have been identified, including antinuclear antibody (ANA), antihistone antibody (AHA), and single-stranded DNA antibody (ss-DNA Ab).[122] The cutaneous lesions are most often on the face and hands, neck, and upper chest, but the entire skin can be involved.

There are massive deposits of collagen with fibrosis, accompanied by inflammatory reactions, vascular changes in the capillary network with a decrease in the number of capillary loops, dilation of the remaining capillaries, enhanced expression of adhesion molecules, endothelial injury and dysfunction, perivascular infiltrates, and ischemia. Fibrosis occurs in the papillary and reticular dermis and in the subcutaneous tissue and deep fascia. The skin is hard, hypopigmented, taut, shiny, and tightly attached to the underlying tissue. The tightness of the facial skin projects an immobile masklike appearance, and the oral aperture is limited. The nose may assume a beaklike appearance. The hands are shiny and sometimes red and edematous (Figure 46-23). The fingers become tapered and flexed, often with contractures, depressed scars, and loss of fingertips from atrophy. Raynaud phenomenon with episodic arteriolar vasoconstriction of the fingers contributes to pain, ulcer formation, and gangrene. The nails may be shed. Calcium deposits develop in the subcutaneous tissue and erupt through the skin. There may be progression to underlying muscle and bone and other body organs with esophageal involvement being most common.

Suitable clothing and a warm environment are essential to protecting the hands. Trauma and smoking should be avoided.[123] Treatment is individualized and based on severity and progression of the disease. Immunosuppressive medications, ultraviolet light treatment, and other therapies are prescribed.[124,125]

Tick Bites

Ticks are significant vectors of transmitted diseases, including Rocky Mountain spotted fever and other rickettsial diseases, tularemia, Congo-Crimean hemorrhagic fever, and Lyme disease.[126] Ticks vary from 1 cm to about the size of a comma on this printed page. They embed their heads in the skin to obtain blood. As they gorge themselves on blood, they enlarge to many times their normal size and may release toxins or transmit microorganisms during feeding. In most instances, there is no consequence from a tick bite, with the exception of papular urticaria at the site of the bite. If mouthparts remain in the skin when the tick is removed, a persistent nodule remains that may require excision; ideally the tick should be removed completely intact. Irritant substances, such as camphor, soft wax, or heat from a match, may stimulate the tick to withdraw its head. Wearing protective clothing and applying tick repellant, such as diethyltoluamide (DEET), butopyronoxyl (Indalone), or benzylbenzoate, help prevent tick bites.

Lyme disease is a multisystem inflammatory disease caused by the spirochete *Borrelia burgdorferi* transmitted by tick bites and is the most frequently reported vector-borne illness. The highest incidence is among children (50% of infected individuals are symptom free). An immune response to *B. burgdorferi* contributes to the pathogenesis of the disease. The microorganism is difficult to culture and it escapes immunodefenses through antigenetic diversity; blocks complement-mediated killing; impedes release of antimicrobial peptides, leukocyte chemotaxis, and antimicrobial killing; and hides in tissue. It spreads to other tissues by entering capillary beds.[127]

Symptoms of the disease occur in three stages.[128] *Localized infection* occurs soon after the bite (3 to 32 days, the incubation period) with erythema migrans (bull's-eye rash) with or without fever, fatigue, malaise, myalgias, and arthralgias. Erythema migrans is a T-cell–mediated response. Within days to weeks after the onset of the illness, there is *disseminated infection* with secondary erythema migrans, usually with arthralgias, meningitis, neuritis, or carditis. *Late persistent infection* (more common in Europe) can continue for years with arthritis, encephalopathy, polyneuropathy, or heart failure. The diagnosis of Lyme disease is based on the clinical presentation and history of tick bite, if known. Serologic tests may be used to confirm the diagnosis.[129] Antibiotics (e.g., doxycycline [not used in children younger than 8 years or in pregnant or breast-feeding women] or amoxicillin) are used for treatment.[130] Reinfection can occur. There is currently not a vaccine for Lyme disease.[131]

Borrelia miyamotoi also is carried by ticks. The first report of infection was in Russia in 2011 and cases have been confirmed in the United States in areas where Lyme disease is endemic. Serum assays confirm diagnosis. Infected individuals have flu-like symptoms and respond to antibiotic therapy (doxycline or amoxicillin).[132]

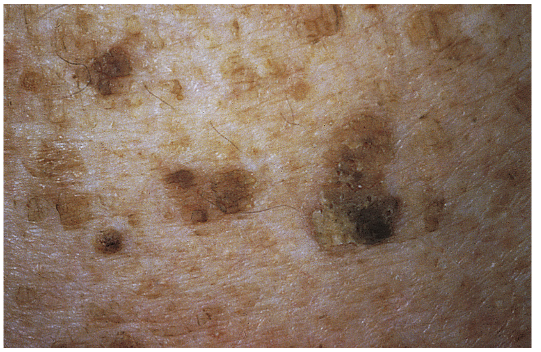

FIGURE 46-24 **Seborrheic Keratosis.** Typical lesion that is broad, flat, and comparatively smooth surfaced. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

FIGURE 46-25 **Keratoacanthoma.** Classic presentation of a fully developed tumor. Round, smooth, dome-shaped mass with a central keratin-filled crater. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Benign Tumors

Most benign tumors of the skin are associated with aging. Benign tumors include seborrheic keratosis, keratoacanthoma, actinic keratosis, and nevi (moles).

Seborrheic Keratosis

Seborrheic keratosis is a benign proliferation of cutaneous basal cells that produces smooth or warty elevated lesions. The pathogenesis is unknown. These tumors are usually seen in older people and occur as multiple lesions on the chest, back, and face. The color varies from tan to waxy yellow, flesh colored, or dark brown-black. Lesion size varies from a few millimeters to several centimeters, and they are often oval and greasy appearing with a hyperkeratotic stuck-on scaly appearance (Figure 46-24). Both cryotherapy with liquid nitrogen and electrocautery are effective treatments, and the lesions usually slough 2 to 3 weeks after treatment.

Keratoacanthoma

A **keratoacanthoma** is a benign self-limiting tumor of squamous cell differentiation arising from hair follicles. It usually occurs on sun-damaged skin of older adults and smokers; the incidence is high in males. The most commonly affected sites are the face, back of the hands, forearms, neck, and legs (Figure 46-25). The lesion develops over a period of 1 to 2 months and

FIGURE 46-26 Actinic Keratosis. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

has a histologic course resembling a well-differentiated squamous cell carcinoma as follows:

Proliferative stage: Lesion develops as a rapidly growing, dome-shaped nodule with a central crust.

Mature stage: Lesion fills with whitish keratin and requires differentiation from squamous cell carcinoma.

Involution stage: Occurs over a 3- to 4-month period with regression of the lesion.

Although the lesions resolve spontaneously, they can be removed by curettage or excision to improve cosmetic appearance and reduce risk of destructive growth or a missed diagnosis of squamous cell carcinoma. Intralesional 5-FU, bleomycin, interferon, or methotrexate also have been effective.[133-135]

Actinic Keratosis

Actinic keratosis is a premalignant lesion composed of aberrant proliferations of epidermal keratinocytes caused by prolonged exposure to UV radiation. The prevalence is highest in individuals with unprotected light-colored skin. Actinic keratosis is rare in black skin. The lesions appear as rough or scaly, poorly defined pink to reddish or reddish brown papules that are felt more than seen (Figure 46-26) and are considered an early in situ squamous cell carcinoma. Surrounding areas may have telangiectasia. Dermoscopy and biopsy aid evaluation. Treatment options include ablative and topical therapies, such as 5-FU and imiquimod. The lesions should continue to be evaluated for progressive squamous cell carcinoma. Protection from the sun with clothing or a sunblock to prevent lesions from developing elsewhere is advised.[136]

Nevi

Nevi (moles) are benign pigmented or nonpigmented lesions (Figure 46-27) that form from melanocytes beginning at ages 3 to 5 years. Melanocytic nevus, formed from melanocytes, may be congenital or acquired. During the early stages of development, the cells accumulate at the junction of the dermis and epidermis and are macular lesions. Over time the cells move deeper into the dermis and the nevi become nodular and symmetric without irregular borders. Nevi may appear on any part of the skin, and vary in size. They occur singly or in groups and are not considered disfiguring. Nevi may undergo transition to malignant melanomas (see p. 1643).[137] Nevi repeatedly traumatized, irritated by clothing, or considered too large can be excised.

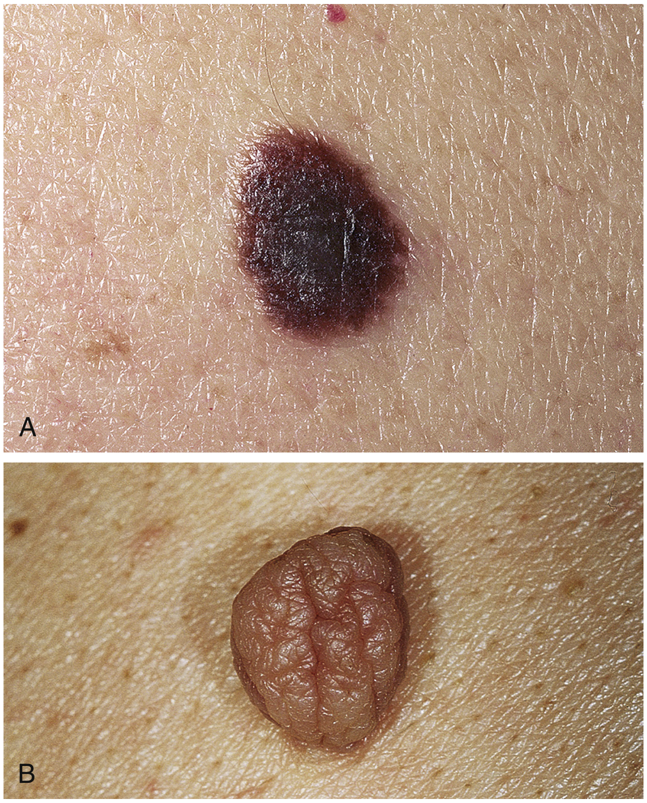

FIGURE 46-27 Nevi. **A,** Junction nevus: slightly raised, dark, and uniform. **B,** Dermal nevus: pedunculated with a soft, flabby, wrinkled surface. (From Habif TP: *Clinical dermatology: a color guide to diagnosis and therapy,* ed 5, Philadelphia, 2010, Mosby.)

Skin Cancer

Basal cell carcinoma and squamous cell carcinoma are the most prevalent forms of cancer. Malignant melanoma is the most serious and the most common cause of death from skin cancer.[138] Important trends related to skin cancer are presented in Box 46-4.

Chronic ultraviolet (UV) radiation causes most skin cancers. Protection from UV radiation from the sun and artificial sources (e.g., tanning beds), particularly during the childhood years, significantly reduces the risk of skin cancer in later years. Areas commonly exposed to the sun's rays—face, neck, and hands—are highly vulnerable for such lesions. Dark-skinned persons and those avoiding sunlight are significantly less likely to develop these malignant tumors. In dark-skinned persons, basal cells contain the pigment melanin, a protective factor against sun exposure.

Basal Cell Carcinoma

Basal cell carcinoma is a surface epithelial tumor of the skin originating from undifferentiated basal or germinative cells. The tumors grow upward and laterally or downward to the

BOX 46-4 IMPORTANT TRENDS FOR SKIN CANCER

Incidence

More than 3.5 million cases per year with likely underreporting because of lack of a non–melanoma skin cancer registry

Greater in women younger than age 40 years; greater in men after age 40 years; 40 times more prevalent in whites than in blacks; increases steadily with age; increasing among young individuals with chronic exposure to artificial UV radiation

Majority of cases are highly curable **basal** or **squamous** cell cancers and the most serious is **malignant melanoma** with an estimated 76,690 new cases in 2013; it represents 4% of all skin cancer cases but causes about 79% of all skin cancer deaths

Mortality

Total estimated deaths in 2013 were 9480 from melanoma and approximately 3170 from other nonepithelial types of skin cancer

Risk Factors

Excessive exposure to ultraviolet radiation from the sun

Exposure to artificial UV radiation, particularly in ages less than 25 years

Fair complexion, blue eyes, blonde hair

Occupational exposure to coal tar, pitch, creosote, arsenic compounds, and radium

Exposure to human papillomavirus and human immunodeficiency virus

Immunosuppression

Family history of skin cancer

Skin cancer is negligible in blacks because of heavy skin pigmentation

Warning Signals

Any change on the skin, especially a change in the size or color of a mole or other darkly pigmented growth or spot

Prevention and Early Detection

Avoidance of artificial UV radiation and sun when ultraviolet light is strongest (e.g., 10 AM to 3 PM); use of protective clothing and sunscreen preparations, especially those containing ingredients such as *para*-aminobenzoic acid (PABA); prevention for all types of skin cancer should begin in childhood

Survival

For basal cell and squamous cell cancers, cure is highly likely with early detection and treatment; malignant melanoma metastasizes quickly, accounting for a lower 5-year survival rate

Data from American Cancer Society: *Cancer facts and figures 2013,* Atlanta, 2013, The Society; Rogers HW et al: *Arch Dermatol* 146(3):283–287, 2010; Wehner MR et al: *BMJ* 345:e5909, 2012.

dermal-epidermal junction. They usually have depressed centers and rolled borders. Early tumors are so small that they are not clinically apparent.

Basal cell carcinoma is the most common type of skin cancer in whites and is thought to be caused by UV radiation exposure. It also is associated with arsenic from groundwater wells[139] and autosomal dominant nevoid basal cell carcinoma syndrome. Basal cell carcinoma arises from mutation in the *TP53* tumor-suppressor gene, leading to loss of keratinocyte repair functions and apoptosis resistance of DNA-damaged cells. Other oncogenic pathways include mutation in the *PTCH1* gene that has tumor-suppressor activity, and alteration in the Sonic Hedgehog signaling pathway genes (codes for a protein important for cell growth and differentiation).[140]

Lesion subtypes include superficial, nodular, and sclerosing/morpheaform, which can be pigmented or nonpigmented (Figure 46-28). Early tumors are so small that they are not clinically apparent. The lesion often begins as a nodule (greater than 5 mm across) that is pearly or ivory in appearance and slightly elevated above the skin surface with small blood vessels on the surface (telangiectasias). The tumors grow upward and laterally or downward to the dermal-epidermal junction. They usually have depressed centers and rolled borders. As the lesion grows, it often ulcerates, develops crusting, and becomes firm to the touch. If left untreated basal cell lesions invade surrounding tissues and, over months or years, can destroy a nose, an eyelid, or an ear. Metastatic spread is rare because these tumors do not invade blood or lymph vessels. Treatment includes complete surgical excision, radiotherapy, curettage, cryotherapy, photodynamic therapy, and topical applications of imiquimod or 5-fluorouracil.[140]

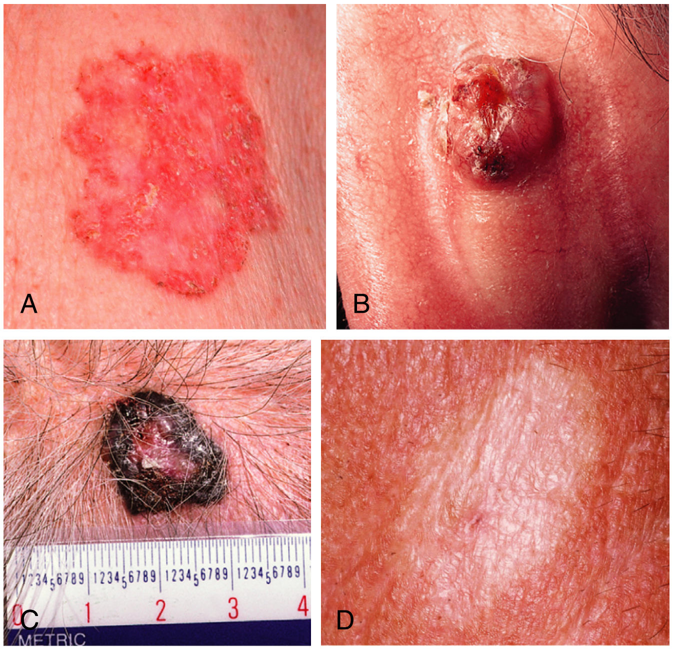

FIGURE 46-28 Types of Basal Cell Carcinoma. **A,** Superficial. **B,** Nodular. **C,** Pigmented. **D,** Morpheaform—recurrent tumor. (**A** and **D** from Bolognia JL, Jorizzo JL, Schaffer JV: *Dermatology,* ed 3, Philadelphia, 2012, Saunders; **B** and **C** from James WD, Berger TG, Elston DM: *Andrews' diseases of the skin: clinical dermatology,* ed 11, Philadelphia, 2011, Saunders.)

Squamous Cell Carcinoma

Squamous cell carcinoma (SCC) is a tumor of the epidermis and the second most common human cancer. Two types are characterized: in situ (Bowen disease [BD]) and invasive. Areas affected are the head and neck (75%) and the hands (15%), with 10% of squamous cell carcinomas occurring elsewhere on the body. These tumors are more predominant in countries where arsenic is found in higher rates in drinking water. UV light exposure from sun and the use of tanning beds are the primary risk factors. Gamma rays and x-rays are also associated

FIGURE 46-29 Squamous Cell Carcinoma. The sun-exposed ear is a common site for squamous cell carcinoma. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

with squamous cell carcinoma. In addition, patients who are immunosuppressed experience a greater occurrence of this carcinoma.

UV exposure causes SCC, particularly mutation of the *TP53* gene and other oncogenic signals.[141] It is unclear how UV light produces alterations in DNA, and DNA repair. Invasive SCC can arise from premalignant lesions of the skin. It rarely arises from normal-appearing skin or de novo. The premalignant lesions include sun-damaged skin or dysplasias (actinic keratosis); leukoplakia, or whitish, discolored areas; scars; radiation-induced keratosis; tar and oil keratosis; and chronic ulcers and sinuses.

In situ SCC is usually confined to the epidermis (intraepidermal) but may extend into the dermis. Common premalignant skin lesions associated with in situ squamous cell carcinomas are actinic (solar) keratosis and BD. Actinic keratosis is a white, scaly, keratotic (horny) lesion on the exposed areas of the body (see Figure 46-26). BD is a dysplasia of the basal layer of the dermis or carcinoma in situ. It often is found on unexposed areas of the body and is demonstrated by flat, reddish, scaly patches. These lesions may enlarge to more than 1 cm in diameter, rarely invading surrounding tissue and very rarely metastasizing. Other cellular components in the skin (e.g., sweat glands, hair follicles) can give rise to SCC but these cancers are relatively uncommon. Invasive SCC grows more rapidly than basal cell carcinomas and can spread to regional lymph nodes with metastasis. These tumors are firm and increase in elevation and diameter. The surface may be granular and bleed easily (Figure 46-29). Treatment includes surgical excision and radiotherapy with consideration of adjuvant chemotherapy for advanced disease.[142] Mohs micrographic surgery (MMS), a tissue-sparing surgical technique, is indicated for non-melanoma skin cancers (NMSCs) with a high risk of recurrence, lesions involving the face, ears, genitalia, or when wider excision may risk functional impairment.[142a]

Cutaneous Melanoma

Cutaneous melanoma is a malignant tumor of the skin originating from melanocytes, or cells that synthesize the pigment melanin. The incidence of melanoma is increasing, and young to middle-age adults are at highest risk. Risk factors implicated in melanoma induction include genetic predisposition, exposure to ultraviolet light (solar and artificial), acquired melanocytic nevi, family history of melanoma, fair hair, light skin with a propensity to sunburn, and the presence of susceptibility genes (e.g., *BRAF* and *RAS* mutations).[143,144] Specific genetic alterations are associated with particular clinical and histopathologic features of the disease.[145]

TABLE 46-9 CLASSIFICATION OF NEVI

NEVI	COMMON CHARACTERISTICS
Junctional nevus	Flat, well circumscribed, vary in size up to 2 cm, dark color, hairs may be present; originate in basal layer of epidermis and can eventually reach the cutaneous surface; rarely develop into a melanoma
Compound nevus	Most common in adolescents; the majority of pigmented lesions are in children; rarely develops into melanoma; usually 1 cm in size; hairs may be present; surface is elevated and smooth
Intradermal nevus	Small (less than 1 cm) with regular edges and bristle-like hairs; color ranges from skin tone to light brown; has a slight likelihood of developing into a melanoma

The relationship between nevi (see Figure 46-27) and melanoma makes it important for the clinician to understand the various neval forms (Table 46-9). Most nevi never become suspicious; however, suspicious nevi should be evaluated and removed. Indications for biopsy include changes in color and size, irregular notched margin, itching, bleeding or oozing, nodularity, scab formation, ulceration, or an unusual pattern of presentation. The ABCDE rule is used as a guide: **A**symmetry, **B**order irregularity, **C**olor variation, **D**iameter larger than 6 mm, and **E**levation, which includes raised appearance or rapid enlargement.[146] Clinical characteristics are summarized in Table 46-10.

Melanomas arise as a result of malignant degeneration of melanocytes located either along the basal layer of the epidermis or in a benign melanocytic nevus. The clinical types of cutaneous melanoma are based on their growth pattern and include lentigo malignant melanoma (LMM) (Figure 46-30), superficial spreading melanoma (SSM) (the most common), primary nodular melanoma (PNM), and acral-lentiginous melanoma. Rare and difficult to diagnose subtypes include desmoplastic melanoma, which resembles a scar, and amelanotic (nonpigmented) melanoma.[147] The pathogenesis of malignant melanoma is complex and a number of proto-oncogenes have been identified.[148]

Surveillance strategies include clinician-based total body skin examination, total body photography, dermoscopy, and individual-based self-skin examination. Detection of volatile biomarkers are in development.[148a] Staging of melanoma is determined using tumor, node, metastasis (TMN) criteria established by the American Joint Committee on Cancer and is summarized in Box 46-5.

Prognostic factors include the thickness of the lesion, mitotic index, immunohistochemical assessment, ulceration and metastasis (e.g., number of lymph nodes or viscera involved).[149]

TABLE 46-10 CLINICAL CHARACTERISTICS OF VARIETIES OF CUTANEOUS MELANOMA

CHARACTERISTIC	DESCRIPTION
Lentigo Malignant Melanoma	
Frequency	4% to 15% of cutaneous melanomas
Age at diagnosis	50 to 80 years old, mean age 65 years
Primary location	Head, neck, dorsum of hands (sun-exposed areas)
Pigmentation according to thickness	
<1.5 mm (levels I and II)	Tan and brown
>1.5 mm (level III)	Tan, brown, and blue-black
>1.5 mm (levels IV and V)	Nodule formation
Superficial Spreading Melanomas	
Frequency	57% to 70% of cutaneous melanomas
Age at diagnosis	20 to 60 years old
Primary location	Legs of females; upper back of both genders
Pigmentation according to thickness	
<1.5 mm (levels I and II)	Tan and brown
>1.5 mm (level III)	Tan, brown, and blue-black
>1.5 mm (levels IV and V)	Nodule formation
Primary Nodular Melanoma	
Frequency	12% to 21% of cutaneous melanomas
Age at diagnosis	20 to 60 years old, mean age 53 years
Primary location	Trunk, head, or neck
Pigmentation according to thickness	
>1.5 mm (level III)	Small nodule (any hue)
>1.5 mm (levels IV and V)	Large nodule (any hue)
Acral-Lentiginous Melanoma	
Frequency	2% to 8% in whites; 30% to 75% in blacks, Hispanics, Asians
Age at diagnosis	20 to 60 years old
Primary location	Palms, soles of feet, mucous membranes
Pigmentation at any thickness	Blue-black irregular macules, papules, or nodules

Data from Bolognia JL, Jorizzo JL, Schaffer JV: *Dermatology,* ed 3, Philadelphia, 2012, Saunders; Greenwald HS, Friedman EB, Osman I: *Melanoma Res* 22(1):1–8, 2012; Habif TP, editor: *Clinical dermatology,* ed 5, St Louis, 2010, Mosby; Scolyer RA, Long GV, Thompson JF: *Mol Oncol* 5(2):124–136, 2011; Situm M, Buljan M: *G Ital Dermatol Venereol* 147(1):21–27, 2012.

BOX 46-5 TNM STAGING CRITERIA FOR MELANOMA

Stage 0: carcinoma in situ (TisN0M0)
Stage I A/B: includes lesions up to 2 mm with no nodal or distant metastases (T1aN0M0, T1bN0M0, T2aN0M0).
Stage II A/B/C: includes larger lesions, greater than 2 mm without positive nodes or distant metastases (T2bN0M0, T3aN0M0, T3bN0M0, T4aN0M0, T4bN0M0).
Stage III: includes lesions of any size with positive lymph nodes (TxN1M0, TxN2M0, TxN3M0).
Stage IV: includes lesions of any size with distant metastases (TxNxM1).

Data from Piris A, Lobo AC, Duncan LM: Melanoma staging: where are we now?, *Dermatol Clin* 30(4):581–592, v, 2012.

FIGURE 46-30 Lentigo Malignant Melanoma. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

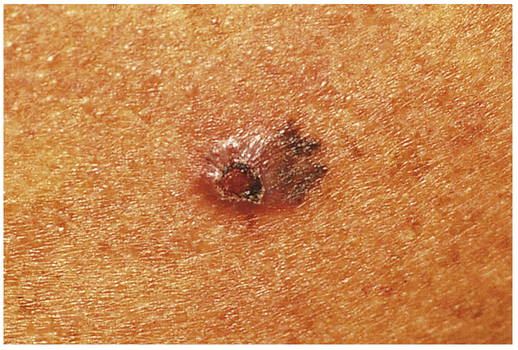

FIGURE 46-31 Nodular Melanoma. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Figure 46-31 illustrates a nodular melanoma. Efforts are in progress to refine the morphologic classifications by adding subgroups that include molecular markers for proto-oncogene mutations and specific signaling pathways.[150] Early recognition of cutaneous melanomas can have a major effect on achieving a surgical cure.

Prevention of melanoma includes avoidance of UV radiation exposure through use of protective clothing and sunscreens, and avoidance of artificial UV radiation exposure. Treatment of melanoma with no evidence of metastatic disease involves surgical excision to the primary site and regional lymph nodes. The extent of surgery is determined by the staging of disease. Lesions of the extremities have the best prognosis; head and neck lesions and trunk lesions have the poorest prognosis. Survival rate for advanced disease is very low. Immunotherapy is advancing. Ipilimumab blocks cytotoxic T-lymphocyte antigen 4 and vemurafenib has prolonged survival with *BRAF*-mutated melanoma, and new drugs are in clinical trials. Improving response and survival rates with novel cellular targets and combination therapies to overcome tumor resistance is an ongoing need.[151,152] Vaccines, biomarkers, and genetically-modified T cells are under investigation.[153,154]

FIGURE 46-32 Kaposi Sarcoma. The purple lesion commonly seen on the skin. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Kaposi Sarcoma

Kaposi sarcoma (KS) is a vascular malignancy associated with different presentations: (1) drug-induced immunosuppressions, for example, after kidney transplantation; (2) an endemic form in equatorial Africa; (3) classic form presenting on the lower legs of older men; (4) epidemic and nonepidemic forms related to acquired immunodeficiency syndrome (AIDS), and (5) iatrogenic.[155]

Kaposi-associated herpesvirus 8 (HHV-8) is found in all forms of KS and may be a common etiology for all types of KS in combination with host immune dysfunction and the local inflammatory state.[155] Immunosuppression allows for opportunistic infections and malignancy. Proliferation of the tumor depends on the presence of platelet-derived and other growth factors.[156]

The endothelial cell is thought to be the progenitor of KS but the specific origin is elusive. The lesions emerge as purplish brown macules and develop into plaques and nodules. They tend to be multifocal rather than spreading by metastasis. The lesions initially appear over the lower extremities in the classic form (Figure 46-32). The rapidly progressive form associated with AIDS tends to spread symmetrically over the upper body, particularly the face and oral mucosa. The lesions are often pruritic and painful. About 75% of individuals with epidemic KS have involvement of lymph nodes, particularly in the gastrointestinal tract and lungs. Organ involvement is much less common in the classic form. The rapidly progressive form has a poor prognosis and shorter survival rates than the classic form. (See Chapter 10 for a further discussion on AIDS.)

Diagnosis is by skin biopsy, with a high index of suspicion for those with immunodeficiency. The disease is incurable. Local lesions can be excised. Multiple disseminated lesions may be treated with a combination of immunomodulatory, cytotoxic, and antiviral drugs. The new, highly active antiretroviral therapy (HAART) for AIDS treatment is decreasing the incidence of KS in resource rich countries, but new treatments are needed.[157]

Primary Cutaneous Lymphomas

Primary cutaneous lymphomas are cutaneous T-cell and B-cell lymphomas that are present in the skin without

FIGURE 46-33 Mycosis Fungoides. **A,** Hypopigmented patches of mycosis fungoides. **B,** Plaques of mycosis fungoides. **C,** Tumors of mycosis fungoides combined with patches. (Courtesy of Ellen Korn, M.D. In James WD, Berger TG, Elston DM: *Andrews' diseases of the skin: clinical dermatology,* ed 11, Philadelphia, 2011, Saunders.)

evidence of extracutaneous disease at the time of diagnosis (see Chapter 29 for classification and general pathophysiology of lymphomas). Cutaneous lymphomas are rare but are the second most common site of extranodal non-Hodgkin lymphoma. The incidence rate is about 14/100,000 and their cause is unknown.[158] Cutaneous lymphomas are more common in men and generally present after age 50 years; 75% of cases are T-cell lymphomas and 25% are B-cell lymphomas. The most common cutaneous T-cell lymphoma is mycosis fungoides (50% of cases), which is more common among blacks. Sézary syndrome (a leukemic variant of T-cell lymphoma) and primary cutaneous CD30-positive lymphoproliferations (less than 10% of cases) are the most aggressive. Cutaneous lymphomas develop from clonal expansion of B cells, T helper cells, and rarely T suppressor cells. **Mycosis fungoides** can present as focal or widespread erythematous patches or plaques, follicular papules, comedone-like lesions, and tumors (Figure 46-33). There may be patches of alopecia. The lesions progress over a period of months or years. Mycosis fungoides lesions are pruritic and cause considerable distress and debilitation.[159] Involvement of other organs can occur in advanced stages of the disease.

The differential diagnosis of the different types of cutaneous lymphomas is based on clinical manifestations, histologic appearance, immunologic and cytogenetic features, and response to appropriate treatment.[160,160a] Lesions also must be distinguished from psoriasis, eczema, generalized dermatitis, and drug reactions. Treatment is based on staging of the disease following consensus-based guidelines that include a range of topical and systemic therapies, such as anti-inflammatory, immunomodulatory, and biologic agents; histone deacetylase inhibitors; rexinoids; and chemotherapeutics.[161,162] Radiotherapy has historically been the most common successful therapy.[163]

Cold Injury

Exposure to extreme cold includes a spectrum of injuries[164]:

1. *Frostnip*—mild and completely reversible injury characterized by skin pallor and numbness
2. *Chilblains*—more serious injury with violaceous skin color with plaques or nodules, pain, and pruritus but without ice crystal formation; a chronic vasculitis can develop and is usually located on the face, anterior lower leg, hands, and feet
3. *Frostbite*—tissues freeze and form ice crystals at temperatures below −2° C (28° F), progressing from distal to proximal; is potentially reversible
4. *Flash freeze*—rapid cooling with intracellular ice crystals associated with contact with cold metals or volatile liquids

Areas most commonly affected are fingers, toes, ears, nose, and cheeks. Initially the body responds with alternating cycles of vasoconstriction and vasodilation—the "hunting reflex." The mechanism of injury is complex but is related to direct cold injury to cells, indirect injury, cell death from extracellular and intracellular ice crystal formation, impaired circulation with anoxia because of thrombosis in the exposed area, and reperfusion injury. With tissue reperfusion there is infiltration of neutrophils and mast cells and these cells and the damaged epithelium release inflammatory mediators (e.g., prostaglandins, thromboxanes, bradykinin, and histamine). Edema can cause capillary compression and vascular stasis. Frozen skin becomes white or yellowish, waxy, and firm to the touch. There is numbness and no sensation of pain.

Skin damage can range from mild to severe. With mild frostbite, redness and discomfort occur during rewarming, followed by a return to normal in a few hours. In more severe cases, cyanosis and mottling develop, followed by redness, swelling, throbbing, and burning pain on rewarming. Within 24 to 48 hours, vesicles and bullae appear and resolve into crusts that eventually slough off, leaving thin, newly formed skin. The most severe cases result in gangrene with loss of the affected part. Frostbite may be classified by depth of injury after rewarming as follows:

First degree: superficial, characterized by a numb central white area surrounded by erythema and edema and including partial skin freezing without blistering

Second degree: full-thickness skin freezing with blistering surrounded by edema and hyperemia

Third degree: deep, characterized by full-thickness skin and subcutaneous freezing with tissue necrosis and hemorrhagic vesicles and blisters

Fourth degree: deep tissue freezing with full-thickness necrosis and gangrene with a line of demarcation.

Immediate treatment of frostbite is to cover affected areas with other body surfaces and warm clothing. The area should not be rubbed or massaged. Local, dry heat should be avoided. Immersion in a warm water bath (40° to 42° C [104° to 107.6° F]) until frozen tissue is thawed is the best treatment. Ibuprofen is used to inhibit prostaglandins, and aloe vera is a topical inhibitor of thromboxane. Thrombolytic therapy reduces the incidence of amputation when administered within 24 hours of injury.[165]

Pain during the thawing period is severe and should be treated with potent analgesics. Gentle cleansing and no pressure on the skin should be maintained during healing. Amputation of necrotic tissue is delayed until a clear line of demarcation is established.[166]

DISORDERS OF THE HAIR

Alopecia

Male-Pattern Alopecia (Androcentric Alopecia)

Alopecia means loss of hair. Localized hair loss in men is not a disease but rather a variation in the androgen receptor *(AR)* gene that clusters in families. The mechanism of inheritance is unknown. Within the distribution of hair over the scalp, androgen-sensitive hair follicles are on top and androgen-insensitive follicles are on the sides and back. In genetically predisposed men, the androgen-sensitive follicles are transformed into vellus follicles. The normal hair is shed and replaced by fine, light, short hair. Male-pattern baldness begins with frontotemporal recession and progresses to loss of hair over the top of the scalp. Minoxidil may be used to stimulate hair growth and finasteride may decrease the effect of androgens on hair follicles. New treatments are being evaluated.[167] Affected men may choose to wear wigs or have hair transplants.

Female-Pattern Alopecia

Women in their twenties and thirties (6% to 12%) and women older than 70 years (55%) experience progressive thinning and loss of hair over the central part of the scalp. Contrary to male-pattern baldness, no loss of hair occurs along the frontal hairline but follicles are smaller and less functional. Many of these women have elevated levels of serum adrenal androgen dehydroepiandrosterone sulfate (DHEAS), and treatment with antiandrogens can be effective. Lower levels of estrogen can also decrease hair growth after menopause. Finasteride, minoxidil, light therapy or combinations of therapy may be used and work best when started early.[168,169] In rare instances a male-pattern baldness develops. Laboratory evaluation of serum androgenic hormones shows elevations, and some women have decreased hair loss when treated with daily doses of spironolactone.

Alopecia Areata

Alopecia areata is an autoimmune T-cell–mediated chronic inflammatory disease directed at hair follicles that results in baldness. Hair loss occurs in multiple areas of the scalp, usually in round patches. The eyebrows, eyelashes, beard, and other areas of the body are rarely involved. The cause is unknown, but stressful events, cell-mediated immune factors, and genetic susceptibility are linked to hair loss.[170] Metabolic disorders, such as Addison disease, thyroid disease, and lupus erythematosus, also are associated with alopecia areata.[171]

The affected areas of skin are smooth or may have short shafts of poorly developed hair that breaks at the surface. Regrowth occurs within 1 to 3 months, but hair loss may recur at the same site. Permanent regrowth of hair usually occurs. Total loss of hair (alopecia totalis) occurs in some young people; the long-term prognosis for total hair regrowth is poor.

Diagnosis is made by observation of the pattern of hair loss. Biopsy may show a lymphocytic infiltrate around the follicle. There are several treatments for alopecia areata including watchful waiting, corticosteroids, minoxidil, and topical immunotherapy.[172]

Hirsutism

Hirsutism is the abnormal growth and distribution of hair on the face, body, and pubic area in a male pattern that occurs in women. There is also frontotemporal hair recession. These areas of hair growth are androgen sensitive. Variations of hair growth in women are great, and a male pattern can be normal. Women who develop hirsutism may be secreting hormones associated with ovarian or adrenal disease, and such women should be evaluated for polycystic ovaries, adrenal hyperplasia, or adrenal tumors.[173] If no hormonal pathologic conditions exist, undesirable hair can be mechanically removed. Endocrine therapy to suppress androgens may be considered.[174]

DISORDERS OF THE NAIL

Paronychia

Paronychia is an acute or chronic infection of the cuticle.[175] Acute paronychia is manifested by the rapid onset of painful inflammation of the cuticle, usually after minor trauma. An abscess may develop, requiring incision and drainage (I&D) for relief of pain. The most common causative microorganisms are *Staphylococci, Streptococci,* and occasionally *Candida*.

Chronic paronychia develops slowly, with tenderness and swelling around the proximal or lateral nail folds. One or more fingers or toes may be involved. Individuals whose hands are frequently exposed to moisture are at greatest risk. Manipulation or chronic wetting of the cuticle increases risk because it disrupts the natural protective barrier provided by the cuticle, leaving a moist, warm medium for pathogenic microorganisms to incubate. The skin around the nail becomes more edematous and painful with progressive infection. Pus may be expressed from the proximal nail fold. The nail plate is usually not affected, although it can become discolored and develop ridges with chronic infections.

Treatment includes keeping the hands dry. Abscesses are treated with incision and drainage; severe bacterial cases may require systemic antibiotics. Oral antifungals are not very effective because they do not penetrate the affected tissues but efficacy is increased with topical application of steroid creams.[175]

Onychomycosis

Onychomycosis is a fungal or dermatophyte infection of the nail plate that occurs in 2% to 18% of the population.[176] The most common pattern is a nail plate that turns yellow or white (infection develops from the dorsal surface) and becomes elevated as a result of the accumulation of hyperkeratotic debris within the plate. Fungal infections of the nail may require culture and microscopy. Treatment includes débridement and systemic antifungal therapy. Surgical excision of the nail may be required. New systemic and topical antifungals are being investigated.[177]

SUMMARY REVIEW

Structure and Function of the Skin

1. The skin is the largest organ of the body and equals about 20% of body weight.
2. The skin has three layers: the dermis, epidermis, and subcutaneous layer.
3. Keratinocytes produce keratin to form the superficial layer of the epidermis. The underlying epidermis contains a basal and a spinous layer with melanocytes, Langerhans cells, and Merkel cells.
4. The dermis is composed of connective tissue elements, hair follicles, sweat glands, sebaceous glands, blood vessels, nerves, and lymphatic vessels.
5. The subcutaneous layer contains fat cells and connective tissue.
6. The dermal appendages include the nails, hair, sebaceous glands, and the eccrine and apocrine sweat glands.
7. The papillary capillaries provide the major blood supply to the skin, arising from deeper arterial plexuses. The sympathetic nervous system regulates skin blood flow.
8. Heat loss and heat conservation are regulated by arteriovenous anastomoses that lead to the papillary capillaries.
9. Older skin is thinner and drier with less collagen; it has fewer capillary loops and fewer changes in pigmentation.
10. Loss of melanocytes and hair follicles leads to gray and thinner hair.
11. The skin of older adults is more permeable; there is decreased sweating and loss of thermal regulation and decreased protective functions.
12. Pressure ulcers develop from continuous pressure and shearing forces that occlude capillary blood flow with resulting ischemia and necrosis. Areas at greatest risk are pressure points over bony prominences, such as the greater trochanter, sacrum, ischia, and heels. Immobilized individuals with fractures and neurologic deficits are most likely to develop pressure ulcers.
13. Keloids are scars that extend beyond the border of injury and result from abnormal fibroblast activity and excess collagen formation. Hypertrophic scars are elevated erythematous fibrous lesions that do not expand beyond the border of injury.
14. Pruritus (itching) is associated with many skin disorders. Itch mediators, peripheral polymodal C nerve fibers, and central processes contribute to itching. Scratching can cause skin trauma, infection, and scarring.

Disorders of the Skin

1. Allergic contact dermatitis is a form of delayed hypersensitivity that develops with sensitization to allergens, such as metals, chemicals, or poison ivy.

SUMMARY REVIEW—cont'd

2. Irritant contact dermatitis develops as an inflammatory response to prolonged exposure to chemicals, such as acids or soaps.
3. Atopic or allergic dermatitis is associated with a family history of allergies, hay fever, elevated IgE levels, and increased histamine sensitivity; it is more common in children.
4. Stasis dermatitis occurs on the legs and results from venous stasis and edema.
5. Seborrheic dermatitis involves scaly, yellowish, inflammatory plaques of the scalp, eyebrows, eyelids, ear canals, chest, axillae, and back. The cause is unknown.
6. Papulosquamous disorders are characterized by papules, scales, plaques, and erythema.
7. Psoriasis is a chronic autoimmune T-cell–mediated inflammatory skin disease with thickening of the epidermis and dermis characterized by scaly, erythematous pruritic plaques. The forms of psoriasis are plaque, inverse, guttate, pustular, and erythrodermic. Systemic complications can accompany the disease including arthritis and cardiovascular disease.
8. Pityriasis rosea is a self-limiting disease characterized by oval lesions with scales around the edges located along skin lines of the trunk.
9. Lichen planus is a papular violet-colored autoimmune inflammatory lesion involving T cells and inflammatory cytokines manifested by severe pruritus and can involve both skin and mucous membrane lesions.
10. Acne vulgaris is a facial inflammation of the pilosebaceous follicles with hypertrophy of sebaceous glands and telangiectasia, particularly of the nose.
11. Acne rosacea develops on the middle third of the face with hypertrophy and inflammation of the sebaceous glands that may be the result of infection or immune-mediated inflammation.
12. Lupus erythematosus is an inflammatory autoimmune disease that can affect only the skin (discoid) or have a systemic presentation. The inflammatory lesions usually occur in sun-exposed areas with a butterfly distribution over the nose and cheeks.
13. Pemphigus is a chronic, autoimmune, blistering disease that begins in the mouth or on the scalp and spreads to other parts of the body, often with a fatal outcome. The forms of pemphigus include pemphigus vulgaris (most common), pemphigus foliaceus, paraneoplastic pemphigus, and IgA pemphigus.
14. Bullous pemphigoid is a benign autoimmune blistering disease that resolves rapidly.
15. Erythema multiforme is an acute inflammation of the skin and mucous membranes with lesions that appear target-like with alternating rings of edema and inflammation; it is often associated with allergic reactions to drugs.
16. Folliculitis is a bacterial infection of the hair follicle.
17. A furuncle is an infection of the hair follicle that extends to the surrounding tissue.
18. A carbuncle is a collection of infected hair follicles that forms a draining abscess.
19. Cellulitis is a diffuse infection of the dermis and subcutaneous tissue.
20. Erysipelas is a superficial streptococcal infection of the skin commonly affecting the face, ears, and lower legs.
21. Impetigo may have a bullous or an ulcerative form and is caused by *Staphylococcus* or *Streptococcus* and is more common in children.
22. HSV-1 causes cold sores but can infect the cornea, mouth, and labia. HSV-2 causes genital lesions and is usually spread by sexual contact.
23. Herpes zoster and varicella (chickenpox) are both caused by the same herpesvirus, with herpes zoster manifesting years after the initial infection.
24. Warts (verrucae) are benign, rough, elevated lesions caused by papillomavirus. Venereal warts (condylomata acuminata) are spread by sexual contact.
25. Tinea skin infections (fungal infections) can occur anywhere on the body and are classified by location (i.e., tinea pedis, tinea corporis, tinea capitis).
26. Candidiasis is a yeastlike fungal infection caused by *C. albicans* occurring on skin, on mucous membranes, and in the gastrointestinal tract.
27. Cutaneous vasculitis is an immune-mediated inflammation of skin blood vessels with purpura, ischemia, and necrosis resulting from vessel necrosis.
28. Urticarial lesions are associated with type I hypersensitivity responses and appear as wheals, welts, or hives.
29. Localized scleroderma is an immune-mediated sclerosis of the skin that also may affect muscle, bone, and other body organs.
30. Ticks cause a local reaction on the skin of humans and can cause systemic disease when mouthparts pierce the skin and remain embedded in the tissue.
31. Lyme disease is a multisystem inflammatory disease caused by *B. burgdorferi* transmitted by tick bites. Complications may persist for years.
32. Seborrheic keratosis is a proliferation of squamous cells that produce elevated, smooth, or warty lesions of varying size usually in sun-damaged skin. They are most common among older adults.
33. Keratoacanthoma arises from hair follicles on sun-exposed areas. There are three stages of development that result in a dome-shaped, crusty lesion filled with keratin that resolves in 3 to 4 months.
34. Actinic keratosis is a pigmented scaly lesion that develops in sun-exposed individuals with fair skin. The lesion may become malignant in the form of squamous cell carcinoma.
35. Nevi arise from melanocytes and may be pigmented or fleshy pink. They occur singly or in groups and may undergo transition to malignant melanoma.
36. Basal cell carcinoma is the most common skin cancer and occurs most often on sun-exposed areas.

SUMMARY REVIEW—cont'd

37. Squamous cell carcinoma is a tumor of the epidermis associated with sun exposure and can be localized (in situ) or invasive.
38. Cutaneous melanoma arises from melanocytes; if it is not excised early, metastasis occurs through the lymph nodes.
39. KS is a vascular malignancy associated with immunodeficiency states and is associated with herpesvirus 8.
40. Cutaneous lymphomas are cutaneous T-cell and B-cell lymphomas that are present in the skin without evidence of extracutaneous disease at the time of diagnosis.
41. Frostbite usually occurs on cheeks and digits, causing direct injury to cells and impaired circulation.

Disorders of the Hair

1. Male-pattern alopecia is an inherited form of irreversible baldness with hair loss in the central scalp and recession of the temporofrontal hairline.
2. Female-pattern alopecia is a thinning of the central hair of the scalp beginning in women at 20 to 30 years of age.
3. Alopecia areata is patchy loss of hair associated with an autoimmune process and triggered by stress or metabolic diseases; it is usually reversible.
4. Hirsutism is a male pattern of hair growth in women that may be normal or the result of excessive secretion of androgenic hormones.

Disorders of the Nail

1. Paronychia is an inflammation of the cuticle that can be acute or chronic and is usually caused by staphylococci or streptococci.
2. Onychomycosis is a fungal infection of the nail plate.

- Review Questions and Answers

CHAPTER OUTLINE

Children often develop alterations in the skin that may be minor or severe and localized or generalized. Skin diseases in children may have a different causative mechanism of expression than those found in adults, although there may be similarities. Diagnosis is commonly made from the history, appearance, and distribution of the lesion or lesions. Common skin diseases of childhood are presented here.

ACNE VULGARIS

Acne vulgaris is the most common skin disease and affects 85% of the population between the ages of 12 and 25 years. Onset is occurring at a younger age and may be associated with earlier onset of puberty in the United States. Genetic influences may determine an individual's susceptibility and severity of disease. Severe acne tends to have a genetic predisposition.[1] The incidence of acne is the same in both genders, although severe disease affects males more often.

Acne develops at distinctive pilosebaceous units, known as *sebaceous follicles*. Located primarily on the face and upper parts of the chest and back, these follicles have many large sebaceous glands, a small vellus hair (very short, nonpigmented, and very thin hair), and a dilated follicular canal that is visible as a pore on the skin surface. Acne lesions may be inflammatory (pustules, papules, nodules) or noninflammatory. In **noninflammatory acne** the comedones are open (blackheads) and closed (whiteheads), with the accumulated material causing distention of the follicle and thinning of follicular canal walls. **Inflammatory acne** develops in closed comedones when the follicular wall ruptures, expelling sebum into the surrounding dermis and initiating inflammation. Pustules form when the inflammation is close to the surface; papules and cystic nodules can develop

FIGURE 47-1 Cystic Acne. Multiple pustules (erythematous papules and pustules) are present, and several have become confluent. Note areas of scarring. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

when the inflammation is deeper, causing mild to severe scarring (Figure 47-1). Many types of lesions may exist in the same individual.

The exact cause of acne is unknown and various pathophysiologic factors contribute to the development of acne. The principal factors are follicular hyperkeratinization, excessive sebum production, follicular proliferation of *Propionibacterium acnes,* and inflammation and rupture of a follicle from accumulated debris and bacteria within the follicle. Androgens (dihydrotestosterone and testosterone) synthesized in increasing amounts during puberty boost the size and productivity of the sebaceous glands and promote *P. acnes*. Acne also is associated with polycystic ovarian syndrome, congenital adrenal hyperplasia, and various endocrine tumors as a result of higher circulating levels of androgens. The *P. acnes* anaerobic bacteria produce extracellular porphyrins and proinflammatory molecules, including chemotactic factors and lipolytic and proteolytic enzymes. The hydrolytic action of the enzymes converts triglycerides into free fatty acids that stimulate inflammation and edema and result in breakdown of the follicle wall. Chemotactic substances also may be released that involve mediation of inflammation by attraction of polymorphonuclear leukocytes.[2]

Treatment of acne should address the causative factors and be individualized according to severity. The combination of a topical retinoid, benzoyl peroxide, and antimicrobial agents is preferred. Retinoids are anticomedogenic and comedolytic and have some anti-inflammatory effects. Benzoyl peroxide is antimicrobial with some keratolytic effects. Topical antibiotics (e.g., erythromycin and clindamycin) have anti-inflammatory and antimicrobial effects. Combined oral contraceptives may be effective for acne in women.[3] Use of systemic therapies, including oral antibiotics, corticosteroids, and isotretinoin, is encouraged in more severe cases but may be limited by side effects. Dietary based guidelines need further investigation.[4] Acne surgery, including comedo extraction, intralesional steroids, and cryosurgery, may be useful in selected individuals. Severe scarring may be treated with dermabrasion, lasers, and resurfacing techniques. Special consideration must be given to treatment for those with darker skin because they have greater risk for hyperpigmentation and keloidal scarring.[5] Psychosocial morbidity is significant, particularly in adolescents.[5-7]

Acne conglobata is a highly inflammatory form of severe acne with communicating cysts and abscesses beneath the skin that can cause scarring. Remissions tend to occur during the summer, perhaps from more exposure to sunlight. This type of acne requires the use of systemic and combination therapies to prevent drug resistance.

DERMATITIS

Atopic Dermatitis

Atopic dermatitis (AD), also known as atopic eczema, occurs with a prevalence rate up to 20% in children. AD is increasing throughout the world.[8] Onset is usually from 2 to 6 months of age, and 85% of cases occur within the first 5 years of life; 75% to 80% of individuals with AD have a personal or family history of asthma, allergic rhinitis (hay fever), or food allergy. The cause of this chronic relapsing form of pruritic eczema involves an interplay of genetic predisposition, altered skin barrier function associated with filaggrin gene missense mutations (proteins that bind keratin in the epidermis), reduced ceramide (a stratum corneum lipid) levels, altered innate immunity, and altered immune responses to allergens, irritants, and microbes.[9]

There is debate as to whether the pathophysiology favors an "inside-out" explanation with immunologic dysregulation leading to epidermal barrier abnormality or an "outside-in" explanation with primary barrier dysfunction as the cause of the immunologic perturbations.[10] Regardless of the debate, both are involved in the disease. Positive skin tests to a variety of common food and inhalant allergens are seen in approximately 80% of individuals. Children with atopic dermatitis are more likely to have asthma.[11]

In AD, memory T cells in the blood express cutaneous lymphocyte antigen (CLA), which leads to the homing of lymphocytes to the skin. Inflammation is associated with activation of Th2 and Th1 cells with release of numerous cytokines, chemokines, interferon-gamma (IFN-γ), and granulocyte-macrophage colony-stimulating factor (GM-CSF). Activation of mast cells, eosinophils, and macrophages and expression of IgE contribute to the inflammation.[12]

Alterations in filaggrin protein lead to a defect of the epidermal barrier that causes transepidermal water loss and allows easy penetration of pathogens and allergens through the skin and a systemic hyperactive immune response. Filaggrin gene mutations also are associated with increased risk for asthma in AD and ichthyosis vulgaris (dry, scaly skin). In AD keratinocytes are deficient in their ability to express Toll-like antimicrobial peptides (see Chapter 7), and may predispose such individuals to skin colonization and infection with *Staphylococcus aureus,* viruses, and fungi.[13]

AD has a long-term course with frequent exacerbations, severe pruritus, and characteristic eczematoid appearance with redness, edema, and scaling (Figure 47-2). The skin becomes increasingly dry, sensitive, itchy, and easily irritated because the barrier function is impaired. Microscopic epidermal cracks that allow water to be expelled and irritants, allergens, and microbes

FIGURE 47-2 **Atopic Dermatitis.** Characteristic lesions with crusting from irritation and scratching over knees and around ankles. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

to enter further inflammation, drying, and cracking. Itching is the hallmark of atopic dermatitis, and rubbing and scratching to relieve the itch are responsible for many of the clinical skin changes of AD. Histamine level is elevated in AD lesions but is not considered a major pruritogen because blockage of H1 and H2 receptors alone is ineffective at relieving itch. However, H4 receptor blockers are being evaluated.[14] Pruritus is a complex process with immune and neurologic pathways.[15,16]

In infants, the rash appears primarily on the face, scalp, trunk, and extensor surfaces of the arms and legs. In older children and adults, the rash tends to be found on the neck, antecubital and popliteal fossae, and hands and feet. Lichenification (thickening of the epidermis from constant scratching) is more common in adults with chronic eczema. Individuals with AD tend to develop viral, bacterial, and fungal skin infections in the areas with eczema. The irritation and itching interfere with sleep and cause irritability.

There are no specific laboratory features of AD that can be used for diagnostic purposes, and diagnosis is based on clinical history and presentation of symptoms. Management of AD requires a systematic, multidimensional, individualized approach that considers the individual's skin reaction pattern and acuity of the rash.[17] Treatment guidelines establish the foundation of AD management, addressing the skin barrier defect with regular use of emollients and skin hydration along with the identification and avoidance of specific and nonspecific trigger factors. Various topical agents are mainstays of treatment. Topical corticosteroids and calcineurin inhibitors continue to dominate therapy and, to date, their safety record seems good (despite the Black Box warning issued in the United States). In severe cases that cannot be controlled, guidelines suggest systemic treatment options including systemic corticosteroids, cyclosporine A, ultraviolet light therapy, and wet wrap therapy being added to the topical treatment regimen. Systemic corticosteroids are known to be effective in short-term treatment of AD, but evidence is limited to support their use because of long-term side effects and rebound flaring.[18-20] Research is in progress to develop targeted molecular therapy that is safe and cost-effective.

Diaper Dermatitis

Diaper dermatitis is a form of irritant contact dermatitis initiated by a combination of factors that include prolonged exposure to and irritation by urine and feces, maceration by wet diapers, complications from use of airtight plastic diaper covers, and possibly increased association with intercurrent illnesses and early introduction of cereals. Disposable diaper designs have decreased diaper dermatitis in infants.[21] Diaper dermatitis is frequently secondarily infected with *Candida albicans.*

The lesions vary from mild erythema to erythematous papular lesions. Candidal (monilial) diaper dermatitis is usually very erythematous, with sharp margination and pustulovesicular satellite lesions (Figure 47-3).

Treatment includes changing the diaper frequently to keep the area clean and dry or frequently exposing the perineal area to air, using super-absorbent diapers, and applying topical protection with a product containing petrolatum or zinc oxide, or both. Topical antifungal medication is used to treat *C. albicans* when present.[22]

FIGURE 47-4 Impetigo. Multiple crusted and oozing lesions of impetigo. (From Kliegman RM et al: *Nelson textbook of pediatrics,* ed 19, Philadelphia, 2011, Saunders.)

INFECTIONS OF THE SKIN

Infectious diseases caused by bacteria, viruses, and fungi constitute the major forms of skin disease. Breaks in the skin integrity, particularly those that inoculate pathogens into the dermis and epidermis, may cause or exacerbate infections. Most infections tend to occur superficially; however, systemic signs and symptoms do develop occasionally and can be life threatening in immunosuppressed children.

Bacterial Infections

Impetigo Contagiosum

Impetigo is a common bacterial skin infection in infants and children. The mode of transmission is by both direct and indirect contact. The disease is more common in midsummer to late summer, with a higher incidence in hot, humid climates. Impetigo is particularly infectious among people living in crowded conditions with poor sanitary facilities or in settings such as daycare facilities. It affects children in good health, but conditions such as anemia and malnutrition are predisposing factors. There are two common types of impetigo: nonbullous and bullous. Both start as vesicles with a very thin vesicular roof composed of stratum corneum.

Nonbullous impetigo is a contagious, acute, superficial, vesiculopustular form of impetigo caused by *Staphylococcus aureus* or group A *Streptococcus pyogenes* (alone or in combination with *S. aureus*). The microorganisms are disseminated by direct physical contact from other infected individuals or through insect bites. The lesions begin as small vesicles with a honey-colored serum. Yellow to white-brown crusts form as the vesicles rupture (Figure 47-4). The lesions must be differentiated from herpes simplex lesions (see Figure 46-17, p. 1636). Untreated lesions may last for weeks and extend to cover a large area. In contrast to bullous impetigo, regional lymphadenitis is common.

Bullous impetigo is a rarer variant of impetigo caused by *S. aureus.*[23] The pathogen is often carried in the anterior nares, perineal region, or fingernails and is transmitted by contact with the individual or contaminated equipment.[24] The staphylococci produce bacterial toxins called *exfoliative toxins (ETs)* that cause a disruption in desmosomal adhesion molecules with blister formation.[25] The blisters enlarge or coalesce to form superficial bullae. There may be a few localized lesions or many lesions scattered over the skin. As the bullae rupture, a thin, flat, honey-colored crust appears.

The crust is the hallmark of impetigo. A moist, inflamed serum-weeping base is revealed when the crust is removed. The lesions are often located on the face around the nose and mouth, but the hands and other exposed areas are also involved. Regional lymphadenitis is uncommon. Treatment of choice for both types of impetigo is topical mupirocin and topical fusidic acid or oral antibiotics. Antibiotic therapy should be determined by bacterial culture and drug sensitivity because the prevalence of community-acquired methicillin-resistant *S. aureus*–associated impetigo is increasing. For extensive or complicated impetigo, systemic antibiotics may be warranted but beta-lactam antibiotics should be avoided if methicillin-resistant *S. aureus* (MRSA) is suspected.[23,26] Prompt treatment avoids complications, such as glomerulonephritis, necrotizing fasciitis, and septic shock syndrome. Handwashing and isolation of the infected child's washcloth, towels, drinking glass, and linen are important practices to control this highly contagious disease.

Staphylococcal Scalded-Skin Syndrome

Staphylococcal scalded-skin syndrome (SSSS) is the most serious staphylococcal infection that affects the skin and usually is seen in infants and children younger than 5 years.[27] SSSS is caused by virulent group II staphylococci, which produce an exfoliative toxin that attacks desmoglein and adhesion molecules and causes a separation of the skin just below the granular layer of the epidermis.[28] The toxins are usually produced at body sites other than the skin and arrive at the epidermis through the circulatory system. Staphylococci typically are not found in the skin lesions themselves. Adults have circulating antistaphylococcal antibodies and are better able to metabolize and excrete the toxin. Newborns and premature infants are at the highest risk because of immature immunity (absence of prior exposure to the toxin).

The clinical symptoms begin with fever, malaise, rhinorrhea, and irritability followed by generalized erythema with exquisite tenderness of the skin. There may be an associated impetigo, but the infection often begins in the throat or chest. The erythema spreads from the face and trunk to cover the entire body except the palms, soles, and mucous membranes. Within 48 hours, blisters and bullae may develop, giving the child the appearance of being scalded (Figure 47-5). The pain is severe. Fluid loss from ruptured blisters and water evaporation from denuded areas may cause dehydration and loss of body heat. Perioral and nasolabial crusting and fissures develop. In severe cases the skin of the entire body may slough. When secondary infection can be prevented, healing of the involved skin occurs in 10 to 14 days, usually without scarring.

Before medical intervention is begun, culture, histology, or exfoliative cytology must be done to differentiate SSSS from toxic epidermal necrolysis (TEN) (see p. 1664). When the infection is confirmed, treatment with oral or intravenous antibiotics is begun. Topical antibiotics are ineffective. The skin should be treated the same as that with a severe burn—with meticulous aseptic technique. Skin substitutes may be used for adjuvant

FIGURE 47-5 Staphylococcal Scalded-Skin Syndrome (SSSS). The skin lesions, showing desquamation and wrinkling of the skin margins, appeared 1 day after drainage of a staphylococcal abscess. (From Habif TP: *Clinical dermatology: a color guide to diagnosis and therapy*, ed 5, St Louis, 2010, Mosby.)

therapy.[29] Special care is required in serious cases and when the lips and eyelids are involved.[27]

Fungal Infections

Fungal disorders are known as *mycoses* and, when caused by dermatophytes (fungi that thrive on keratin), the mycoses are termed *tinea* (dermatophytosis or ringworm). The different types of tinea are classified according to their location on the body. **Tinea pedis** (a chronic, superficial fungal infection of the skin of the foot) occurs in children but is rare. Scaling disorders of the toes and feet in prepubertal children are usually eczema. Tinea capitis (infection of the scalp) and tinea corporis (infection of the body) are much more common in children than in adults. Dermatophytes of the genus *Epidermophyton* are the major cause of superficial fungal infections in children.[30] These dermatophytes invade the stratum corneum and not the remainder of the epidermis or dermis. The inflammatory response is thought, in part, to be secondary to the toxins released by the dermatophyte. It is important to confirm by culture the exact microorganism that is causing the fungal infection before commencing therapy.

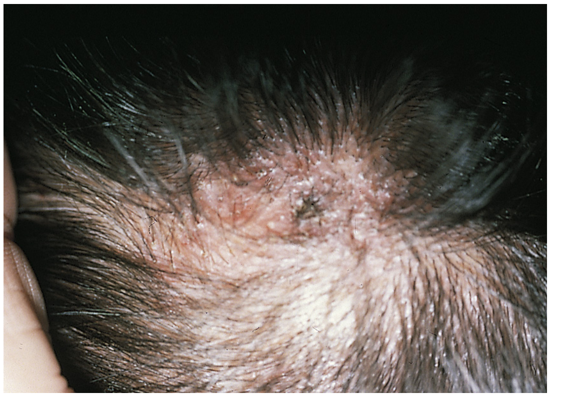

FIGURE 47-6 Tinea Capitis. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Tinea Capitis

Tinea capitis, a fungal infection of the scalp, is the most common fungal infection of childhood. It rarely affects infants and is seen in children younger than age 12. Primary microorganisms responsible for the disease are *Trichophyton tonsurans and Microsporum canis. T. tonsurans* is transmitted by human-to-human contact. Areas of crowding are the most prevalent environments for this microorganism, which frequently affects inner-city children. *T. tonsurans* is often the predominant dermatophyte found in North America; many of these infections are not symptomatic.[31] The prevalence of asymptomatic carriers among household contacts of a child with active *T. tonsurans* disease is high. *M. canis* is found on cats, dogs, and certain rodents. Humans appear to be a terminal host for *M. canis,* and children who handle such animals are possible hosts. Human-to-human transmission does not occur with *M. canis.*

When symptoms are present, the clinical presentations vary, depending on the microorganism. Often the lesions are circular and manifest by broken hairs 1 to 3 mm above the scalp, leaving a partial alopecia 1 to 5 cm in diameter[32] (Figure 47-6). Slight erythema and scaling with raised borders can be observed.

Diagnosis is best confirmed by performing Wood light examination, potassium hydroxide (KOH) examination, and fungal culture, in that order. *T. tonsurans* does not fluoresce with Wood light examination. Oral griseofulvin is the treatment of choice because topical fungicides do not penetrate to the hair bulb. Terbinafine, itraconazole, and fluconazole are effective alternatives.[31] Adjunct therapy includes 2% ketoconazole and 1% selenium sulfide shampoos. Treatment of household contacts with a sporicidal shampoo should be considered and co-sleeping and comb-sharing must be discouraged.

Tinea Corporis

Tinea corporis (ringworm) is a common superficial dermatophyte infection in children. The microorganisms most commonly responsible for this disease are *M. canis* and *Trichophyton mentagrophytes.* As in tinea capitis, contact with kittens and puppies is a common source of the disorder. Tinea corporis preferentially affects the nonhairy parts of the face, trunk, and limbs. Lesions are often erythematous, round or oval scaling patches that spread peripherally with clearing in the center,

creating the ring appearance, which is why this disease is commonly referred to as *ringworm.* The lesions are distributed asymmetrically, and multiple lesions (when present) overlap. Transmission occurs by direct contact with an infected lesion and through indirect contact with personal items used by the infected person. Potassium hydroxide examination of the scale from the border of the lesions confirms the diagnosis for most lesions. Most lesions respond well to applications of appropriate topical antifungal medications.[30]

Thrush

Thrush is the term used to describe the presence of *Candida albicans* in the mucous membranes of the mouth of infants and less commonly in adults, and both may be immune compromised. *C. albicans* penetrates the epidermal barrier more easily than other microorganisms because of its keratolytic proteases and other enzymes. *C. albicans* attracts neutrophils to skin sites of invasion but evades neutrophil killing.[33] Thrush is characterized by the formation of white plaques or spots in the mouth that lead to shallow ulcers. The tongue may have a dense, white covering. The underlying mucous membrane is red and tender and may bleed when the plaques are removed. The disease is often accompanied by fever and gastrointestinal irritation. The infection commonly spreads to the groin, buttocks, and other parts of the body. Treatment may be difficult and may include oral antifungal washes, such as nystatin oral suspension. Gentian violet can also be effective but is messy.[34] Simultaneous treatment of a *Candida* nipple infection or vaginitis in the mother is helpful in reducing the *C. albicans* surface colonization of the infant. Feeding bottles and nipples should be sterilized to prevent reinfection. The diaper area should be kept clean and dry.

Viral Infections

Viral infections of the skin in children are caused by poxvirus, papovavirus, and herpesvirus. The most common infections are described here.

Molluscum Contagiosum

Molluscum contagiosum is a common highly contagious poxvirus infection of the skin and occasionally conjunctiva that affects school-aged children and sexually active young adults. The disease can be more severe or prolonged in individuals with atopic dermatitis and a variety of immunodeficient states, including acquired immunodeficiency syndrome (AIDS). It is transmitted by skin-to-skin contact (e.g., contact sports), autoinoculation, and fomites, such as clothing, wash devices, and towels. The poxvirus induces epidermal cell proliferation and blocks immune responses that would control the virus. The epidermis grows down into the dermis to form saccules containing clusters of virus. The characteristic molluscum body is composed of mature, immature, and incomplete viruses and cellular debris.[35]

The lesions of molluscum are discrete, slightly umbilicated, dome-shaped papules 1 to 5 mm in diameter that appear anywhere on the skin or conjunctiva. The skin distribution in children is mainly on the trunk, face, and extremities (Figure 47-7). The pubic, genital, and perineal areas are favored in adults. Usually no inflammation surrounds molluscum lesions unless they are traumatized or secondary infection occurs. Scarring may occur with healing.

The best three diagnostic procedures are: (1) staining smears of the expressed molluscum body, (2) examining a biopsy, and (3) inoculating a molluscum suspension into cell cultures to demonstrate the cytotoxic reactions. Most lesions are self-limiting and clear in 6 to 9 months if not manipulated. However, because children often do manipulate these lesions, spontaneous involution may take 2 to 4 years without therapy.

Treatment options include immunomodulatory and antiviral therapy and destructive procedures (cryotherapy, curettage, or laser ablation); however, no treatment is universally effective. Treatment is recommended for genital molluscum to prevent sexual transmission and autoinoculation.[36] Destructive therapy is poorly tolerated by children. Measures to prevent spread of infection must be taken and recurrences are common.

Rubella (German or 3-Day Measles)

Rubella is a common communicable disease of children and young adults caused by a ribonucleic acid (RNA) virus that enters the bloodstream through the respiratory route. This disease is mild in most children. The incubation period ranges from 14 to 21 days. Prodromal symptoms are few but may include enlarged cervical and postauricular lymph nodes, low-grade fever, headache, sore throat, runny nose, and cough. A faint-pink to red, coalescing maculopapular rash develops on the face, with spread to the trunk and extremities, sparing the palms of the hands and soles of the feet, 1 to 4 days after the onset of initial symptoms (Figure 47-8). The rash is thought to be the result of virus dissemination to the skin. The rash subsides after 2 to 3 days, usually without complications. Children are generally not contagious after development of the rash. There is lifelong immunity to rubella—as there is for measles, chickenpox, and roseola—after contracting the disease. Differential presentations of viral diseases producing rashes are given in Table 47-1.

FIGURE 47-7 **Molluscum Contagiosum.** Waxy pink globules with umbilicated centers. (From Habif TP: *Clinical dermatology: a color guide to diagnosis and therapy,* ed 5, St Louis, 2010, Mosby.)

Vaccination for rubella is usually combined with vaccines for mumps and measles (rubeola) (MMR). Vaccine recommendations are presented in Chapter 10. Measles are known to occur in previously immunized children.[37] Rubella has almost been eliminated in the United States because of vaccination campaigns. However, challenges to maintain elimination include large outbreaks of measles in highly traveled developed countries, frequent international travel, and clusters of U.S. residents who remain unvaccinated because of personal belief exemptions.[38]

FIGURE 47-8 **Rubella (Measles).** Maculopapular rash with tendency to coalesce. The rash is similar to rubeola (red measles) but less intense. (From Marx JA et al: *Rosen's emergency medicine: concepts and clinical practice,* ed 7, Philadelphia, 2010, Mosby.)

Although the MMR vaccine may rarely be associated with adverse neurologic events (e.g., seizures because of fever, deafness), studies conclude that MMR immunization does not cause autism.[39,40] Lack of vaccination, however, leads to significant morbidity and mortality, with pneumonia, croup, and encephalitis being causes of death worldwide.[41,42]

Women of childbearing age are immunized if their rubella hemagglutination-inhibition titer is low. Pregnancy should be avoided for 3 months after vaccination because the attenuated virus in the vaccine may remain for this period. However, accidental receipt of MMR vaccination is not known to cause maternal or fetal complications, or both.[43] Pregnant women who have rubella early in the first trimester may have a fetal death or a fetus that develops congenital defects.[44]

There is no specific treatment for rubella. Recovery is spontaneous, although lymph nodes may remain enlarged for weeks. Supportive therapy includes rest, fluids, and use of a vaporizer. In rare cases a mild encephalitis or peripheral neuritis may follow rubella.

Rubeola (Red Measles)

Rubeola is a highly contagious, acute viral disease of children. It is transmitted by direct contact with droplets from infected persons and is caused by an RNA-containing paramyxovirus with an incubation period of 7 to 12 days, during which time no symptoms manifest. The virus enters the respiratory tract and attaches to dendritic cells and alveolar macrophages, amplifies in local lymphatic tissue, and progresses to systemic disease.[45] Prodromal symptoms include high fever (up to 40.5° C [104.9° F]), malaise, enlarged lymph nodes, runny nose, conjunctivitis, and "barking" cough. Within 3 to 4 days, an erythematous maculopapular rash develops over the head and spreads distally over the trunk, extremities, hands, and feet. Early lesions blanch with pressure, followed by a brownish hue that does not blanch as the rash fades. Characteristic pinpoint white spots surrounded by an erythematous ring develop over the buccal mucosa and are known as *Koplik spots.* These spots precede the

TABLE 47-1 DIFFERENTIAL PRESENTATION OF VIRAL DISEASES PRODUCING RASHES

VIRAL DISEASE	INCUBATION	PRODROMAL SYMPTOMS	DURATION/ CHARACTERISTICS	CLINICAL SYMPTOMS
Rubella (German measles)	14-21 days	1-2 days Mild fever Malaise Respiratory symptoms	1-3 days Pink-red maculopapular rash Face and trunk	Enlarged and tender occipital and periauricular nodes
Rubeola (measles)	7-12 days	2-5 days Fever Cough Respiratory symptoms	3-5 days Purple-red to brown maculopapular papules Face, trunk, extremities	Koplik spots 1-3 days before rash Rash develops when fever subsides
Roseola (exanthema subitum)	5-15 days	2-5 days High fever	1-3 days Red macular papules Neck and trunk	
Varicella (chickenpox)	11-20 days	1-2 days Low-grade fever Cough May be asymptomatic	Red papules, vesicles, pustules in clusters	Eruption of new lesions for 4-5 days Occasional ulcerative lesion in the mouth

rash by 1 to 2 days and are usually missed because they appear so early. The rash then subsides within 3 to 5 days.

Complications associated with measles may be caused by the primary infection or a secondary bacterial infection. Measles encephalitis occurs in about 1 of 800 cases, and most children recover completely. Only a small minority develop permanent brain damage or die. Bacterial complications include otitis media and pneumonia, usually caused by group A hemolytic streptococcus, *Haemophilus influenzae,* or *S. aureus* infection.

Measles is prevented by a single vaccination of live attenuated measles virus. There is no specific treatment for measles, and supportive therapy is the same as for rubella. Antibiotic therapy is initiated if secondary bacterial infections develop.

Roseola (Exanthema Subitum)

Roseola is a presumed viral infection of infants between 6 months and 2 years of age, but it can be seen in children as old as 4 years. The incubation period is 5 to 15 days, followed by the sudden onset of fever (38.9° to 40.5° C [102° to 104.5° F]) that lasts 3 to 5 days. After the fever an erythematous, nonpruritic macular rash that lasts about 24 to 48 hours develops primarily over the trunk, neck, and arms. Children usually feel well, eat normally, and have few other symptoms. Usually no treatment is required and there are no complications.

Chickenpox and Herpes Zoster

Chickenpox (varicella) and herpes zoster (shingles) are produced by the varicella-zoster virus (VZV). VZV is a complex herpes group deoxyribonucleic acid (DNA) virus. The incubation period is 10 to 27 days, averaging 14 days. Productive infection occurs within keratinocytes such that the vesicular lesions occur in the epidermis, and an inflammatory infiltrate is often present. Histologically, VZV lesions form intraepidermal vesicles. Infected keratinocytes degenerate, swell, detach from each other, and often contain inclusions surrounded by a clear halo and a circle of darkly staining chromatin. As the vesicle evolves, polymorphonuclear cells enter the vesicle and can lead to a pustular appearance. The vesicle eventually ruptures and is followed by crust formation. On mucous membranes the vesicles rupture and leave superficial, transient ulcers. Varicella occurs in people not previously exposed to VZV, whereas herpes zoster occurs in partially immune individuals who have had varicella.[46]

Chickenpox (Varicella). **Chickenpox** is a disease of early childhood, with 90% of children contracting the disease during the first decade of life. It is a highly contagious virus that is spread by person-to-person contact and airborne droplets. Introduction of an infected person into a household results in a 90% possibility of susceptible persons in the household developing the disease within the incubation period—usually 14 days. Children are contagious for at least 1 day before development of the rash. Transmission of the virus may occur until approximately 5 to 6 days after the onset of the first skin lesions in healthy children. In immunocompromised children the virus is recoverable for a longer period, but these children must be considered contagious for at least 7 to 10 days. Healthy children who develop chickenpox have no prodromal symptoms. The first sign of illness may be itching or the appearance of vesicles, usually on the trunk, scalp, or face. The rash later spreads to the extremities. Characteristically, lesions can be seen in various stages of maturation with macules, papules, and vesicles present in a particular area at the same time (Figure 47-9). The vesicular lesions are superficial and can be easily ruptured. New lesions will erupt for 4 to 5 days, until there are approximately 100 to 300 in different stages of development. The vesicles become crusted, with only the crust remaining. Occasionally a vesicle may appear on the palm later in the disease. Although uncommon, ulcerative lesions are sometimes seen in the mouth and, less commonly, on the conjunctiva and pharynx. Fever usually lasts 2 to 3 days and ranges from 38.5° to 40° C [101.3° to 104° F]).

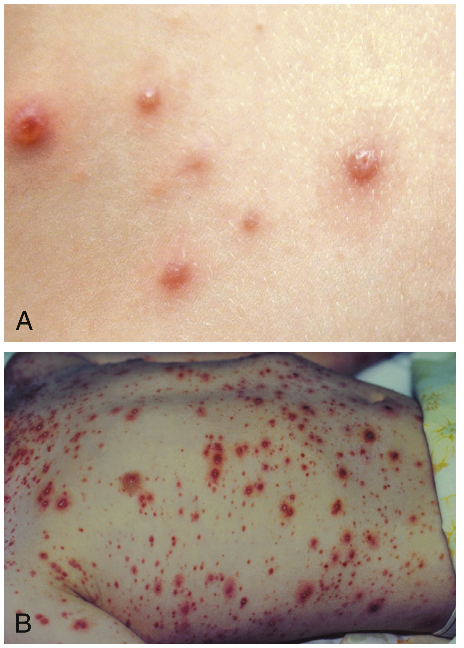

FIGURE 47-9 Chickenpox. **A,** Early stage lesions; **B,** late stage lesions. (**A** from Long SS et al: *Principles and practice of pediatric infectious diseases,* ed 4, Philadelphia, 2012, Saunders. **B** courtesy of David Effron, MD. From Marx J et al: *Rosen's emergency medicine: concepts and clinical practice,* ed 7, Philadelphia, 2010, Mosby.)

Complications are rare in children but more common in adults. They can include transient hematuria (from rupture of vesicles in the bladder), epistaxis, laryngeal edema, and varicella pneumonia. One case of chickenpox produces almost complete immunity against a second attack. Rarely, the fetus may be malformed (congenital varicella syndrome) if chickenpox develops in the mother in the first trimester of pregnancy.[47]

Infants whose mothers have chickenpox at any stage of pregnancy have a higher risk of developing herpes zoster during the first few years of life. Administration of maternal varicella-zoster immunoglobulin before rash development, with or without antiviral medication, can modify the progression of the disease.[48]

Uncomplicated chickenpox requires no specific therapy. Baths, wet dressings, and oral antihistamines are occasionally helpful to relieve itching and to prevent secondary infection as a result of scratching. Oral antistaphylococcal drugs should be given if secondary bacterial infection is present. Zoster immune globulin may be administered to immunodeficient individuals

if given within 72 hours after exposure to chickenpox. Oral antiviral drugs may be valuable in reducing symptoms in otherwise healthy children as well as in immunosuppressed or other select groups of children.[49] Chickenpox can be prevented with a safe and effective vaccine (see Chapter 10).

Herpes Zoster. Although herpes zoster (shingles) occurs mainly in adults, approximately 5% of cases are in children younger than 15 years.[50] The pathophysiology and treatment are reviewed in Chapter 46.

Smallpox

Smallpox (variola) is a highly contagious and deadly but preventable disease. It is caused by poxvirus variolae. Because of worldwide mass immunization, the world is now virtually free of smallpox. Concerns regarding smallpox as a weapon of bioterrorism have led to vaccination programs for the military and for selected civilian populations. The U.S. government has an adequate supply of smallpox vaccine to vaccinate the population in the event of an emergency.[51]

INSECT BITES AND PARASITES

Insect bites and infestations are common causes of skin disorders in children and adults. Skin damage occurs by various mechanisms, including trauma of bites and stings, allergic reactions, transmission of disease, injection of substances that cause local or systemic reactions, and inflammatory reactions from retained mouthparts.

Scabies

Scabies is a contagious disease caused by the itch mite, *Sarcoptes scabiei* (Figure 47-10, *A*), that can colonize the human epidermis. Scabies is a common skin infection in tropical settings and affects large numbers of people, particularly children. It is transmitted by personal contact and by infected clothing and bedding. Scabies is often epidemic in areas of overcrowded housing, in areas with poor sanitation, or in long-term care institutions. Scabies is often associated with immunocompromised individuals, such as those with human T-cell leukemia/lymphoma virus I (HTLV-1) and human immunodeficiency virus (HIV), and can facilitate *Streptococcus pyogenes* and *Staphylococcus aureus* skin infection.[52] Infestation is initiated by a female mite that tunnels into the stratum corneum, depositing eggs and creating a burrow several millimeters to 1 cm long. Over a 3-week period, the eggs mature into adult mites, which sometimes can be recognized as tiny dots at the end of intact burrows.

Symptoms appear 3 to 5 weeks after infestation. The primary lesions are burrows, papules, and vesicular lesions, with severe itching that worsens at night. Two or three bites (commonly referred to as "breakfast, lunch, and dinner") usually appear in a line on exposed areas of the skin. Itching is thought to be related to sensitization to the larval stages of the parasite. In older children and adults the lesions occur in the webs of fingers, axillae, and creases of the arms and wrists; along the belt line; and around the nipples, genitalia, and lower buttocks. Infants and young children have a different pattern of distribution, with involvement of the palms, soles, head, back, neck, and face (see Figure 47-10, *B*). Secondary infections and crusting develop from scratching and eczematous changes.

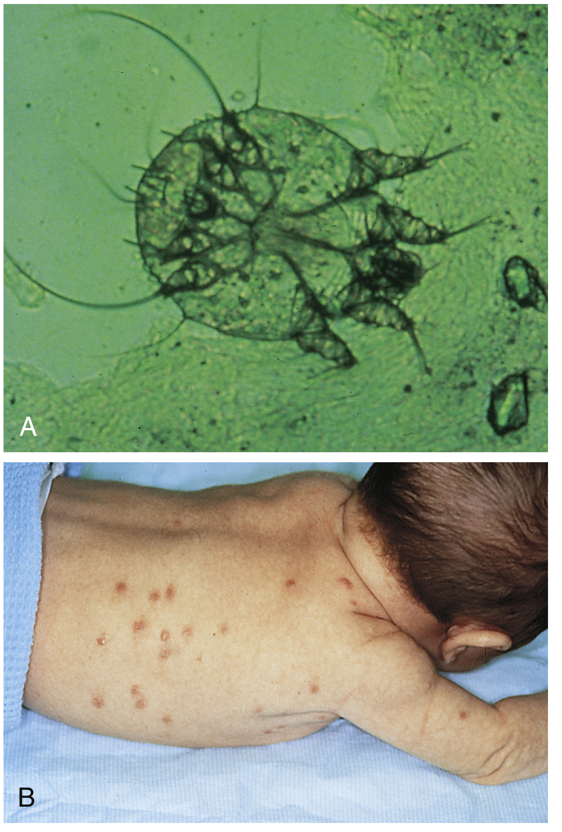

FIGURE 47-10 Scabies. **A,** Scabies mite, as seen clinically when removed from its burrow. **B,** Characteristic scabies bites. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Diagnosis of scabies is made by observation of the tunnels and burrows and by scraping of the skin with microscopic examination of the mite or its eggs or feces. Treatment is the application of permethrin cream, a scabicide. Generalized scabies is treated with oral ivermectin.[53] Even with elimination of all viable scabies microorganisms, itching may persist for 10 days or longer. All clothing and linens should be washed and dried in hot cycles or dry-cleaned.

Pediculosis (Lice Infestation)

The three known types of human lice are: (1) the head louse *(Pediculus capitis)*, (2) the body louse *(Pediculus corporis)*, and (3) the crab or pubic louse *(Phthirus pubis)*. They are highly contagious parasites that survive by sucking blood. The female louse reproduces every 2 weeks, producing hundreds of nits as newly hatched lice mate with old lice. The mouthparts are shaped for piercing and sucking and attach to the skin while feeding. When piercing the skin, the louse secretes a toxic saliva; the mechanical trauma and toxin produce a pruritic dermatitis. Head and body lice are acquired by personal contact, combs, or brushes. Crab lice are spread by body contact, such as contact with an infected adult. Sharing clothing is also a common source of transmission.[54]

FIGURE 47-11 **Flea Bites.** Flea bite producing an urticarial wheal with central puncture. (Courtesy Department of Pediatrics, Division of Allergy and Immunology, National Jewish Health.)

Itching is the major symptom of lice infestation. In head lice infestation the ova attach to hairs above the ears and in the occipital region. The primary lesion of the body louse is a pinpoint red macule, papule, or wheal with a hemorrhagic puncture site. The primary lesion often is not seen because it is masked by excoriations, wheals, and crusts. The crab louse is found on pubic hairs but also may involve other body hair such as eyelashes, mustache, beard, and axillae. Young children particularly may become infected with crab lice on their eyebrows or eyelashes.

The live louse, 2 to 3 mm long, is rarely observed, although the ova, or nits, can be observed as oval, yellowish pinpoint specks fastened to a hair shaft. The ova fluoresce under an ultraviolet light (Wood lamp) and can be best observed with a microscope. Infestations can be treated with a topical pediculicide (i.e., permethrin) or oral ivermectin.[55] Head lice are effectively treated with topical ivermectin.[56] All clothes, towels, bedding, combs, and brushes should be washed and dried in hot air or boiled, or the clothes should be ironed. Individuals who have personal contact also should be treated.

Fleas

Young children are very susceptible to **flea bites,** and the most common are the bites of cat, dog, and human fleas.[57] Bites occur in clusters along the arms and legs or where clothing fits tightly. The bite produces an urticarial wheal with a central hemorrhagic puncture (Figure 47-11). Treatment includes spraying carpets, crevices, and furniture with malathion or lindane powder. Infected animals should be treated, and clothes and bedding should be washed in hot water.

FIGURE 47-12 **Bullous Bedbug Bites.** (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Bedbugs

The common bedbug, *Cimex lectularius,* is a blood-sucking nocturnal parasite of man. Chickens, bats, and some domestic animals are the other hosts for this bug.[58] **Bedbugs** live in the crevices and cracks of floors, walls, and furniture and in bedding or furniture stuffing. They are 3 to 5 mm long and reddish brown. Bedbugs are nocturnal, emerging to feed in darkness, are attracted by warmth and carbon dioxide, and attach to the skin to suck blood. Feeding occurs for 5 to 15 minutes; then the bedbug leaves. It will move long distances to search for food and can travel from house to house.

Immunologic reactions to bedbug saliva vary, but bites typically yield erythematous and pruritic papules. The face and distal extremities, areas uncovered by sleeping clothes or blankets, are preferentially involved. If the host has not been previously sensitized, the only symptom is a red macule that develops into a nodule, lasting up to 14 days. In sensitized children and adults, pruritic wheals, papules, and vesicles may form (Figure 47-12) and, rarely, anemia and angioedema. Most lesions respond to antihistamines or corticosteroids. Secondary infections require antibiotic treatment. Bedbugs are eliminated by inspecting and cleaning or disposing of bedding, mattresses, furniture, and other contaminated items, and by using applications of approved insecticides, usually by a professional.[59]

HEMANGIOMAS AND CUTANEOUS VASCULAR MALFORMATIONS

Cutaneous vascular anomalies are frequent tumors of early infancy and can be categorized as either hemangiomas or vascular malformations.

Hemangiomas

Hemangiomas are benign tumors that form from the rapid growth of vascular endothelial cells, which results in formation of extra blood vessels. Hemangiomas can be superficial or deep.[60] Superficial hemangiomas are known as strawberry hemangiomas, and deep lesions are known as cavernous hemangiomas. The etiology may be related to embolization of fetal placental endothelial cells in association with placental trauma or loss of placental angiogenic inhibitor of placental and maternal origin.[61] There is proliferation of mast cells that are thought

FIGURE 47-13 Strawberry Hemangioma. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

FIGURE 47-14 Cavernous Hemangioma. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

to promote the angiogenesis. Infiltration of fat cells, fibrosis, and the rich vascular network give the lesions a firm, rubbery feel. Females are affected more often than males. About 30% of hemangiomas are apparent at birth, with most emerging during the first few weeks of life; they grow rapidly during the first few years, and then shrink or involute during childhood years. With involution the lesions become darker in color and then gradually turn to a flesh color. There may be some residual telangiectasia. Most require no treatment depending on location. Hemangiomas located over the eye, ear, nose, mouth, urethra, or anus may require treatment because they interfere with function and have a higher risk for infection or injury. Rapidly progressing hemangiomas are treated with propranolol with regression occurring within 2 weeks; propranolol should be considered a first-line agent.[62] Other therapies include systemic or intralesional steroids, cryosurgery, laser surgery, sclerotherapy, and embolization. Interferons, vincristine, cyclophosphamide, and radiotherapy can suppress angiogenesis.

Strawberry hemangiomas are distinct superficial hemangiomas that may be present at birth but usually emerge 3 to 5 weeks after birth. They proliferate and become bright red and elevated with minute capillary projections that give them a strawberry appearance. Only one lesion is usually present, and it is located on the head and neck area or trunk (Figure 47-13). After the initial growth, the lesion grows at the same rate as the child and then starts to involute at 12 to 16 months of age. Approximately 90% of strawberry hemangiomas involute by 5 to 6 years of age, usually without scarring.

Cavernous (congenital) hemangiomas are present at birth and have larger and more mature vessels within the lesion than strawberry hemangiomas. Some lesions, however, are composed of a mixture of strawberry and cavernous hemangiomas. They appear primarily on the head and neck, are bluish red, and have less distinct borders (Figure 47-14). Cavernous hemangiomas grow rapidly up to 6 months of age and mature by 1 year of age. A period of involution begins and proceeds for 6 to 12 months, with complete involution by 2 to 3 years in 30% of children and by 9 years of age in 90% of children.

Vascular Malformations

Vascular malformations are congenital anomalies of blood vessels present at birth but may not be apparent for several years. They grow proportionately with the child and never regress.[63] The malformations occur equally among males and females. Occasionally they expand rapidly, particularly during the hormonal changes of puberty or pregnancy and in association with trauma. Vascular malformations are classified as low flow or high flow. *Low-flow malformations* involve capillaries, veins, and lymphatics. *High-flow malformations* involve arteries. In addition to locations within the skin they may involve the gastrointestinal tract, bone (Maffucci syndrome), facial capillary malformation, skin, vascular malformation of the eye, and vascular malformation of the brain (leptomeningeal hemangioma—Sturge-Weber syndrome).[64] *Overgrowth syndromes* can occur with either high- or low-flow malformations, with overgrowth of the underlying structures (i.e., legs, arms, facial bones). The most common vascular malformation is nevus flammeus (port-wine stain) and salmon patches (stork bite, angel kiss).

Port-wine (nevus flammeus) stains are congenital malformations of the dermal capillaries. **Sturge-Weber syndrome** is a port-wine stain distributed along the ophthalmic branch of the trigeminal nerve and is associated with the leptomeninges of the brain and choroid, glaucoma, seizures, stroke, and intellectual disability. These capillary malformation are associated with a mutation in the *GNAQ* gene (Guanine nucleotide-binding protein G, q polypeptide).[64a] The lesions are flat, and their color ranges from pink to dark reddish purple. They are present at birth or within a few days after birth and do not fade with age. Involvement of the face and other body surfaces is common, and the lesions may be large (Figure 47-15). During adolescence and later adult years, the port-wine stain may become papular and cavernous. The flashlamp pulsed dye laser

FIGURE 47-16 Miliaria Rubra. Note discrete erythematous papules or papulovesicles. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

is the treatment of choice to successfully lighten the color and flatten the more nodular and cavernous lesions.[64] Waterproof cosmetics may be used to cover the lesions.

Salmon patches (nevus simplex) are macular pink lesions present at birth and located on the nape of the neck, forehead, upper eyelids, or nasolabial fold. They are a more superficial variant of nevus flammeus and one of the most common congenital malformations in the skin. The pink color results from distended dermal capillaries, and 95% fade by 1 and 3 years of age. Those located at the nape of the neck may persist for a lifetime, but generally do not present a cosmetic problem.

OTHER SKIN DISORDERS

Miliaria

Miliaria is a dermatosis commonly seen in infants. It is characterized by a vesicular eruption after prolonged exposure to perspiration, with subsequent obstruction of the eccrine ducts. There are two forms of miliaria: miliaria crystallina and miliaria rubra. In **miliaria crystallina,** ductal rupture occurs within the stratum corneum and appears as 1- to 2-mm clear vesicles without erythema. They rupture within 24 to 48 hours and leave a white scale. In miliaria rubra the ductal rupture occurs in the lower epidermis, with inflammatory cells attracted to the site of the rupture. **Miliaria rubra (prickly heat)** is characterized by 2- to 4-mm discrete erythematous papules or papulovesicles (Figure 47-16). Both forms may become secondarily infected, requiring treatment with systemic antibiotics. The key to management is avoidance of excessive heat and humidity, which cause sweating. Light clothing, cool baths, and air conditioning assist in keeping the skin surface dry and cool.

Erythema Toxicum Neonatorum

Erythema toxicum neonatorum (toxic erythema of the newborn) is a benign, erythematous accumulation of macules, papules, or pustules that appear at birth or 3 to 4 days after birth. The lesions first appear as a blotchy, macular erythematous rash. The macules vary from 1 mm to 1 cm. When papules or pustules develop, they are light yellow or white and 1 to 3 mm in diameter. There may be few or several hundred lesions and any surface of the body can be affected, with the exception of the palms and soles, where there are no pilosebaceous follicles. The cause of the lesion is unknown but it may be related to an innate immune response to the first commensal microflora with release of mast cell mediators. Eosinophils are abundant in the lesions.[65] It is self-limiting and resolves spontaneously within a few weeks of birth. No treatment is required.

Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis

Stevens-Johnson syndrome (SJS) and **toxic epidermal necrolysis (TEN)** are rare, severe, immune drug reactions that are considered to be the same pathologic process but with TEN being more extensive. The mortality is between 5% and 35%. Hypersensitivity to drugs includes allopurinol, sulfonamides, nonsteroidal anti-inflammatory agents, anticonvulsants (i.e., phenytoin), and others. There is widespread epidermal (keratinocyte) apoptosis and detachment with drug-specific cytotoxic T cells and macrophages involved in the immunopathology.[66,67] Bursts of nitric oxide formation have been proposed as the cause of epidermal apoptosis and necrosis. There is destruction of the epidermis in toxic epidermal necrolysis.[68]

The onset of skin eruptions is preceded by malaise, anorexia, fever, and mild inflammation of the eyelids, conjunctiva, mouth, or genitalia. Erythema with tenderness is first described in the trunk, face, and palms, extending to the groin and mucous membranes. Blisters and bullae form and large areas of necrotic epidermis may be shed, leaving open, weeping, painful areas of underlying skin. Complications can include dehydration, protein loss, altered temperature regulation, ocular complications leading to blindness, and organ failure. About one third of children have pulmonary complications.[69] A severity of illness score for toxic epidermal necrolysis (SCORTEN)

syndrome guides treatment and predicts mortality.[70] TEN must be confirmed by skin biopsy to differentiate from staphylococcal scalded-skin syndrome (SSSS) and acute graft-versus-host disease. Skin biopsy shows full-thickness epidermal necrosis and subepidermal blister formation. Treatment requires prompt withdrawal of causative drugs and intensive burn equivalent management, preferably in a burn unit. Treatment with corticosteroids and intravenous immunoglobulin is controversial and needs further study, which is difficult because the disease is so rare.[71,72]

SUMMARY REVIEW

Acne Vulgaris

1. Acne vulgaris is the most common skin disease, affecting 85% of the population between the ages of 12 and 25 years.
2. Acne is characterized by noninflammatory and inflammatory lesions related to follicular hyperkeratinization, excessive sebum production, plugging of sebaceous glands, and *P. acnes* colonization. Acne conglobata is a severe form of acne with communicating cysts and abcesses.

Dermatitis

1. Atopic dermatitis is associated with elevated IgE levels, a family history of asthma and hay fever, and altered skin barrier function. Red, scaly lesions commonly occur on the face, cheeks, and flexor surfaces of the extremities in infants and young children.
2. Diaper dermatitis is a type of irritant contact dermatitis initiated by a combination of factors that include prolonged exposure to urine and feces; frequently the infant becomes infected secondarily with *C. albicans*.

Infections of the Skin

1. Impetigo is a contagious bacterial disease that occurs in two forms: bullous and vesicular (contagious). The toxins from the bacteria produce a weeping lesion with a honey-colored crust.
2. SSSS is a staphylococcal skin infection that occurs more commonly in young children with low titers of antistaphylococcal antibody. Painful blisters and bullae form over large areas of the skin, requiring systemic antibiotics for treatment.
3. Tinea capitis (infection of the scalp) and tinea corporis (infection of the body) are fungal infections caused by dermatophytes.
4. *C. albicans* infection is a superficial fungal infection of the mouth (thrush).
5. Molluscum contagiosum is a poxvirus of the skin that produces pale papular lesions filled with viral and cellular debris.
6. Rubella (also known as *German* or *3-day measles*) is a communicable disease characterized by fever, sore throat, enlarged cervical and postauricular nodes, and a generalized maculopapular rash that lasts 1 to 4 days.
7. Rubeola is a highly contagious disease of children. Symptoms include high fever, enlarged lymph nodes, conjunctivitis, and a red rash that begins on the head and spreads to the trunk and extremities and lasts 3 to 5 days. Bacterial and viral complications may accompany rubeola.
8. Roseola is a benign disease of infants with a sudden onset of fever that lasts 3 to 5 days, followed by a rash that lasts 24 hours.
9. Chickenpox (varicella) is a highly contagious disease caused by the VZV. Vesicular lesions occur on the skin and mucous membranes. Individuals are contagious from 1 day before the development of the rash until about 6 days after the rash develops.
10. Herpes zoster (shingles) is a viral eruption of vesicles on the skin along the distribution of a sensory nerve caused by latent activation of the VZV. Children with immune suppression develop more serious complications.
11. Smallpox (variola) is a highly contagious, deadly disease that has been eradicated worldwide by vaccination.

Insect Bites and Parasites

1. Scabies is an itching lesion caused by the itch mite that burrows into the skin, forming papules and vesicles. The mite is very contagious and is transmitted by direct contact.
2. Pediculosis (lice infestation) is caused by blood-sucking parasites that secrete a toxic saliva and damage the skin to produce a pruritic dermatitis. Lice are spread by direct contact and are recognized by the ova, or nits, that attach to the shaft of body hairs.
3. Flea bites produce a pruritic wheal with a central puncture site and occur as clusters in areas of tight-fitting clothing.
4. Bedbugs are blood-sucking parasites that live in cracks of floors, furniture, or bedding and feed at night. They produce pruritic wheals and nodules.

Hemangiomas and Vascular Malformations

1. Hemangiomas are benign vascular tumors that emerge at birth and resolve spontaneously through the childhood years. Strawberry hemangiomas (distinct, raised vascular lesions) are more superficial, and cavernous hemangiomas, with larger and more mature vessels, are deeper lesions.
2. Vascular malformations are congenital anomalies of blood vessels. Low-flow malformations involve capillaries, veins, and lymphatics; high-flow malformations involve arteries.
3. Nevus flammeus (port-wine stain) is a deeper congenital malformation of the dermal capillaries, and salmon patches are more superficial vascular malformations.

Other Skin Disorders

1. Miliaria is characterized by small pruritic papules or vesicles that result from prolonged exposure to perspiration and subsequent obstruction of the eccrine ducts in infants.
2. Erythema toxicum neonatorum is a benign, erythematous, accumulation of macules, papules, and pustules that appear at birth or 3 to 4 days after birth and then spontaneously resolve within a few weeks.
3. SJS and TEN (the severe form of SJS) are severe immune blistering skin reactions to drugs.

- Online Course: Module 19

CHAPTER OUTLINE

Shock occurs when the cardiovascular system fails to perfuse tissues, cells, and organs adequately, resulting in widespread impairment of cellular metabolism and tissue function. **Tissue perfusion** is defined as the adequacy of blood flow through the small vessels of the extremities to maintain tissue function.[1] Tissue perfusion can be disrupted by any factor that alters delivery of blood to cells and tissues and increases oxygen consumption, such as decreased cardiac output, blood volume, or blood pressure. Shock has many causes and clinical manifestations related to the type of shock. Ultimately, shock from any cause will progress to organ failure and death, unless physiologic mechanisms reverse the process or clinical intervention succeeds in stopping the progression. Untreated, severe shock overwhelms the body's compensatory mechanisms that may result in multisystem organ failure.

Multiple organ dysfunction syndrome (MODS) is progressive and often involves the ultimate failure of two or more organ systems after a severe illness or injury. The disease process is initiated and perpetuated by uncontrolled systemic inflammatory and stress responses and is characterized by a hypermetabolic and hyperdynamic state that persists as organ dysfunction develops. For many years the syndrome was referred to as *multiple organ failure* or *multiple systems organ failure.* Gradually it was recognized that the term *organ dysfunction* more accurately describes the syndrome as a process of physiologic deterioration.

Major burns result in extensive immediate tissue injury and thus are a form of trauma with wide-reaching effects on all organ systems. The cause of injury may be thermal contact, flame, chemical agents, or electrical agents; each cause requires a different approach in diagnosis and treatment. Closely associated with thermal burns is smoke inhalation injury, which accounts for about 25% of all burn unit admissions. As a multiorgan problem, thermal injuries can have an overwhelming effect on survival of the burned individual. Regardless of the cause of burns, the result is a final common pathway of physiologic response dependent on the extent of burn surface involvement and the depth of tissue destruction.

SHOCK

Shock can be classified by type, principal pathophysiologic process, or clinical manifestations. Classification by type is perhaps the most useful because it suggests the cause and pathophysiologic process of the underlying disorder, which must be treated

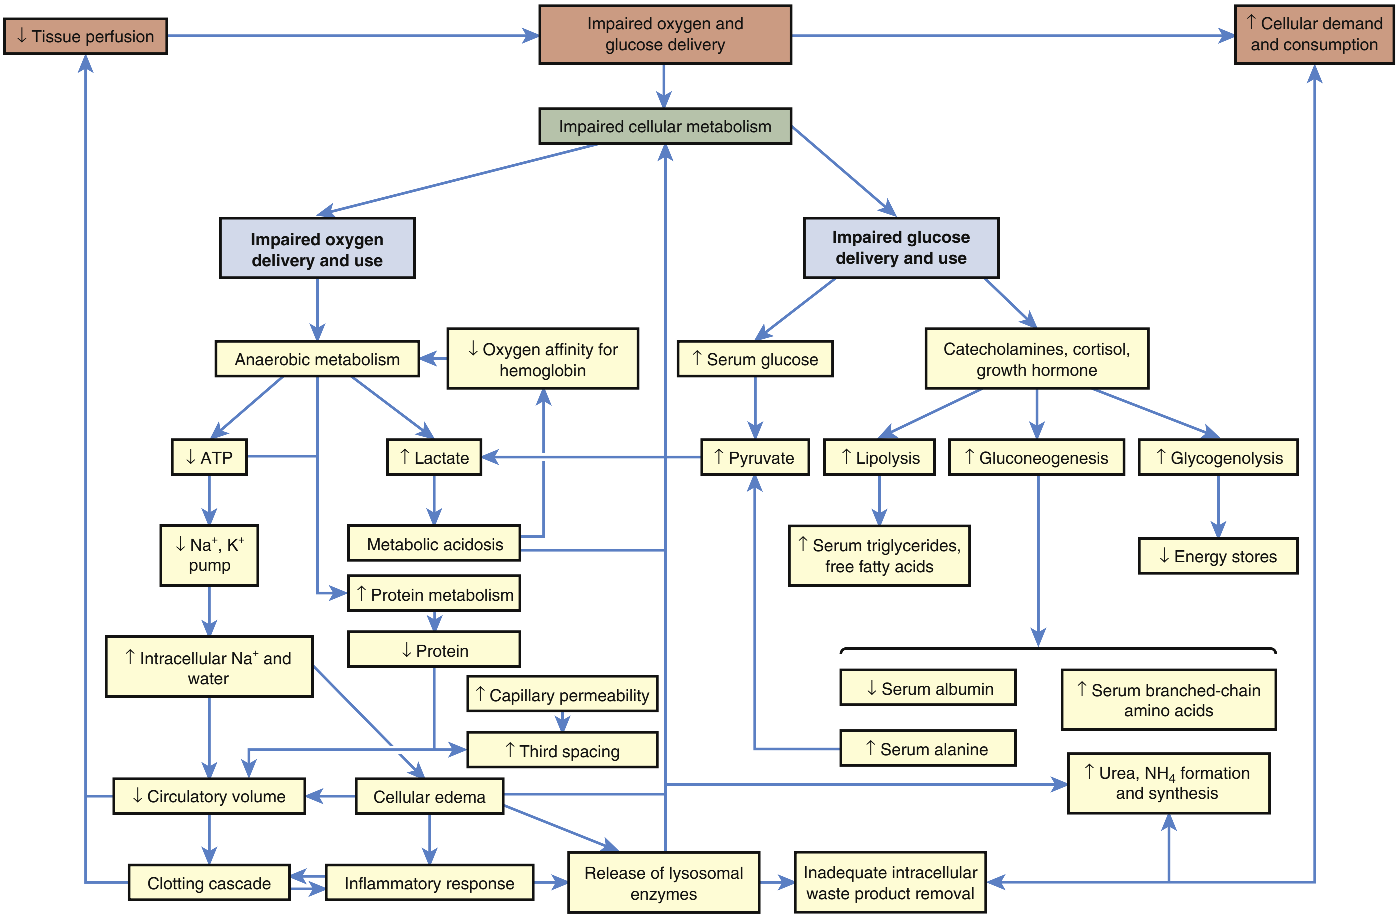

FIGURE 48-1 Impairment of Cellular Metabolism by Shock. *ATP*, Adenosine triphosphate.

to prevent the irreversible cellular alterations and impairment of cellular metabolism. **Shock** is classified as cardiogenic (caused by heart failure); neurogenic or vasogenic (caused by alterations in vascular smooth muscle tone); anaphylactic (caused by hypersensitivity); septic (caused by infection); or hypovolemic (caused by insufficient intravascular fluid volume).

Cellular Alterations and Impairment of Cellular Metabolism

The body consists of many organs, tissues, and cells that may function or malfunction at different stages of metabolic impairment. The common pathway in all types of shock is impairment of cellular metabolism, attributable to decreased delivery of oxygen and nutrients, frequently coupled with an increased demand and consumption of oxygen and nutrients and a decreased removal of cellular waste products.[2] Figure 48-1 illustrates the pathophysiology of shock at the cellular level.

Impairment of Oxygen Delivery and Use

In all types of shock, the cells do not receive adequate amounts of oxygen because of decreased delivery or increased cellular consumption, or both, and are therefore unable to use oxygen normally (see Figure 48-1). In cardiogenic shock cardiac output is too low to deliver adequate oxygen to the cell. In hypovolemic shock, oxygen delivery is impaired by inadequate numbers of red cells that carry oxygen and inadequate blood volume. In neurogenic, anaphylactic, and septic shock, systemic vascular resistance (SVR) becomes very low because of vasodilation, resulting in inadequate perfusion pressure in the capillaries. Thus, the pressure needed to drive oxygen and nutrients across cell membranes is inadequate. In septic shock, hypoxia is worsened by increased inflammatory responses, such as fever, that increase the cell's oxygen demand and consumption rate, and by direct toxic and inflammatory chemical disruption of cellular metabolism, that impairs the cells' ability to use oxygen.

Both positive and negative compensatory mechanisms, such as anaerobic metabolism, lysosomal enzyme release, decreased intravascular volume, and activation of the clotting cascade, may further impair oxygen delivery and use. Anaerobic metabolism results in disruption of electrolyte and lysosomal enzymatic processes, thus changing the normal ionic and osmotic levels in cells governed by the physical law of diffusion. Diffusion of nutrients and wastes into and out of the cell takes longer, and cellular metabolism is further altered. Without oxygen, the cell shifts from aerobic to anaerobic metabolism. Anaerobic metabolism is a less efficient method of extracting energy from carbon bonds, and the cell begins to use adenosine triphosphate (ATP) faster than it can be replaced. Without ATP the cell loses its ability to maintain an electrochemical gradient across its selectively permeable membrane. Specifically, the cell cannot operate the

sodium-potassium pump. Sodium and chloride accumulate inside the cell and potassium exits the cell. Cells of the nervous system and myocardium are profoundly and immediately affected. The resting potentials of these cells are reduced, and the action potentials decrease in amplitude (see Chapter 1). Myocardial depressant factor also decreases the contractility of the heart. A variety of clinical manifestations of impaired central nervous system and myocardial function result.

As sodium moves into the cell, water follows. Throughout the body, the water drawn from the interstitium into the cells is "replaced" by water that is in turn drawn out of the vascular space, often called "third spacing" of fluid. This decreases circulatory volume. Within the cells, water causes cellular edema that disrupts cellular membranes, releasing lysosomal enzymes that injure the cells internally and leak into the interstitium.

In addition to decreasing ATP stores, anaerobic metabolism affects the pH of the cell, and metabolic acidosis develops. A compensatory mechanism is initiated that enables cardiac and skeletal muscles to use lactic acid as a fuel source, but only for a limited time. The decreasing pH of the cell that is functioning under anaerobic conditions has serious consequences. Enzymes necessary for cellular function dissociate under acidic conditions. Enzyme dissociation stops cell function, repair, and division. As lactic acid is released systemically, blood pH drops, reducing the oxygen-carrying capacity of the blood (see Chapter 2), and the heart's ability to pump. Therefore, less oxygen is delivered to the cells and further hypoxia results in acidosis, which triggers more lysosomal enzyme release caused by disruption of lysosomal membrane integrity. Lysosomal enzymes released during shock injure the cell that released them and injure adjacent cells. By damaging the mechanisms of surrounding cells, lysosomal enzymes extend areas of impaired metabolism and cellular injury.

Intravascular fluid loss into the intracellular and interstitial spaces, described as "third spacing" earlier, is amplified when serum albumin and other plasma proteins are consumed for fuel, which results in decreased intravascular osmotic pressure, shift of fluid to the interstitial or extracellular spaces, and decreased circulatory volume. Decreased circulatory volume magnifies decreased tissue perfusion in all types of shock. Decreased intravascular volume causes decreased cardiac output in septic shock and further reduces cardiac output in cardiogenic shock. In individuals with anaphylactic, neurogenic, or septic shock and an already dilated vasculature, hypotension worsens as a result of decreased circulatory volume. New data on additional mechanisms for hypotension (vasodilation) are illustrated in Figure 48-7 (p. 1678).

Concurrently, diffusion across capillary membranes occurs more slowly, as blood flow in the capillary beds becomes sluggish, caused by decreased fluid volume with increased viscosity of blood. Sluggish capillary flow decreases tissue perfusion further, microvascular clots form, and activation of the clotting cascade may begin (see Chapter 27). Microemboli formation and platelet aggregation account for common complications of shock, such as acute tubular necrosis, acute respiratory distress syndrome (ARDS), and disseminated intravascular coagulation (DIC). It also may activate or be activated by the inflammatory response.[3]

Impairment of Glucose Delivery and Use

Impaired glucose use can be caused by either impaired glucose delivery or impaired glucose uptake by the cells (see Figure 48-1). The reasons for inadequate glucose delivery are the same as those enumerated for inadequate oxygen delivery. In addition, in septic and anaphylactic shock, glucose metabolism may be increased or disrupted because of fever or bacteria, and glucose uptake can be prevented by the presence of vasoactive toxins, endotoxins, histamine, and kinins.

Some of the compensatory mechanisms activated by shock contribute to decreased glucose uptake and use by the cells. High serum levels of cortisol, growth hormone, and catecholamines account for hyperglycemia and insulin resistance, tachycardia, increased SVR, and increased cardiac contractility. Cells shift to glycogenolysis, gluconeogenesis, and lipolysis to generate fuel for survival (see Chapter 1). Except in the liver, kidneys, and muscles, the body's cells have extremely limited stores of glycogen. In fact, total body stores can fuel the metabolism for only about 10 hours. The depletion of fat and glycogen stores is not itself a cause of organ failure, but the energy costs of glycogenolysis and lipolysis are considerable and contribute to the cellular failure.

The depletion of protein is, however, a cause of organ failure. When gluconeogenesis causes proteins to be used for fuel, these proteins are no longer available to maintain cellular structure, function, repair, and replication. The breakdown of protein occurs in starvation states, hyperdynamic metabolic states, and septic shock. Under anaerobic metabolism, protein breakdown liberates alanine, which is converted to pyruvate. Pyruvic acid is changed into lactic acid, leading to an increased affinity for oxygen to bind to hemoglobin with resultant hypoxia and metabolic acidosis.

As proteins are metabolized anaerobically, ammonia and urea are produced. Ammonia is toxic to living cells. Uremia develops, and uric acid further disrupts cellular metabolism. Proteins are broken down preferentially. Serum albumin and other plasma proteins are consumed for fuel first. Serum protein consumption decreases capillary osmotic pressure and contributes to the development of interstitial edema, creating another negative compensatory outcome that decreases circulatory volume. In septic shock, plasma protein breakdown includes breakdown of immunoglobulins, thereby impairing immune system function when it is most needed.

Muscle wasting caused by protein breakdown weakens skeletal and cardiac muscle. Skeletal muscle wasting impairs the muscles that facilitate breathing. Muscle wasting therefore alters the actions of both heart and lungs. The delivery of oxygen and glucose to the cells is directly reduced, as is the removal of metabolic waste products, such as the formation of carbon dioxide and lactic acid, causing metabolic acidosis with resultant inability of muscles, organs, and tissues to function mechanically and electrically.

The metabolic wastes that accumulate in the cell and interstitial spaces are toxic to the cells and further disrupt cellular function and membrane integrity. In septic shock, for example, a deficiency in cellular metabolism and the buildup of toxins may precede and cause decreased tissue perfusion.

Types of Shock, Clinical Manifestations, and Treatment

Each type of shock (cardiogenic, hypovolemic, neurogenic, anaphylactic, septic) involves numerous clinical manifestations, signs, and symptoms that also may characterize other conditions, making diagnosis difficult. An individual's history and situation are correlated with the specificity of the shock state suspected or anticipated. Clinical manifestations common in septic shock are fever, high heart rate, high respiratory rate, or elevations in immune responses, such as increased levels of white blood cells and circulating blood glucose. Subjective complaints often are nonspecific and general. The individual may report feeling sick, weak, cold, hot, nauseated, dizzy, confused, afraid, thirsty, and short of breath.

The initial management for shock is to discover, diagnose, and correct or remove the underlying cause. Although this seems a simple tenet, it is one that is not always remembered. Thus treatment for cardiogenic shock begins with diagnosis and treatment of heart failure or at least enhancement of cardiac output. If hypovolemia is the cause of shock, hemorrhage and other causes of fluid loss must be stopped. In neurogenic shock, as a result of spinal cord trauma, stabilization of the spine and surrounding tissue is an initial approach and pain usually can be decreased to a level at which neutrally-mediated decreases of SVR cease. The initial treatment for anaphylactic shock is to remove or neutralize the antigen. Treatment for septic shock begins with eradication of the infective agent, usually with antimicrobials.

Simultaneous to correcting the underlying cause or condition, treatment is directed at targeting improvement of microcirculatory tissue perfusion.[4] Optimizing oxygenation is an absolute necessity in all shock states. The goal has a dual purpose to both optimize oxygen delivery and reduce oxygen consumption. Intravenous fluid is administered to expand intravascular volume and thereby improve tissue perfusion by increasing blood pressure and cardiac output, except in cases of cardiogenic shock, which require diuresis to reduce preload.

Effective glucose level control in various shock states has been shown to improve outcomes. Hyperglycemia, caused by insulin resistance in the liver and muscle, is a common finding in the critically ill. This is most likely an adaptive response providing glucose for the brain, red blood cells, and wound healing. The extent of appropriate glucose level control has been evaluated in recent years, leading to more aggressive treatment with continuous, titrating insulin infusions to maintain blood glucose levels closer to normal, thus promoting normal cellular function and healing.[5]

Once cellular and organ dysfunction and physiologic derangement are established, risk of morbidity and mortality increases. Prevention and early treatment offer the best prognosis.

Cardiogenic Shock

Cardiogenic shock results from the inability of the heart to pump adequate blood to tissues and end organs from any cause, the most common being the short-term consequences of an acute myocardial infarction or a severe episode of myocardial ischemia. **Cardiogenic shock** is defined as persistent hypotension and tissue hypoperfusion caused by cardiac dysfunction in the presence of adequate intravascular volume and left ventricular filling pressure.[6] Pathologic conditions that reduce contractility, cause pump failure, impair diastolic filling, or cause obstruction can lead to cardiogenic shock. Decreased contractility and pump failure can result from (1) acute myocardial infarction (AMI), cardiomyopathy, sepsis, myocarditis, pericarditis, aneurysm, dysrhythmias, contusion, metabolic abnormalities, papillary muscle rupture; (2) impaired diastolic filling related to dysrhythmias; and (3) obstruction attributable to pulmonary embolism, cardiac tamponade, valvular disorders, tumors, and wall rupture or defects.[7]

Overall hospital mortality because of cardiogenic shock has decreased from approximately 90% in the 1970s to a recent estimate of 50%.[8]

As cardiac output decreases, compensatory adaptive responses are activated, such as the renin-angiotensin, neurohormonal, and sympathetic nervous systems, that lead to fluid retention, systemic vasoconstriction, and tachycardia.[9] Activation of the inflammatory response (resulting in expression of inducible nitric oxide synthase), activation of inflammatory cytokines, and activation of the complement system appear to play an important role in the pathogenesis and outcome of cardiogenic shock.[10] Increases in contractility, heart rate, and blood pressure are maintained in mild shock states through vasoconstriction in response to catecholamine release from the adrenals. Vasoconstriction increases vascular resistance to normalize blood pressure and increases cardiac performance by returning more blood volume and increasing perfusion to the heart; however, this increases myocardial demand and consumption of oxygen and nutrients by the heart. Increasing myocardial requirements burden the already failing heart, which can no longer pump an adequate volume of blood with sufficient force to perfuse the tissues. Thus increased coronary, tissue, and cellular ischemia further deteriorates myocardial function and shock.

Mortality in cardiogenic shock is reduced by use of intra-aortic balloon counterpulsation (IABP); cardiosupportive drug regimens and early coronary interventions have also improved outcomes.[10-12] Following myocardial infarction, reperfusion and revascularization can be achieved with treatment modalities that include fibrinolytic therapies (medications that disintegrate the coronary thrombus) and percutaneous interventions (balloon angioplasty, stent placement, and thrombectomies). Surgery (coronary artery bypass, ventriculoplasty, or heart transplant) is also utilized to open the coronary vessels during an acute myocardial infarction or to replace irreparable heart muscle. Cardio-supportive drug and fluid regimens are initiated to maintain adequate blood pressure and essential fluid and electrolyte balance, and to optimize coronary perfusion to the myocardium. Mechanical assist devices, specifically intra-aortic balloon pumps and percutaneous or ventricular assist devices (VADs), are used to support cardiac output temporarily until the individual improves or transplantation is possible.[11] Implantable VADs, pacemakers, or internal defibrillator devices are sometimes used as permanent treatment

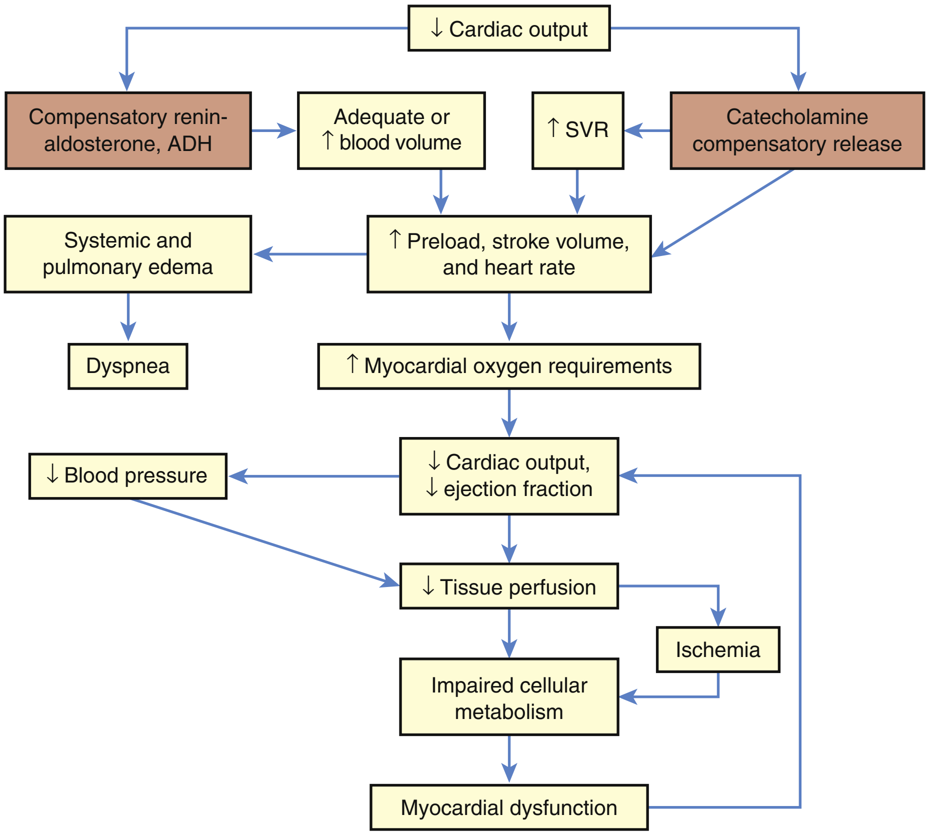

FIGURE 48-2 **Cardiogenic Shock.** Shock becomes life threatening when compensatory mechanisms (orange boxes) cause increased myocardial oxygen requirements. *ADH,* Antidiuretic hormone; *SVR,* systemic vascular resistance.

for those who survive cardiogenic shock. Continuous hemodynamic monitoring should be employed to evaluate vascular volume and pressures, optimize fluid levels, and monitor drug administration with the goal of improving cardiac output and tissue perfusion.[13]

The clinical manifestations of cardiogenic shock are caused by inadequate perfusion to the heart and end organs (Figure 48-2). Subjective complaints of chest pain, dyspnea, and faintness, along with feelings of impending doom, are often revealed. Classic observable signs and symptoms of tachycardia, tachypnea, hypotension, jugular venous distention, dysrhythmia, and low measured cardiac output are hallmarks. Cyanosis; skin mottling; rapid, faint, or irregular pulses; low urine output; and occasional peripheral edema are additional signs and symptoms of end-organ hypoperfusion. Myocardial dysfunction from fluid overload may result in extra heart sounds, pulmonary edema, hypoxemia, and elevated end-organ laboratory values. The amount of brain natriuretic peptide, produced when the heart stretches in relation to increased volume with decreased cardiac output, is increased to help diurese the fluid volume excess.[9] Pulmonary edema increases as volume accumulates and expands from the heart into the lungs as evidenced by audible crackles and wheezes as well as abnormal vascular congestion on chest radiography. Metabolic abnormalities involving electrolyte imbalances and elevated levels of inflammatory markers may result from or concur with the cardiac cascade of shock.

Hypovolemic Shock

Hypovolemic shock is caused by loss of whole blood (hemorrhage), plasma (burns), or interstitial fluid (diaphoresis, diabetes mellitus, diabetes insipidus, emesis, or diuresis) in large amounts. Loss of whole blood or plasma causes hypovolemia directly. Loss of interstitial fluid causes an indirect "relative" hypovolemia by promoting diffusion of plasma from the intravascular to the extravascular space. Hypovolemic shock begins to develop when intravascular volume has decreased by about 15%.

Hypovolemia is offset initially by compensatory mechanisms (Figure 48-3). Heart rate and SVR increase as a result of catecholamine release by the adrenals. This boosts cardiac output and tissue perfusion pressures. Compelled by a decrease in capillary hydrostatic pressures, interstitial fluid moves into the vascular compartment. The liver and spleen add to blood volume by disgorging stored red blood cells and plasma. In the kidneys, renin (through several intermediaries) stimulates aldosterone release and the retention of sodium (and hence water), whereas antidiuretic hormone (ADH, or vasopressin) from the posterior pituitary gland increases water retention. Data on the compensation of ADH, however, show that as shock worsens, ADH in plasma decreases. Hypovolemic shock results in compensatory vasoconstriction and increased SVR and afterload in order to improve blood pressure and perfusion to core organs of the body.

These compensatory mechanisms are, however, finite. If the initial fluid or blood loss is great or if loss continues,

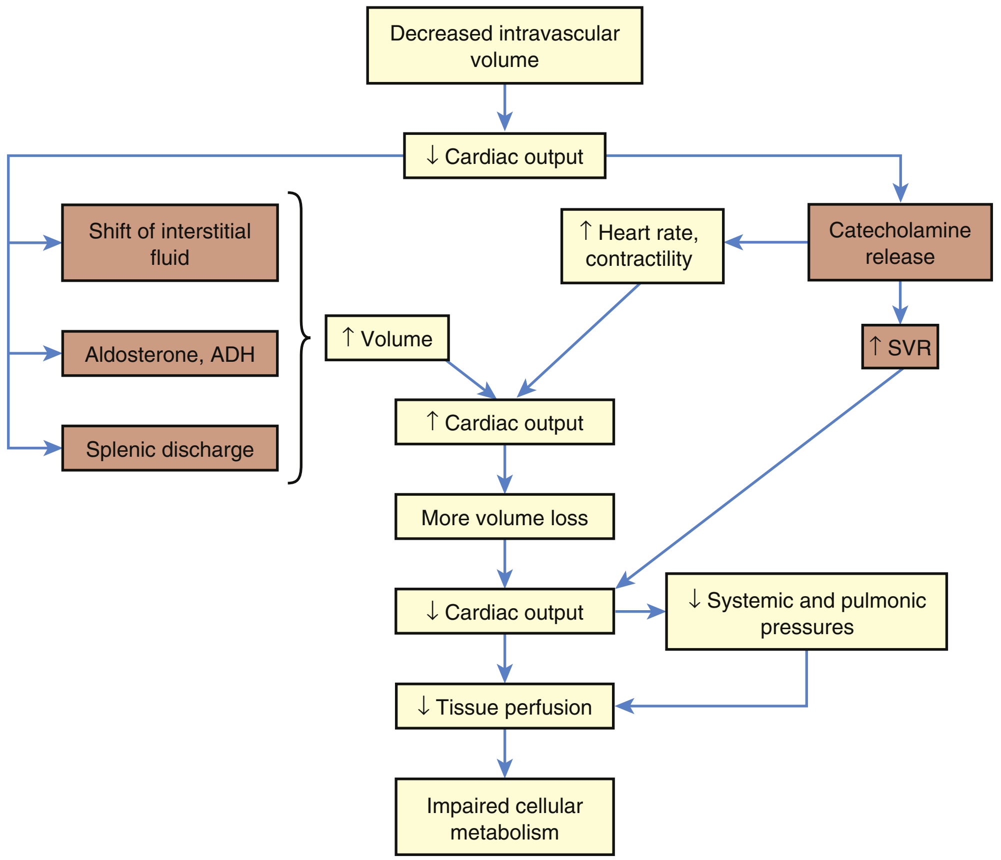

FIGURE 48-3 **Hypovolemic Shock.** This type of shock becomes life threatening when compensatory mechanisms *(orange boxes)* are overwhelmed by continued loss of intravascular volume. *ADH,* Antidiuretic hormone; *SVR,* systemic vascular resistance.

compensation fails, resulting in decreased tissue perfusion. Nutrient delivery to the cells is impaired, and cellular metabolism fails. Mortality from traumatic hemorrhagic shock ranges from 10% to 31%. Prompt control of hemorrhage is the treatment of choice. Fluid replacement is also important, but the type of fluid to be used and the rate of replacement are controversial.[14,15] The clinical manifestations of hypovolemic shock include high SVR, poor skin turgor, increased thirst, oliguria, low systemic and pulmonary preloads, and rapid heart rates.

Neurogenic Shock

Neurogenic shock also is called **vasogenic shock.** Both terms refer to a widespread and massive vasodilation that results from an imbalance between parasympathetic and sympathetic stimulation of vascular smooth muscle (see Chapter 31). Occasionally, parasympathetic overstimulation or sympathetic understimulation persists, causing vasodilation for an extended period. Extreme, persistent vasodilation leads to neurogenic shock (Figure 48-4). Neurogenic shock creates "relative hypovolemia." Blood volume has not changed, but the amount of space containing the blood has increased, so that SVR decreases drastically; thus pressure in the vessels is inadequate to drive nutrients across capillary membranes, and nutrient delivery to the cells is impaired. As with other types of shock, this leads to impaired cellular metabolism.

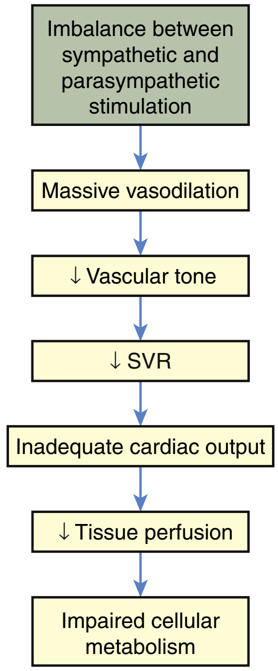

FIGURE 48-4 **Neurogenic Shock.** *SVR,* Systemic vascular resistance.

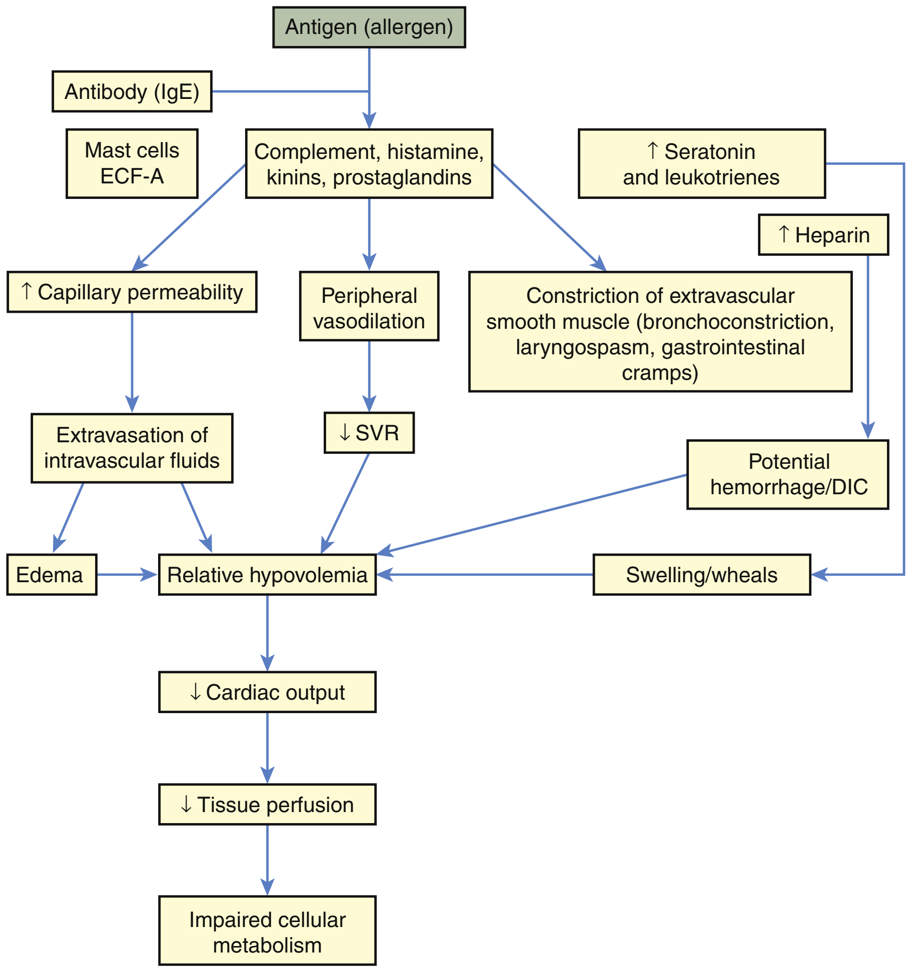

FIGURE 48-5 Anaphylactic Shock. *DIC,* Disseminated intravascular coagulation; *ECF-A,* eosinophil chemotactic factor anaphylaxis; *IgE,* immunoglobulin E; *SVR,* systemic vascular resistance.

Neurogenic shock can be caused by any factor that stimulates parasympathetic activity or inhibits sympathetic activity of vascular smooth muscle. (Parasympathetic stimulation automatically inhibits sympathetic activity and vice versa; see Chapter 31.) Normally, sympathetic stimulation maintains muscle tone. If sympathetic stimulation is interrupted or inhibited, vasodilation occurs. Therefore, trauma to the spinal cord or medulla, conditions that interrupt the supply of oxygen to the medulla, or conditions that deprive the medulla of glucose (e.g., insulin reactions) can cause neurogenic shock by interrupting sympathetic activity. Depressive drugs, anesthetic agents, and severe emotional stress and pain are other causes of neurogenic shock.

The clinical hallmark of neurogenic shock is a very low SVR, along with other indicators of excessive parasympathetic activity. Bradycardia is the most obvious manifestation, especially in the early stages. Bradycardia may cease when compensatory mechanisms, particularly an increase in sympathetic system activity, have been initiated. The ejection fraction remains high, indicating a healthy myocardium, whereas central venous pressure decreases as the veins dilate. Neurogenic shock causes fainting if blood pressure decreases to the point that cerebral metabolism is not sufficient to support consciousness. Most episodes of fainting are *not* shock, however; for such episodes to progress to shock is rare. By allowing the blood pressure to equalize from head to toe as the individual becomes prone, fainting can actually prevent shock.

Anaphylactic Shock

Anaphylactic shock is the outcome of a widespread hypersensitivity to an allergen that triggers a reaction known as *anaphylaxis.* (An allergen is an antigen to which an individual is hypersensitive; see Chapters 7, 8, and 9 for discussions of immunity, inflammation, and hypersensitivity.) Immunologic causes are related to the inflammatory and vasodilatory effects triggered by a pathologic allergic reaction to an antigen. Production of mast cells, IgE, and low-affinity IgE receptor (FceRI) is induced by cellular response to the antigen. *Anaphylactoid* type reactions, which are nonimmunologic in origin, can be related to cold weather, exercise, and contaminants in medications.[16] Physiologic alterations related to the inflammatory and immune response, similar to neurogenic shock, are massive—vasodilation, peripheral pooling, and relative hypovolemia lead to decreased tissue perfusion and impaired cellular metabolism (Figure 48-5). Anaphylactic shock is often severe and has immediate symptoms, including an itchy rash, throat swelling,

and low blood pressure, related to the massive vasodilation and systemic inflammation that may progress to death in minutes if emergency treatment is not rendered.

Some allergens known to cause hypersensitivity reactions are foods, insect and snake venoms, pollens, medications, and latex. Once in the body, the allergen causes the extensive immune and inflammatory response. The vascular effects of this response include vasodilation and increased vascular permeability, resulting in peripheral pooling and tissue edema. The extravascular effects include constriction of extravascular smooth muscle. Constriction often causes respiratory difficulty because it tends to affect smooth muscle layers in the airway walls (e.g., the larynx and bronchioles; see Chapter 34).

Clinical manifestations of anaphylactic and anaphylactoid shock may be anxiety, difficulty in breathing, gastrointestinal cramps, edema, hives (urticaria), sensations of burning or itching of the skin, fever, and hemolysis. A precipitous decrease in blood pressure occurs and is followed by impaired mentation. Other signs include decreased SVR (with high or normal cardiac output) and oliguria. Treatment begins with removal of the antigen (if possible). Epinephrine is administered to decrease mast cell and basophil degranulation, cause vasoconstriction, and reverse airway constriction.[17] Volume expanders (e.g., lactated Ringer solution) are given intravenously to reverse the relative hypovolemia, and antihistamines and corticosteroids are given to stop the inflammatory reaction.

In response to the need for improved anaphylaxis diagnosis and treatment, the World Allergy Organization (WAO) formulated global guidelines in 2011 for assessment and management of anaphylaxis.[17] These guidelines were further updated in 2012 to include recommendations for validation of the clinical criteria for diagnosis, use of epinephrine, development of in vitro tests to distinguish clinical risk from asymptomatic sensitization, and immune modulation to prevent anaphylaxis[16] (see What's New? Anaphylactic Shock).

Septic Shock

Septic shock is the endpoint of a continuum of progressive dysfunction.[18] The syndrome begins with systemic inflammatory response syndrome (SIRS), then sepsis, then severe sepsis, and then septic shock. Consensus on definitions of each component was updated at an international sepsis conference in 2003 (Table 48-1).[18] The International Sepsis Forum reviewed research for sepsis to identify and define the six most common infection sites (pneumonia, bloodstream, intravascular catheter, intra-abdominal, urosepsis, and surgical wound infection) associated with sepsis in the intensive care setting.[19]

Severe sepsis is the tenth most common cause of death in the United States.[20] Mortality ranges from 28% to 60%.[21] Septic shock is caused by gram-negative bacteria, gram-positive bacteria, and fungi. Advances in antibiotic therapy for gram-negative sepsis have made gram-positive bacteria the leading cause of sepsis.[22] Even when properly treated with available therapies, it carries a high mortality rate. Prognosis is significantly affected by the source and virulence of the infectious microorganism.

WHAT'S NEW?

Anaphylactic Shock

In response to the need for improved anaphylaxis diagnosis and treatment, the World Allergy Organization (WAO) formulated global guidelines in 2011 for assessment and management of anaphylaxis. These guidelines were further updated in 2012 to include recommendations for validation of the clinical criteria for diagnosis, use of epinephrine, development of in-vitro tests to distinguish clinical risk form asymptomatic sensitization, and immune modulation to prevent anaphylaxis.

Data from Simons FE et al: *Curr Opin Allergy Clin Immunol* 12(4): 389–399, 2012.

Septic shock begins with a nidus of infection that may be readily discernible or extremely difficult to locate (Figure 48-6). Bacteria and fungi enter the bloodstream to produce bacteremia in one of two ways: (1) directly from the site of infection, or (2) indirectly from toxic substances released by the bacteria directly into the bloodstream. These toxic substances, which act as triggering molecules in the septic syndrome, include endotoxins released by gram-negative microorganisms, lipoteichoic acids and peptidoglycan released by gram-positive microorganisms, and superantigens.[22]

The triggering molecules cause the host to initiate a proinflammatory response. Proinflammatory cells released include polymorphonuclear leukocytes, macrophages, monocytes, and platelets. Proinflammatory mediators released include cytokines (interleukins [IL]-1, IL-2, IL-6, IL-8, and IL-15; tumor necrosis factor-alpha [TNF-α]; and granulocyte cell–stimulating factor), complement and complement cascade activation, kinins, arachidonic acid metabolites (prostaglandins, prostacyclin, leukotrienes, and thromboxane), soluble adhesion molecules, platelet-activating factor, endorphins, vasoactive neuropeptides, histamine, serotonin, monocyte chemoattractant proteins 1 and 2, proteolytic enzymes (e.g., elastase and lysosomal enzymes), protein kinase, tyrosine kinase, CD14, toxic oxygen metabolites (e.g., superoxide, hydroxyl radical, hydrogen peroxide, peroxynitrite), neopterin, and clotting cascade activation.[3,23,24] Proinflammatory cytokines enhance tissue factors, which initiates coagulation. Diminished thrombomodulin (cell surface glycoprotein of endothelial cells) inhibits the conversion of protein C and activated protein C. A compensatory anti-inflammatory response syndrome is presumed to follow this response.[3,23,24] Anti-inflammatory mediators released include lipopolysaccharide-binding protein; IL-1 receptor antagonist; soluble CD-14; type 2 IL-1 receptor; leukotriene B_4 receptor antagonist; IL-4, IL-10, and IL-13; soluble tumor necrosis factor receptor; transforming growth factor-beta (TGF-β); epinephrine; and nitric oxide.[3,23,24] Presumably the end result is a mixed antagonistic response syndrome as proinflammatory and anti-inflammatory mediators respond, intensify, and lead the host into MODS.

Clinical manifestations of septic shock are persistent low arterial pressure, low SVR from vasodilation, and an alteration in oxygen extraction by all cells. Septic shock and states of prolonged shock causing tissue hypoxia with lactic acidosis increase nitric oxide synthesis, activate ATP-sensitive and

TABLE 48-1 DEFINITIONS OF SEPTIC SHOCK COMPONENTS

TERM	BASIC DEFINITION	COMMENTS
Infection	A pathologic process that results from an invasion of a normal part of the body by pathogenic or potentially pathogenic microorganisms	Still viewed as an imperfect definition Infection can be strongly suspected without microbiologic confirmation
Bacteremia	Presence of viable bacteria in the blood	Neither necessary nor sufficient to make a diagnosis of sepsis
SIRS	Systemic inflammatory response syndrome is manifested by two or more of general variables: 1a through 1d or 2a through 2c	*Diagnostic criteria:* 1. General variables a. Fever—core temperature >38.3° C (100.9° F) b. Hypothermia—core temperature <36° C (96.8° F) c. Heart rate >90 beats/minute d. Tachypnea e. Altered mental status f. Significant edema or positive fluid balance (>20 ml/kg over 24 hr) g. Hyperglycemia (blood sugar >140 mg/dl) in the absence of diabetes 2. Inflammatory variables a. Leukocytosis (WBC count >12,000) b. Leukopenia (WBC count <4000) c. Normal WBC with >10% immature forms d. Plasma C-reactive protein >2 SD above the normal value e. Plasma procalcitonin >2 SD above the normal value 3. Hemodynamic variables a. Arterial hypotension (SBP <90 mmHg; MAP <70, or an SBP decrease >40 mmHg) b. $S\bar{v}O_2$ >70% c. Cardiac index >3.5 L/min 4. Organ dysfunction variables a. Arterial hypoxemia (PaO_2/FiO_2 <300) b. Acute oliguria (urine output <0.5 ml/kg/hr or 45 ml for at least 2 hr) c. Creatinine increase >0.5 mg/dl d. Coagulation abnormalities (INR >1.5 or a PTT >60) e. Ileus f. Thrombocytopenia (platelet count <100,000) g. Hyperbilirubinemia (plasma total bilirubin >4 mg/dl or 70 mmol/L) 5. Tissue perfusion variables a. Hyperlactatemia (>1 mmol/L) b. Decreased capillary refill or mottling
Sepsis	Systemic response to infection, which is manifested by two or more of the SIRS criteria	
Severe sepsis	Sepsis complicated with one or more organ system dysfunctions	May be difficult to differentiate underlying organ dysfunction from sepsis-related organ dysfunction
Septic shock	Severe sepsis complicated by persistent hypotension refractory to early fluid therapy	Persistent systolic blood pressure <90 mmHg

calcium-regulated potassium channels (K_{ATP} and K_{Ca}, respectively) in vascular smooth muscle (see Chapter 31), and lead to depletion of ADH (vasopressin) (Figure 48-7). Tachycardia causes cardiac output to remain normal or become elevated, although myocardial contractility is reduced. Temperature instability is present, ranging from hyperthermia to hypothermia. Effects on other organ systems may result in deranged renal function, gastrointestinal mucosa changes that result in release of bacteria from the gut, jaundice, clotting abnormalities, deterioration of mental status, and tachypnea that often progresses to ARDS.

Early detection of high-risk illness and rapid implementation of the following standard protocols are increasingly being used by hospitals worldwide: decreasing the time before lactate levels are determined; obtaining blood cultures; starting administration of antibiotics and antifungals; implementing a fluid challenge; achieving goals for blood pressure, central venous pressure (CVP), and central venous oxygen saturation.[25,26] Promptly initiated treatment helps reduce mortality and morbidity related to multiple organ dysfunction. Infection and sepsis identified in the early stages and treated with antibiotics and fluid resuscitation may prevent evolution to severe sepsis and shock; however, once these are identified, more stringent treatment is recommended. The current guidelines for severe sepsis and septic shock[27] recommend immediate resuscitation in patients with lactate levels >4 mmol/L. Elevated lactate levels indicate tissue hypoperfusion and patients should begin early goal-directed therapy or fluid resuscitation within 6 hours, regardless of blood pressure

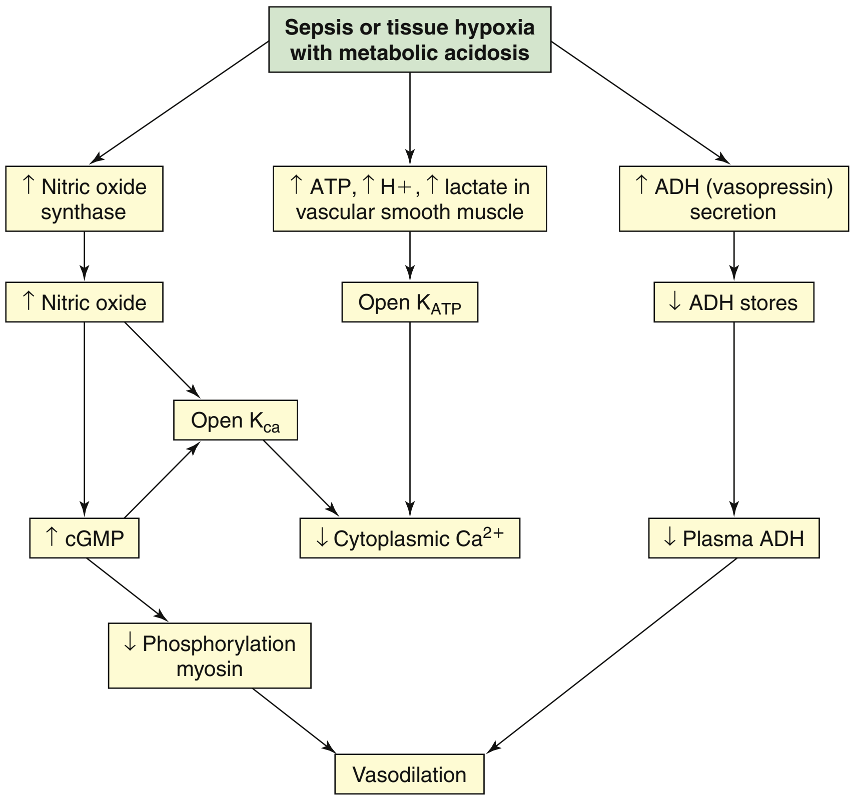

FIGURE 48-7 **Mechanisms of Vasodilation in Shock.** Vasodilatory shock is caused by the inappropriate activation of vasodilatory mechanisms and the failure of constrictor mechanisms. Unregulated nitric oxide, by regulating guanylate cyclase and generating cyclic guanosine monophosphate (cGMP), causes dephosphorylation of myosin and, thus, vasodilation. Nitric oxide synthesis and metabolic acidosis activate the potassium channels (K_{ATP} and K_{ca}) in the plasma membrane of vascular smooth muscle. The resulting hyperpolarization (see Chapter 3) of the membrane presents the calcium that mediates norepinephrine and angiotensin II–induced vasoconstriction from entering the cell. Therefore, hypotension and vasodilation stubbornly persist despite high plasma levels of these hormones. In contrast, and unexpectedly, the plasma level of antidiuretic hormone (ADH) (vasopressin) is low despite the presence of hypotension. The early, massive release of ADH may result in future depletion.

level.[25,26] Specifically, fluid resuscitation with either crystalloid or colloid fluids should be goal-directed to maintain the following values: central venous pressure, 8 to 12 mmHg (or 12 to 15 mmHg when the patient is being mechanically ventilated); mean arterial pressure, 65 mmHg; urine output, 0.5 ml/kg/hr; mixed venous saturation ($S\bar{v}O_2$), 65%. In addition, specific anatomic sites of infection with source identification should be determined so that appropriate antibiotics can be prescribed and control measures can be implemented that eliminate or reduce the spread of infection.[27,28] Fungal assays, including 1,3-β-D-glucan assay and mannan and anti-mannan antibody assays, are recommended to identify suspected fungal infection.[29] Normal saline, at least 1 L or 30 ml/kg body weight, is the initial fluid of choice and hetastarches with molecular weights >200 daltons are not recommended. Adequate and incremental fluid resuscitation is a prerequisite and should be continued to achieve perfusion; supplementation with vasopressors is recommended if the endpoints of tissue perfusion (CVP and normalized lactate levels) are not met.[29]

Pharmacologic hemodynamic support and adjunctive therapy to maintain tissue perfusion include vasoactive agents. Norepinephrine is now considered the initial vasopressor of choice.[29] Dopamine, epinephrine, phenylephrine, and vasopressin are alternatives; however, these are less preferred because of potential tachycardia, dysrhythmias, or reduction in splanchnic blood flow. Dobutamine, an inotropic agent, should be used if myocardial dysfunction is present or hypotension remains after intravascular volume and blood pressure are achieved. Similarly, intravenous corticosteroids are suggested in septic shock to help replace intrinsic loss of cortisol, but only when blood pressure remains unresponsive to volume.[27] Other supportive therapies in the treatment of severe sepsis include blood product administration to maintain hemoglobin levels between 7 and 9 g/dl, targeted tidal volume (6 ml/kg) when mechanically ventilated with plateau pressure less than 30 cm H_2O, utilization of sedation and analgesic protocols when needed, and avoidance of neuromuscular blockers if possible. Glucose concentration is to be maintained at less than 180 mg/dl. If renal dialysis is required, intermittent hemodialysis and continuous venovenous hemofiltration are considered equivalent. Bicarbonate therapy is contraindicated for the purpose of treating hypoperfusion lactic acidemia, unless the pH is <7.15. Use of deep vein thrombosis prophylaxis, such as low-dose unfractionated heparin or low-molecular-weight heparin,

or mechanical compression prophylaxis of heparin, is contraindicated. Stress ulcer prophylaxis with H2-receptor antagonists or proton pump inhibitors is indicated. Digestive tract decontamination and selective oropharyngeal decontamination are recommended in the prevention of ventilator-acquired pneumonia.[29] It is important to discuss advance directives with the individual and family.[27] Seeking to decrease use of antibiotics in the critically ill and, thus, prevent resistance to antibiotics is an important strategy in treating infection (see What's New? Procalcitonin Levels). Recent research suggests that monitoring serial procalcitonin (PCT) levels, a precursor hormone to calcitonin, may be used to shorten antibiotic use in the treatment of respiratory tract infections.[30] PCT, normally not discernible on assay, when elevated may indicate specific proinflammatory response during bacterial infection. PCT levels should not be used as an indicator to start antibiotics, but if monitored sequentially at the start of empiric antibiotics and then dropping to low levels, discontinuation may be clinically indicated.[30,31]

MULTIPLE ORGAN DYSFUNCTION SYNDROME

Multiple organ dysfunction syndrome (**MODS**) is the progressive dysfunction of two or more organ systems resulting from an uncontrolled inflammatory response to a severe illness or injury. The organ dysfunction can progress to organ failure and death. MODS occurs during severe sepsis. In 2001, an international consensus conference developed a set of definitions for sepsis and related disorders (see Table 48-1), and a predisposition-infection-response-organ (PIRO) dysfunction staging system was proposed as a template for staging sepsis (Table 48-2). MODS is the end stage of a variety of injuries that terminate in severe, generalized inflammatory response.

MODS was first recognized as a distinct clinical syndrome in the mid-1970s[32,33] when advances in resuscitation and support technologies allowed many individuals to survive life-threatening illness or trauma only to die of complications of their disease. Today MODS is a leading cause of mortality in surgical intensive care units (ICUs). Mortality for individuals with MODS increases progressively from 54% with two failing organ systems to 100% with five failing organ systems. Moreover, mortality has not improved much over the past 15 to 20 years.[34,35]

Although sepsis and septic shock are the most common causes, MODS can be initiated by any severe injury or disease process that activates a massive systemic inflammatory response by the host. Documented clinical infection is not necessary for its development. Other common triggers are severe trauma, major surgery, burns, circulatory shock, acute pancreatitis, acute renal failure, ARDS, blood transfusion, heat stroke, liver failure, mesenteric ischemia, propofol infusion syndrome, persistent inflammatory foci, DIC, and necrotic tissue (Box 48-1). MODS is the major cause of death following septic shock, trauma, burn injuries, and ARDS. People at greatest risk for developing

TABLE 48-2 PREDISPOSITION-INFECTION-RESPONSE-ORGAN (PIRO) DYSFUNCTION SYSTEM FOR STAGING SEPSIS

DOMAIN	PRESENT	FUTURE	RATIONALE
Predisposition	Premorbid illness with reduced probability of short term survival Cultural or religious beliefs Age Sex	Genetic polymorphisms in components of inflammatory response Enhanced understanding of specific interactions between pathogens and host diseases	Premorbid factors affect the potential attributable morbidity and mortality of an acute insult Deleterious consequences of insult heavily dependent on genetic predisposition (future)
Infection	Culture and sensitivity of infecting pathogens Detection of disease amenable to source control	Assay of microbial products Gene transcription profiles	Specific therapies directed against inciting insult require demonstration of characterization of that insult
Response	SIRS Other signs of sepsis Shock C-reactive protein	Nonspecific markers of activated inflammation or impaired host responsiveness Detection of specific target of therapy	Mortality risk and potential to respond to therapy vary with nonspecific measures of disease severity Specific mediator-targeted therapy is predicated on presence and activity of mediator
Organ dysfunction	Organ dysfunction as number of organs or composite score	Dynamic measures of cellular response to insult—apoptosis, cytopathic hypoxemia, cell stress	Response to preemptive therapy not possible if damage already present Therapies targeting the injurious cellular process require that it be present

MODS are older adults and persons with significant tissue injury or pre-existing disease.[18]

The PIRO system (see Table 48-2), a clinically useful sepsis staging system, stratifies individuals with disease by baseline risk of adverse outcomes and potential to respond to therapy.[18]

PATHOPHYSIOLOGY. In **primary MODS** the organ injury is directly associated with a specific insult, most often ischemia or impaired perfusion from an episode of shock or trauma, thermal injury, soft tissue necrosis, or invasive infection.[36] This decreased perfusion is local (in the injured organs themselves) and generalized. The generalized hypoperfusion in primary MODS usually cannot be detected clinically. As a result of the insult, a stress response is initiated and stress hormones—in particular, catecholamines—are released. The inflammatory and stress responses are not as evident as they are in secondary MODS. In primary MODS during the inflammatory response, presumably neutrophils and macrophages are "primed" by cytokines.[36] Any second insult, such as additional tissue injury, infection, or organ ischemia, may then activate the primed cells to produce an exaggerated response of secondary MODS[36,37] (Figure 48-8).

The progressive organ dysfunction of **secondary MODS** is the result of an excessive inflammatory reaction, after a latent period following the initial injury, in organs distant from the site of the original injury. It is postulated that the resulting organ trauma is caused by the host response to a second insult rather than being a direct result of the primary injury. Often the second insult is mild but produces an immense disproportionate response because of the previous priming of leukocytes. The interaction of injured organs then leads to a self-perpetuating inflammation.

Secondary MODS is initiated by the delayed postinjury insult as primed macrophages release a barrage of mediators, particularly the cytokines TNF and IL-1. These mediators damage the endothelium throughout the body. If a gram-negative bacterial infection is present, endotoxin released from the bacteria also causes severe damage to endothelial cells. Normal endothelial cells have little interaction with leukocytes, but when stimulated by TNF, IL-1, IL-6, or endotoxin, they change to a proinflammatory state and express adhesion molecules that mediate adhesion of neutrophils. The adhered neutrophils then migrate through the endothelium, aggregate in the area of damaged tissue, and amplify the inflammation.[3] The activated endothelial cells increase production and release of nitric oxide (endothelium), a potent vasodilator that is considered an important factor in the blood flow changes and loss of vascular tone noted in systemic inflammation.[38] The injured endothelium also becomes much more permeable, allowing fluid and protein to leak into the interstitial spaces. An important function of normal endothelium is anticoagulation. When damaged, the endothelium loses much of its ability to prevent blood clotting, allowing microvascular thrombi to develop.

The postinjury insult also activates the neuroendocrine system, resulting in a second, more extensive stress response. The normal function of the stress response is to maintain basal and stress-related homeostasis[39]; however, homeostasis cannot be maintained in MODS. In fact, the endocrine response becomes excessive and injurious. There is an early increase in the levels of circulating catecholamines that contributes to many of the clinical manifestations of MODS, such as tachycardia, hypermetabolism, and increased oxygen consumption. Cortisol, glucagon, insulin, human growth hormone, ADH (which may become depleted), and endorphin levels also are increased. Many of these hormones contribute to the extreme catabolic state of MODS, and endorphins, which are vasodilators, decrease SVR. The sympathetic nervous system, to compensate for complications resulting from the injury (e.g., fluid loss, hypotension), also is stimulated. The stimulation persists throughout the period of critical illness.[39] The stress response can be amplified by a number of factors, including pain, anxiety, psychosis, and hyperthermia. (The stress response is discussed in detail in Chapter 11.)

Because of endothelial cell dysfunction and the release of mediators, four major plasma cascades are activated: complement, kallikrein-kinin, coagulation, and fibrinolytic.[40] Complement components, particularly the anaphylatoxins C3a and C5a, cause vasodilation by stimulating release of histamine from mast cells. They also have strong chemotactic properties. C5a, especially, causes adhesion and the activation and degranulation of neutrophils. Complement is thought to be a powerful trigger for the exaggerated inflammatory response. Activation of the kinin system results in the production of bradykinin, a very potent vasodilator known to decrease SVR. Coagulation mechanisms also are activated, and because tissue injury and endothelial dysfunction are extensive, microvascular

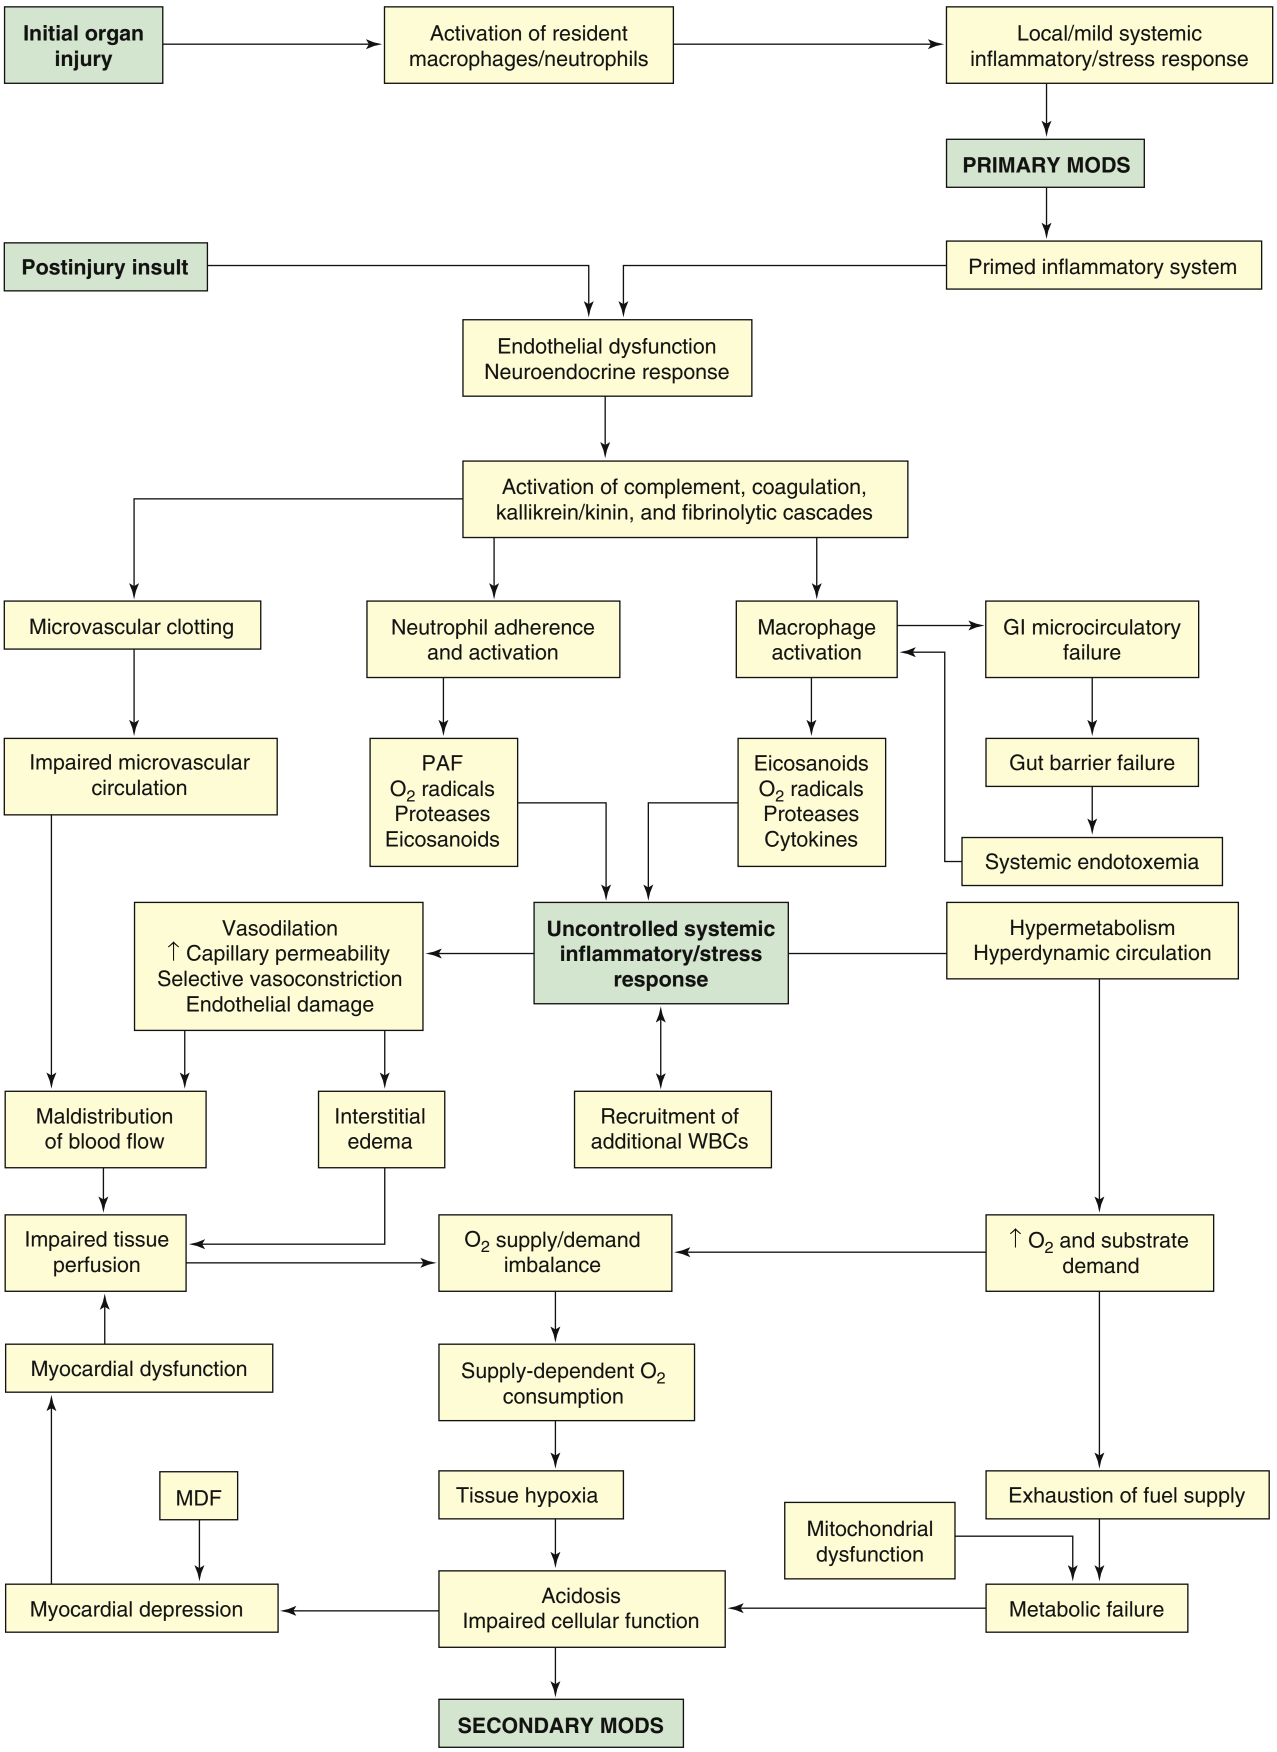

FIGURE 48-8 Pathogenesis of Multiple Organ Dysfunction Syndrome. *GI*, Gastrointestinal; *MDF*, myocardial depressant factor; *MODS*, multiple organ dysfunction syndrome; *PAF*, platelet-activating factor; *WBCs*, white blood cells.

thrombosis occurs throughout the body, resulting in impaired microvascular circulation and organ ischemia. Concurrently, fibrinolytic mechanisms are activated. The tendency toward clotting, however, is greater, resulting in a net procoagulant state that can lead to the development of DIC. The overall effect of the activation of the plasma cascades is a hyperinflammatory and hypercoagulant state that contributes to vasodilation, vasopermeability, cardiovascular instability, endothelial dysfunction, and clotting abnormalities.[41]

Once cytokines and other mediators have been released and the plasma enzyme cascades have been activated, a massive systemic inflammatory response develops. It involves several types of inflammatory cells, particularly neutrophils, macrophages, and mast cells. These cells, having been primed by their response to the initial organ injury, now pour large amounts of chemical mediators into tissues and into the systemic circulation. Neutrophils have tremendous inflammatory potential. The accumulation of activated neutrophils in organs is thought to play a key role in the pathogenesis of MODS.[42] When neutrophils adhere to the endothelium, they undergo a "respiratory burst" (oxidative burst) and release oxygen-free radicals. The respiratory burst occurs as the activated neutrophil experiences a sudden increase in oxidative metabolism, producing large quantities of highly toxic oxygen-free radicals. These reactive oxygen species (ROS) cause oxidative stress. The primary ROS produced are superoxide, hydrogen peroxide (H_2O_2), hydroxyl radical (OH^-), and singlet oxygen (O). Oxygen-free radicals are extremely damaging to vascular endothelium and tissue cells, attacking deoxyribonucleic acid (DNA), cross-linking membrane structures, and inducing membrane peroxidation—reactions that disorganize cell membranes and lead to tissue necrosis[3,24] (also see Chapter 2).

Other important mediators released by neutrophils are proteases, particularly collagenase and elastase. Proteases directly damage endothelium and neighboring cells, resulting in increased capillary permeability and organ damage. When activated, neutrophils also release platelet-activating factor (PAF), a mediator that damages endothelium, stimulates clot formation, and activates increasing numbers of phagocytes. Finally, neutrophils release arachidonic acid metabolites (eicosanoids) as a result of lipid peroxidation of their cell membranes. Of the arachidonic acid metabolites (prostaglandins, thromboxanes, leukotrienes), two are particularly important in the pathogenesis of organ hypoperfusion: prostacyclin (PGI_2) and thromboxane A_2 (TXA_2). TXA_2 is a powerful vasoconstrictor, and PGI_2 is a potent vasodilator. When released in varying amounts in different organ beds, they are largely responsible for the maldistribution of blood flow characteristic of MODS. In total, neutrophils produce at least 50 to 60 toxins.[43,44] Collectively, products released by neutrophils cause endothelial dysfunction, systemic vasodilation, selective vasoconstriction (vasoconstriction of certain organ beds or parts of organ beds), increased vascular permeability, and microvascular coagulation.

Macrophages, present in most tissues, are activated by endotoxin, complement, and monocyte chemotactic substances.[45] Macrophages share a key role in the development of the unregulated inflammation of secondary MODS with the neutrophils. Like neutrophils, they produce oxygen-free radicals, proteases, cytokines, nitric oxide, and arachidonic acid metabolites. It has been reported that excessive or prolonged stimulation of macrophages leads to the overproduction of cytokines and nitric oxide that initiate the cycle of harmful effects in MODS.[3,24,45] TNF and IL-1, which share many of the same functions and act synergistically, are the major cytokines that mediate inflammation.[45,46] TNF has potent metabolic effects, including fever, anorexia, hyperglycemia, hypermetabolism, and weight loss. It activates neutrophils, damages endothelial cells, and potentiates hypotension and shock. IL-1 also has metabolic effects, inducing fever, hypermetabolism, and muscle wasting. Normally, TNF activates cytokines, the coagulation system, fibrinolysis, and neutrophils. With the exception of neutrophil activation, IL-1 causes similar activation in individuals with cancer.[47] In the pathogenesis of MODS, the cytokines are linked to all cellular, hemodynamic, and metabolic alterations.

The gastrointestinal mucosa is particularly vulnerable to inflammatory mediators released by macrophages and neutrophils. Under normal circumstances the gut mucosa serves as a barrier to prevent bacteria from the gastrointestinal tract from entering the systemic circulation. Damage to the mucosa results in microcirculatory failure of the gut and consequent loss of the gut barrier function. The loss of intestinal barrier function leads to the systemic spread of bacteria and/or endotoxin from the gut (systemic endotoxemia). This phenomenon is called *translocation of bacteria.* The idea that the gut acts as a reservoir of bacteria and endotoxin that can initiate or perpetuate the development of MODS is known as the **gut hypothesis.** The gut hypothesis provides a possible explanation for the fact that an infectious focus is not always found in individuals with MODS. Although this hypothesis has been substantiated by animal studies and has much support, the evidence from human studies is inconclusive.[48,49]

The numerous inflammatory processes operating in MODS cause maldistribution of blood flow and hypermetabolism. **Maldistribution of blood flow** refers to the uneven distribution of flow to various organs and between the large vessels and capillary beds of the body. It is caused by generalized vasodilation, increased capillary permeability, selective vasoconstriction, endothelial dysfunction, and impaired microvascular circulation. It is a major factor in the pathophysiology of MODS.[40] The alterations in blood flow—which can occur at the cellular, organ, or regional level—lead to impaired tissue perfusion and a decreased supply of oxygen to the cells. The organs most severely affected by hypoperfusion are the lungs, splanchnic bed, liver, and kidneys. Despite supernormal systemic blood flow, oxygen delivery to the tissues decreases. Several factors contribute to the problem. First, blood is shunted past selected regional capillary beds. Shunting, caused by loss of autoregulation in some organs, may be an early indicator of progression of sepsis into MODS.[50] This occurs because inflammatory mediators, particularly TXA_2, override the normal vascular control mechanisms to cause selective vasoconstriction and because injured endothelial cells are unable to respond to normal vasodilator mediators. Second, interstitial edema, resulting from microvascular permeability, contributes to decreased oxygen

delivery to cells by increasing the distance oxygen must travel to reach the cells. Third, capillary obstruction occurs because of the formation of microvascular thrombi and the aggregation of leukocytes.[3,24,45]

Hypermetabolism, with accompanying alterations in carbohydrate, fat, and lipid metabolism, is initially a compensatory measure to meet the body's increased demands for energy. Eventually, however, hypermetabolism becomes detrimental, placing enormous demands on the heart. Hypermetabolism is the result of: (1) the neuroendocrine response to stress with the release of catecholamines and cortisol, and (2) the action of TNF and IL-1. With increased metabolism the calorie requirements are markedly increased,[34] and the cardiac output increases 1.5 to 2 times normal.[51] The alterations in metabolism affect all aspects of substrate use. Most important is the catabolism of protein, primarily of skeletal muscle and visceral organs. The extreme catabolism of protein can rapidly deplete lean body mass. Hyperglycemia occurs as gluconeogenesis by the liver increases and glucose use by the cells decreases. Fatty acids are mobilized from adipose tissue. The net result of the hypermetabolism is depletion of oxygen and fuel supplies.

Myocardial depression also accompanies MODS. The cause remains unclear, but possible explanations are the effects of myocardial depressant factor (MDF), TNF, and IL-1 on cardiac contractility; alterations in α-adrenergic receptors in the heart; and hypoxia of the myocardium.[52,53]

The decreased oxygen delivery to the cells (resulting from the maldistribution of blood flow) and the increased oxygen needs of the cells (resulting from hypermetabolism) combine to create an imbalance in oxygen supply and demand. This imbalance is critical in the pathogenesis of MODS because it results in a pathologic condition known as **supply-dependent oxygen consumption.** Ordinarily the amount of oxygen consumed by the cells depends only on the needs of the cells because there is an adequate reserve of oxygen that can be delivered if required. In MODS, however, the reserve has been exhausted and the amount of oxygen consumed becomes dependent on the amount the circulation is able to deliver. Because the amount is inadequate in MODS, the tissues become hypoxic. Compounding the hypoxic damage to cells is a phenomenon called *reperfusion injury* (see Chapter 2). Much of the organ damage in MODS occurs with the reestablishment of blood flow after a period of ischemia. During the ischemic episode, energy stores and ATP are depleted and the enzyme *xanthine dehydrogenase* is converted to *xanthine oxidase.* With reperfusion of the ischemic tissue, oxygen-free radicals are formed from oxygen by the action of xanthine oxidase, and they attack the already damaged tissues. Consequently, although reperfusion is necessary to restore oxygen supply to ischemic organs, it can increase the extent of injury. Therefore, because of supply-dependent oxygen consumption and reperfusion injury, tissues become increasingly hypoxic. The result is cellular acidosis, impaired cellular function, and ultimately multiple organ failure.

CLINICAL MANIFESTATIONS. In MODS the organs that show clinical manifestations of failure are not always the organs involved as part of the initial injury, and there is usually a lag time between the initial insult and the development of systemic organ failure. The development of primary MODS is difficult to monitor, but there is a well-established general pattern in the clinical development of secondary MODS.[36,54] Following the inciting event and aggressive resuscitation of the individual for approximately 24 hours, the individual develops low-grade fever, tachycardia, tachypnea, dyspnea, altered mental status, and a general hyperdynamic and hypermetabolic state (Box 48-2). Following this, the lungs begin to fail and ARDS may appear within 24 to 72 hours (see discussion of ARDS, Chapter 35). Between days 7 and 10, the hypermetabolic and hyperdynamic state intensifies; bacteremia with enteric organisms is common; and signs of hepatic, intestinal, and renal failure develop. During days 14 to 21, the renal failure and liver failure become more severe. Hematologic failure and myocardial failure are usually later manifestations. Encephalopathy, characterized by mental status changes ranging from confusion to deep coma, may occur at any time. This sequence can evolve rapidly, with death occurring between 14 and 21 days later, or it can evolve over weeks. Individuals can recover from either the slowly or the rapidly evolving course.

The clinical manifestations of failure of individual organs in MODS are caused by inflammatory mediator damage, tissue hypoxia, and hypermetabolism. Respiratory failure progresses early to ARDS and is characterized by tachypnea, pulmonary edema with crackles and diminished breath sounds, use of accessory muscles, and hypoxemia. Liver failure, although early in its development, is not clinically detectable until the later stages of MODS, when jaundice, abdominal distention, liver tenderness, muscle wasting, and hepatic encephalopathy appear. All aspects of metabolism, substance detoxification, and immune response are impaired. Albumin and clotting factor synthesis decreases, protein wastes accumulate, and liver tissue macrophages (Kupffer cells) no longer function effectively.

The gastrointestinal system is very sensitive to ischemic and inflammatory injury. Clinical manifestations of bowel involvement are hemorrhage, ileus, stress ulcers, malabsorption, diarrhea or constipation, vomiting, anorexia, abdominal pain, and pancreatitis. Intolerance to enteral feeding may develop. Adding to damage caused by injury to the bowel is bacterial translocation into the bloodstream resulting from the loss of the gut barrier function. The overwhelmed liver is unable to clear the bacteria from the systemic circulation. Thus, regardless of whether infection or some other injury was the precipitating cause of MODS, once intestinal bacteria enter the systemic circulation, it is likely that sepsis will be a problem. Renal failure develops at about the same time and is marked by progressive oliguria, azotemia, and edema. If renal shutdown is severe, anuria, hyperkalemia, and metabolic acidosis occur.

The first manifestations of cardiac failure are similar to those of septic shock: tachycardia, bounding pulse, increased cardiac output, fall in SVR, hypotension, warm skin, and supraventricular dysrhythmias. In the terminal stages, profound hypotension and ventricular dysrhythmias may develop. Changes in central nervous system function may be noted. Ischemia and inflammation are responsible for the changes, which include apprehension, confusion, disorientation, restlessness, agitation, headache, decreased cognitive ability and memory, and decreased level of consciousness. When ischemia is severe, seizures and coma can occur.

BOX 48-2 CLINICAL MANIFESTATIONS OF ORGAN DYSFUNCTION

Pulmonary
- Acute respiratory distress syndrome (ARDS) pattern of respiratory failure (dyspnea, patchy infiltrates, refractory hypoxemia, respiratory acidosis, abnormal O_2 indices)
- Pulmonary hypertension

Gastrointestinal
- Abdominal distention and ascites
- Intolerance to enteral feedings
- Paralytic ileus
- Upper and lower gastrointestinal bleeding (guaiac-positive stools)
- Diarrhea
- Ischemic colitis
- Mucosal ulceration
- Decreased bowel sounds
- Bacterial overgrowth in stool

Liver
- Increased serum bilirubin level (hyperbilirubinemia)
- Increased liver enzyme levels (serum aspartate transaminase [SAST], serum alanine aminotransferase [SALT], lactic dehydrogenase [LDH], alkaline phosphatase)
- Increased serum ammonia level
- Decreased serum transferrin level
- Jaundice
- Hepatomegaly

Gallbladder
- Right upper quadrant tenderness or pain
- Abdominal distention
- Unexplained fever
- Decreased bowel sounds

Metabolic/Nutritional
- Decreased lean body mass
- Muscle wasting
- Severe weight loss
- Negative nitrogen balance
- Hyperglycemia
- Hypertriglyceridemia
- Increased serum lactate levels
- Decreased serum albumin, serum transferrin, prealbumin, retinol-binding protein

Renal
- Increased serum creatinine level and blood urea nitrogen
- Oliguria, anuria, or polyuria consistent with prerenal azotemia or acute tubular necrosis
- Urinary indices consistent with prerenal azotemia or acute tubular necrosis

Cardiovascular

Hyperdynamic
- Decreased pulmonary capillary wedge pressure
- Decreased systemic vascular resistance
- Decreased right atrial pressure
- Decreased left ventricular stroke work index
- Increased oxygen consumption
- Increased cardiac output, cardiac index, heart rate

Hypodynamic
- Increased systemic vascular resistance
- Increased right atrial pressure
- Increased left ventricular stroke work index
- Decreased oxygen delivery and consumption
- Decreased cardiac output and cardiac index

Central Nervous System
- Lethargy
- Altered level of consciousness
- Fever
- Hepatic encephalopathy

Coagulation and Hematologic
- Thrombocytopenia
- Disseminated intravascular coagulation

Immune
- Infection
- Decreased lymphocyte count
- Anergy

Modified from Thelan LA et al: *Critical care nursing: diagnosis and management,* ed 6, St Louis, 2010, Mosby.

EVALUATION AND TREATMENT. Because there is no specific therapy for MODS, early detection or prevention is extremely important so that supportive measures are initiated instantly.[34] Frequent assessment of the clinical status of individuals at known risk is essential. Unfortunately, there is no way to determine with certainty when an organ is failing. Indicators of organ dysfunction are presented in Table 48-1.

Several systems for scoring severity of illness also have been developed. Commonly used systems are the **Acute Physiology and Chronic Health Evaluation II and III (APACHE II and APACHE III),** the logistic organ dysfunction score (LODS), the sequential organ failure assessment (SOFA), the MODS score, and the PIRO staging system.[55] Once organ failure develops, monitoring of laboratory values and hemodynamic parameters is necessary to assess the degree of clinical impairment.

The therapeutic management of MODS consists of prevention and support. Prevention of the syndrome is essential! First, if possible, the initial source of inflammation must be eliminated or controlled. Next, a second insult must be avoided. It is paramount to remove any potential site of infection by débriding necrotic tissue, draining abscesses, reducing the numbers of invasive procedures performed, and removing hematomas. Nosocomial infections from contaminated lines and catheters are of concern and must be prevented. Nosocomial infection rates of 15% to 25% have been reported in critically ill individuals.[56] Early reduction of long-bone fractures and surgical repair of injured tissues are also important preventive measures.

The goals of therapy are to control infection, provide adequate tissue oxygenation, restore intravascular volume, and support the function of individual organs.[26] After the initial

injury has been aggressively treated and sources of infection have been removed, antibiotics generally are administered. The choice of agents is based on the individual's disease process, but the regimen is usually a combination of antibiotics that covers both gram-negative and gram-positive organisms.

Because oxygen is not stored in the tissues, it must be continuously delivered. Maintaining an arterial oxygen saturation of 88% to 92% is recommended,[26] and hemoglobin levels should be kept greater than 9 g/dl.[26] Mixed venous oxygen saturation greater than or equal to 70% is recommended. Blood transfusions may be necessary to ensure an adequate hemoglobin level. To deliver oxygen to the organs in the face of profound systemic vasodilation, fluid volume must be restored. Therefore, aggressive fluid therapy is initiated early. Usually large volumes of isotonic crystalloid solutions are administered, although colloids (often albumin) also may be added to maintain adequate preload and circulation volume.[26]

Finally, support for individual organ systems must be provided. Respiratory failure is treated with mechanical ventilation with low tidal volumes, high oxygen concentrations, and positive end-expiratory pressures (PEEP).[57] To provide adequate nutrition and metabolic support, the failing gastrointestinal system is supported with enteral feedings. It is now well recognized that enteral feedings help preserve gut microbial barrier function, and thus are preferred to parenteral feedings.[58] However, if the individual is unable to tolerate the amount of enteral feeding required to meet the enormous metabolic demands, hyperalimentation may be added. Ideally the feeding formula is carefully calculated to meet the individual's nutritional requirements. Tight glucose level control (80 to 110 mg/dl) is recommended.[59] Once renal failure is established, dialysis or continuous hemofiltration may be required to maintain fluid and electrolyte balance. To support the failing cardiovascular system, inotropic drugs, such as low-dose dopamine and dobutamine, or vasopressors, such as norepinephrine, may be required to maximize cardiac contractility and maintain cardiac output. Although steroids have anti-inflammatory effects, their use is controversial because they have been shown to be effective in adults with septic shock. Obtaining an adrenocorticotropic hormone (ACTH) level is not recommended. Deep vein thrombosis prophylaxis is also important.[6]

Scientific knowledge gained about MODS and inflammatory mediators has led to many investigational therapies. Novel molecular approaches targeting a variety of interdependent mediators of MODS are being investigated.[47]

BURNS

Major thermal injury is a source of massive tissue injury and destruction that has wide-reaching effects on virtually all organ systems. **Burn** is a generic term used to describe cutaneous injury resulting from thermal, chemical, or electrical environmental causes. In addition to cutaneous injury, burns are often associated with smoke inhalation injury or other traumatic injuries that aggravate the local and systemic problems of burns. Pulmonary injury, both primary and secondary, is common and often necessitates ventilator support. The use of tracheostomy also has been examined and is controversial.[60,61] This model of multisystem injury provides an opportunity to examine the interaction of shock, inflammation, and immunocompromise in a clinical setting.

Epidemiology and Etiology

The annual number of burns and fire-related injuries that occur in the United States is now estimated to be about 450,000.[62] Deaths consequent to these injuries have decreased more than 50%—from 9000 in 1971[63] to 4000 in 2005.[62] This remarkable progress is the result of several factors, including ongoing research in burn physiology and burn care,[64] an increased national focus on fire safety and burn prevention, the establishment of regional burn centers, the use of smoke detectors, regulation of consumer product safety, and the implementation of occupational safety mandates. A decrease in hospitalization reflects a shift to outpatient care and improved prehospital and emergency treatment, but burn assessment and delivery of care can be improved[65] to reduce medical transport and treatment costs. International interest in telemedicine has increased over the past decade.[66,67] These advances in care are changing emphasis from survival to outcomes in burn survivors.[68,69]

The causes of burn injury may be **thermal** or **nonthermal,** such as chemical, electrical, or radioactive. Thermal burns may result from thermal contact, flame, or scald. Adherent materials (e.g., asphalt, tar, or plastic) may likewise produce a serious contact burn. Chemical injuries are a result of contact with substances that are directly toxic to skin or the lining of the respiratory or alimentary tract. Such chemicals are often acid, alkali, or organic agents, termed **vesicants,** that cause blistering of the epithelial surfaces. Electrical burns may be the result of the conduction of electrical current through the body with heating of tissue or flash over the body surface associated with an electrical discharge. Quality of life can be affected but, by self-reports, may exceed normal population averages with proper intervention.[70]

Burn Wound Depth

The classification of **burn wound depth** is usually based on the physical appearance and the symptoms associated with the affected skin. The definitive diagnosis is determined by the histologic depth of tissue necrosis. Such evaluation, unfortunately, necessitates a skin biopsy. Because of the invasive nature of biopsy, clinical depth assessment is used and the ultimate fate of the wound determines final diagnosis. Recent advances in laser Doppler technology have resulted in extensive exploration of a noninvasive means for burn wound depth assessment.[71-83]

First-degree burns are a **partial-thickness injury** involving only the epidermis without injury to the underlying dermal or subcutaneous tissue (Table 48-3). The skin maintains water vapor and bacterial barrier functions. Many sunburns are first-degree injuries caused by exposure of skin to ultraviolet radiation from the sun. Initially there is local pain and erythema, but no blisters appear until after about 24 hours. An extensive first-degree burn may cause systemic responses such as chills, headache, localized edema, and nausea or vomiting. No treatment of extensive first-degree burns is required unless the person is

TABLE 48-3 **DEPTH OF BURN INJURY**

		SECOND DEGREE		THIRD DEGREE
CHARACTERISTIC	**FIRST DEGREE**	**SUPERFICIAL PARTIAL THICKNESS**	**DEEP PARTIAL THICKNESS**	**FULL THICKNESS**
Morphology	Destruction of epidermis only	Destruction of epidermis and some dermis	Destruction of epidermis and dermis, leaving only skin appendages	Destruction of epidermis, dermis, and underlying subcutaneous tissue
Skin function	Intact	Absent	Absent	Absent
Tactile and pain sensors	Intact	Intact	Intact but diminished	Absent
Blisters	Present only after first 24 hr	Present within minutes, thin walled and fluid filled	May appear as fluid-filled blisters; often is layer of flat, dehydrated "tissue paper" that lifts off in sheets	Blisters rare; usually is a layer of flat, dehydrated "tissue paper" that lifts off easily
Appearance of wound after initial debridement	Skin peels at 24-48 hr, normal or slightly red underneath	Red to pale ivory, moist surface	Mottled with areas of waxy white, dry surface	White, cherry red, or black; may contain visible thrombosed veins; dry, hard leathery surface
Healing time	3-5 days	21-28 days	30 days to many months	Will not heal; may close from edges as secondary healing if wound is small
Scarring	None	May be present; low incidence influenced by genetic predisposition	Highest incidence because of slow healing rate promoting scar tissue development; also influenced by genetic predisposition	Skin graft; scarring minimized by early excision and grafting; influenced by genetic predisposition

elderly or an infant, in which case severe nausea and vomiting may lead to inadequate fluid intake and dehydration. Therapy consists of intravenous hydration until the nausea and vomiting subside 24 to 72 hours after burn injury. Comfort measures for previously healthy children or adults with extensive first-degree burns consist of aspirin for adults or acetaminophen for children every 4 hours in age-appropriate doses and frequent application of a water-soluble lotion. First-degree burns heal in 3 to 5 days without scarring.

Second-degree burns describe two categories of burn depth with markedly different characteristics. Both of these are partial-thickness injuries, but they evoke vastly different responses. The hallmark of **superficial partial-thickness injury** is the appearance of thin-walled, fluid-filled blisters that develop within just a few minutes after injury. Another dominant characteristic of superficial injury is pain. As blisters break or are removed, nerve endings are exposed to air (Figure 48-9). Tactile and pain sensors remain intact throughout healing, with each wound care procedure causing substantial pain. Wounds heal in 3 to 4 weeks if the individual is adequately nourished and no complications develop (Figure 48-10). Scar formation is unusual with this injury. The amount of scarring that develops is a genetically determined trait and is not predictable during the early course of treatment.

FIGURE 48-9 Superficial Partial-Thickness Injury. Scald injury following débridement of overlying blister and nonadherent epithelium. (Courtesy Intermountain Burn Center, University of Utah.)

Deep partial-thickness burns involve the entire dermis, sparing skin appendages such as hair follicles and sweat glands (see Table 48-3). The burn often looks waxy white and is surrounded by margins of superficial partial-thickness injury. The injury is often clinically indistinguishable from a full-thickness injury (Figure 48-11), but by 7 to 10 days after burn injury, skin buds and hair will appear from hair follicles, indicating that skin appendages remain. These wounds take weeks to heal, and current therapy consists of surgical removal of the burn wound (excision) followed by application of the person's own unburned skin from another body area (autograft). Wounds that heal slowly produce more scar tissue and continue to be a potential source of infection until closed. In the presence of relative surgical contraindications, such as cardiopulmonary failure, deep partial-thickness wounds are not surgically treated but are allowed to heal primarily. The fate of partial-thickness burns can be affected by treatment, such as topical antibiotics, or by the condition of biologic membranes.[84] The ultimate healing of deep partial-thickness burns commonly results in hypertrophic scarring with poor functional and cosmetic results.

Third-degree burns, or **full-thickness injuries,** involve destruction of the entire epidermis, dermis, and often the underlying subcutaneous tissue (see Table 48-3). On occasion, all

underlying subcutaneous tissue is destroyed and muscle or bone may be involved. Full-thickness wounds often appear relatively innocuous when their color is white and the delineation between normal and burned skin is not accompanied by a marked color change. Elasticity of the dermis is absent, leaving the wound dry and leathery in appearance and texture (Figure 48-12). As marked edema develops, distal circulation may be compromised in areas of circumferential burns. **Escharotomies** (cutting through burned skin) are performed to release underlying pressure. Full-thickness burns are painless because all nerve endings have been destroyed by the injury.

The extent of the **total body surface area (TBSA)** burn is estimated using either the "rule of nines" (Figure 48-13) or the Lund and Browder chart (Figure 48-14). Areas of partial-thickness and full-thickness injury are marked on the diagram in Figure 48-14. First-degree burns are not included in the TBSA estimate. The surface area of the palm, including palmar finger surface, averages 1% of the body surface area over a wide range of ages; thus it can be used to estimate burn areas of irregular size and shape.[85]

Severity of burn injury is a combination of many factors, including age, medical history, extent and depth of injury, and body area involved. The American Burn Association has defined criteria to assist healthcare professionals in identifying individuals who require care at a specialized burn center (Box 48-3). The multidisciplinary burn center is recommended for those persons who are at high risk for morbidity, mortality, or permanent functional loss.

PATHOPHYSIOLOGY AND CLINICAL MANIFESTATIONS. Burn injury results in dramatic changes in many physiologic functions of the body within the first few hours after the event. The effect of burn depends on two factors: first, the extent of body surface involved and, second, the depth of cutaneous injury. Body surface burn extent is described by the percentage of TBSA injured. Burns exceeding 20% of TBSA in most adults are considered to be major burn injuries and are associated with massive evaporative water losses and flux of large amounts of fluid and electrolytes in the tissues, manifested as generalized edema and circulatory hypovolemia. Depth of cutaneous injury has been categorized in many ways but always depends on the severity of injury of epidermal and dermal elements of the skin and whether the alteration is a permanent or reversible injury.

With a major burn injury, a systemic pathophysiology ensues that requires therapeutic intervention to sustain life. The immediate (acute) physiologic consequences of a major burn injury

BOX 48-3 BURN UNIT REFERRAL CRITERIA

A burn unit may treat adults or children or both.

Burn injuries that should be referred to a burn unit include the following:

1. Partial-thickness burns greater than 10% total body surface area (TBSA)
2. Burns that involve the face, hands, feet, genitalia, perineum, or major joints
3. Third-degree burns in any age group
4. Electrical burns, including lightning injury
5. Chemical burns
6. Inhalation injury
7. Burn injury in individuals with pre-existing medical disorders that could complicate management, prolong recovery, or affect mortality
8. Any patients with burns and concomitant trauma (such as fractures) in which the burn injury poses the greatest risk of morbidity or mortality. In such cases, if the trauma poses the greater immediate risk, the patient's condition may be initially stabilized in a trauma center before being transferred to a burn center; physician judgment will be necessary in such situations and should be in concert with the regional medical control plan and triage protocols.
9. Burned children in hospitals without qualified personnel or equipment for the care of children
10. Burn injury in patients who will require special social, emotional, or long-term rehabilitative intervention

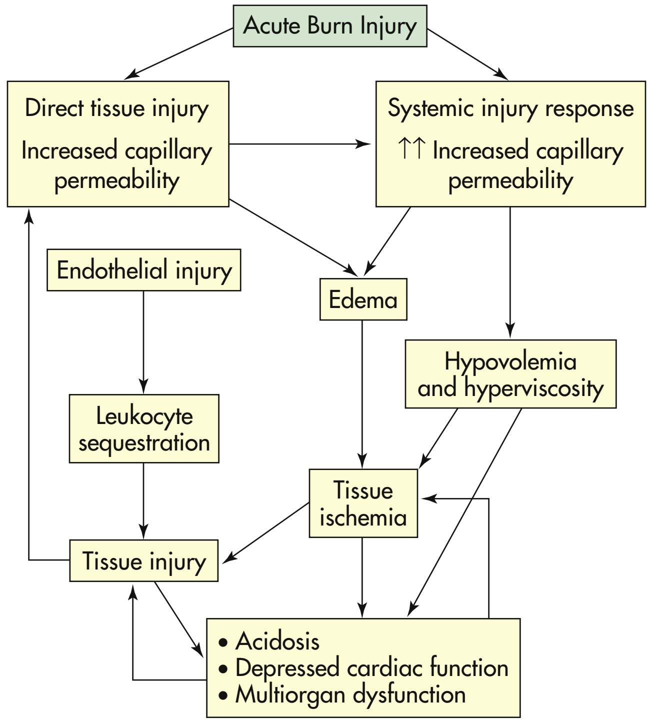

FIGURE 48-15 Immediate Cellular and Immunologic Alterations of Burn Shock.

center around the profound, life-threatening hypovolemic shock that occurs in conjunction with cellular and immunologic disruption within a few hours of injury (Figure 48-15). **Burn shock** is a phenomenon consisting of both a hypovolemic cardiovascular component and a cellular component.

Hypovolemia associated with burn shock results from massive fluid losses from the circulating blood volume. The losses are caused by an increase in capillary permeability that persists for approximately 24 hours after burn injury. **Fluid resuscitation** is the administration of intravenous fluids, such as lactated Ringer solution, in an effort to restore the circulating blood volume during the period of increasing capillary permeability. In addition to hypovolemia, most other organ systems are affected. Cardiac contractility is diminished during the initial 24-hour resuscitation period with shunting of blood away from the liver, kidney, and gut. This is often termed the *ebb phase* of the response to trauma and can be seen with other severe injuries. Normal blood volume does not result in restoration of normal cardiac output because of a phenomenon known as *myocardial depression*. The decrease in perfusion of viscera results in a decrease in their function. This may be an explanation for decreased gut barrier function seen in thermal injury.[86] Other mechanisms include hypoxia and inflammation with histologic damage of intestinal mucosa.[87]

There also is evidence that cellular metabolism is disrupted when the burn wound is created, resulting in altered cell membrane permeability and loss of normal electrolyte homeostasis. This cellular defect may be the pathophysiologic process responsible for the genesis of burn shock. There are numerous circulating factors in burn serum that may play a role in these cellular processes. Although the cardiovascular and systemic responses are intricately interwoven into the cellular response, these responses are presented here as discrete entities for purposes of description.

Cardiovascular and Systemic Response to Burn Injury

The clinical manifestations of burn shock are the result of more than simple loss of extracellular fluid at the burn wound site. Hypovolemia and numerous local mediators in the burn wound,[88] as well as systemic signals, result in alteration of cellular function throughout the body. The restoration of normal intravascular volume with either saline solutions or colloid materials (e.g., albumin, blood, or dextrans) does not reverse changes such as increases in pulmonary vascular resistance or myocardial contractility.[89] This is reflected in cardiac output with precipitous decreases that often result in inadequate perfusion of most tissues at the capillary level, which is the hallmark of burn shock. Fluid infusion, likewise, does not return cardiac output to preburn levels.[90,91] These findings led to the postulation of a specific myocardial depressant factor (MDF).[92-94] Other causes also have been suggested, such as reactive oxygen-free radicals that attack cell membranes and other subcellular organelles as a result of first ischemia and then reperfusion of tissues during burn shock and resuscitation.[95] A third factor may be the level of nitric oxide after burn injury, which could have a direct myocardial depressant effect.[96,97] The relationship of nitric oxide and myocardial function is not yet totally clear. Gamelli and colleagues[98] found nitric oxide production to be significantly depressed in burned individuals who did not survive their injuries. They postulate that nitric oxide may scavenge reactive oxygen-free radicals and protect tissues from oxidative injury.

TABLE 48-4 ELECTROLYTE CONTENT OF RINGER LACTATE SOLUTION AND EXTRACELLULAR FLUID

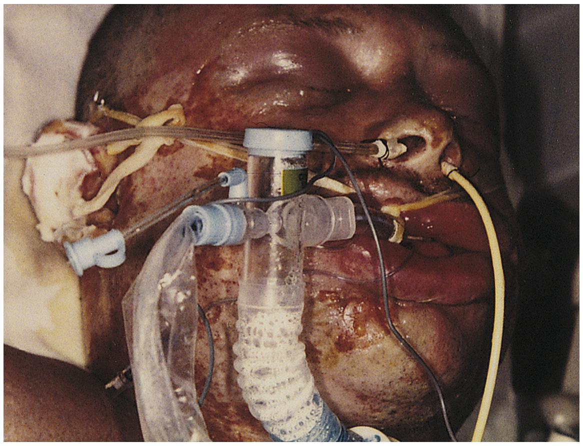

FIGURE 48-16 **Edema Related to Burn Injury.** Superficial facial burns can result in marked swelling, requiring prompt endotracheal intubation to maintain the airway. (Courtesy Intermountain Burn Center, University of Utah.)

Regardless of the contribution of these mechanisms, fluid resuscitation eventually results in improved outcome of the massively burned person. This resuscitation involves infusion of intravenous fluid at a rate faster than the loss of circulatory vascular volume for a period of about 24 hours from the time of burn injury, and may require up to 30 L in a major burn. Resuscitation from burn shock can be accomplished using any of a number of infusion protocols. The most frequently used protocol is the Parkland formula.[99] Lactated Ringer solution is used because it closely approximates extracellular fluid, the repository of fluid leaving the circulatory system during this phase of extensive edema formation (Table 48-4). The use of electrolyte-free fluids, such as D_5W (dextrose 5% in water), results in life-threatening hypovolemia and hyponatremia. Resuscitation with hypertonic saline has been used in some medical centers but is reserved for special circumstances; its use can result in adverse outcomes.[100]

The massive edema associated with burn shock is inevitable with fluid resuscitation, and failure to administer resuscitation fluid results in irreversible hypovolemic shock and death. The edema occurs in unburned as well as burned areas (Figure 48-16). This often leads to mechanical airway obstruction, necessitation of tracheal intubation, and increased severity of the interstitial pulmonary edema associated with inhalation injury.

The most reliable criterion for adequate resuscitation of burn shock is urine output. The individual is in hypovolemic shock and will, as a compensatory mechanism, decrease or stop urine output in an effort to preserve circulation volume. The adult receiving sufficient intravenous fluids will excrete urine amounting to 30 to 50 ml/hr; children will produce 1 ml/kg/hr. If the individual does not have adequate urine output, it often indicates inadequate fluid resuscitation. The massive amount of intravenous fluid required by burned individuals during the shock phase is often intimidating to the person unfamiliar with burns. One common concern is that massive fluid administration will result in pulmonary edema. It should be remembered that the individual is in hypovolemic shock and that fluid is lost dramatically during the resuscitation period through third spacing, exudation, and evaporation.

BOX 48-4 MAINTENANCE FLUID REPLACEMENTS AFTER MAJOR BURN INJURY*

1. *Basal fluid* replacements per day
   1500 ml/day/m^2 body surface area = 24-hour requirements
2. Evaporative water loss from burn wound
   a. Adults: 25 + % total body surface area burn ((m^2 body surface area) = ml/hr
   b. Children: 35 + % total body surface area burn (m^2 body surface area) = ml/hr
3. Total hourly maintenance fluids
   Basal fluid requirements per day ÷ 24 hours + evaporative water loss per hour = ml/hr maintenance fluids
   Example: A 70-kg adult with a 50% total body surface area burn and a body surface area of 2 m requires the following:
   - Basal = (1500 ml/day) (2 m^2 body surface area) = 3000 ml/24 hr, or 125 ml/hr
   - Evaporative = (25 + 50% total body surface burn)
   - (2 m^2 total body surface area) = (75) (2) = 150 ml/hr
   - Total maintenance fluids = 125 ml + 150 ml = 275 ml/hr

*From end of burn shock until wound closure is achieved.

The endpoint of burn shock is defined as the state in which the individual is able to maintain adequate urine output for 2 hours with the intravenous fluid administration rate equal to the individual's calculated maintenance rate (Box 48-4). As burn shock ends, fluid administered remains in the circulating volume and is reflected as an increase in urine output. The mechanism whereby capillary integrity is restored is unknown but usually occurs about 24 hours after burn injury (Figure 48-17). After the individual has reached the endpoint of burn shock, the term used to describe the vascular status of the individual is **capillary seal.** In individuals with large burns, colloid-containing fluids may be given to help maintain oncotic pressure during the resuscitation phase and afterward to enhance the mobilization of interstitial fluid and diuresis.[101] Efforts to decrease burn edema and fluid resuscitation volumes can involve the use of hypertonic fluid resuscitation as well.[102]

Cellular Response to Burn Injury

In addition to capillary endothelial permeability changes resulting in vascular fluid losses, transmembrane potential changes occur in cells not directly damaged by heat. The normal potential of −90 mV decreases to nearly −70 mV, with an increase in intracellular sodium and water. Such membrane potential

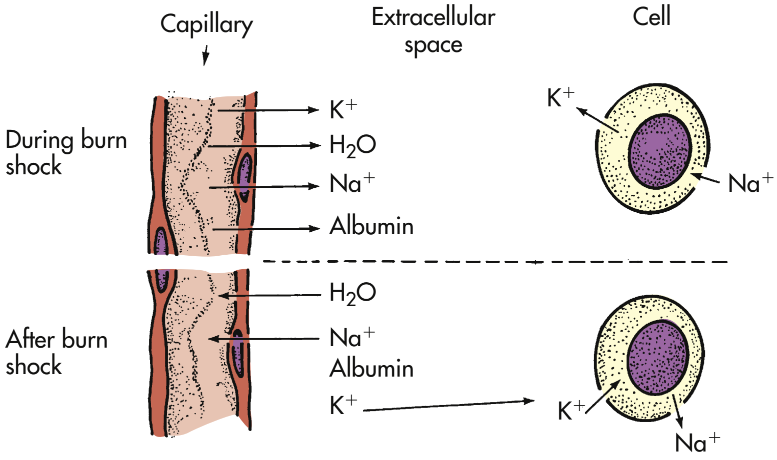

FIGURE 48-17 Direction of Fluid and Electrolyte Shifts Associated with Burn Shock. (Courtesy Intermountain Burn Center, University of Utah.)

changes may be caused by a circulating shock factor.[103] Apoptosis is central to the cellular responses to burn injury.[104] Other changes can be categorized as: (1) a metabolic response to the burn injury or (2) an immunologic response to the burn injury.

Metabolic Response. The metabolic changes after a burn injury were described in 1967 by Welt and associates as "sick cell syndrome."[105] This was considered to be a cell membrane transport defect related to an alteration in the steady-state composition characterized by high intracellular concentrations of sodium. Trunkey and colleagues[106] found a marked decrease in primate muscle extracellular water and an increase in intracellular sodium and water during hypovolemic shock. In addition, other researchers demonstrated an associated decrease in resting membrane potential, a decrease in amplitude of the action potential, and a prolongation of the repolarization and depolarization times in association with a decreased intracellular potassium concentration.[107,108] The cellular dysfunction of burn injury extends beyond the transmembrane potential disruption and the sodium-potassium pump impairment to include a loss of intracellular magnesium and phosphate[109] and elevated serum lactic acid dehydrogenase (LDH) levels.[110] Thus impairment of basic cellular function may be the underlying cause of the diminished membrane potentials. The data suggest a decrease in the efficiency of the pump. The failure of rapid intravascular volume repletion to restore membrane potential completely suggests other pathways for cellular metabolic derangement.[111]

Metabolic reactions to the stress of a major burn injury involve the response of the sympathetic nervous system and other homeostatic regulators. Catecholamines are found in elevated amounts in both the serum and urine of burned individuals. Cortisol, glucagon, and insulin levels are elevated, with a corresponding increase in gluconeogenesis, lipolysis, and proteolysis. Changes in lipid metabolism are reflected as an elevation in the levels of plasma free fatty acids (FFAs) and a decrease in the levels of plasma cholesterol and phospholipids.[112] Herndon and colleagues found that the use of propranolol, a nonselective beta$_1$- and beta$_2$-blocker, could decrease symptoms of the hypermetabolic, hypercatabolic, and osteopenic responses in pediatric patients, including a decrease in heart rate and lipolysis.[112a] Glucose and lactate kinetics are altered after burn injury. Although tissue hypoxia produces lactic acidosis, its persistence in the presence of adequate tissue perfusion suggests an increased rate of glycogenolysis.[113]

Burn injury induces a hypermetabolic state that persists until wound closure. Wilmore and colleagues[114] described the hypermetabolic state of 20 burned individuals as unrelated to ambient temperatures, with persistent elevation of core body temperatures. The metabolic rate increased with burn size in a curvilinear relationship, with oxygen consumption rarely exceeding two times basal levels. Evaporative water loss and surface cooling are not the primary stimulus for the hypermetabolic state; rather, the hypermetabolism is related to an increase and resetting of the thermal regulatory set point. A core body temperature of 38.5° C (101.3° F) is typical. A reflex arc mobilizes neural or hormonal afferent stimuli to the hypothalamus, producing a catecholamine response clinically manifested as hypermetabolism, hyperthermia, and hyperglycemia.

Evidence also exists that the burn wound itself directly mediates the response to injury at both the local and system levels. Cytokines, oxygen-free radicals, chemotactic substances, and eicosanoids contribute to the systemic inflammatory response and hypermetabolic state. The inflammatory response to the wound level is magnified into a generalized systemic inflammatory response that is often deleterious.[115-117] Vasodilation, increased capillary permeability, and edema occur to facilitate healing of the local area. The distribution of the peripheral circulation after burn injury transports heat and glucose preferentially to the wound. The energy cost of these reparative and transport processes is reflected in the increased metabolism and hyperdynamic circulation.

The extensive evaporative water loss that occurs in burn tissue is a heat-consuming process, and the energy of evaporation is provided by increased visceral heat production. The signal for the response is unknown because individuals whose wounds have been denervated continue to have a **posttraumatic hypermetabolic response.** Hypothalamic function alterations result in the elevation of human growth hormone (hGH) serum levels in the presence of hyperglycemia, a finding opposite that

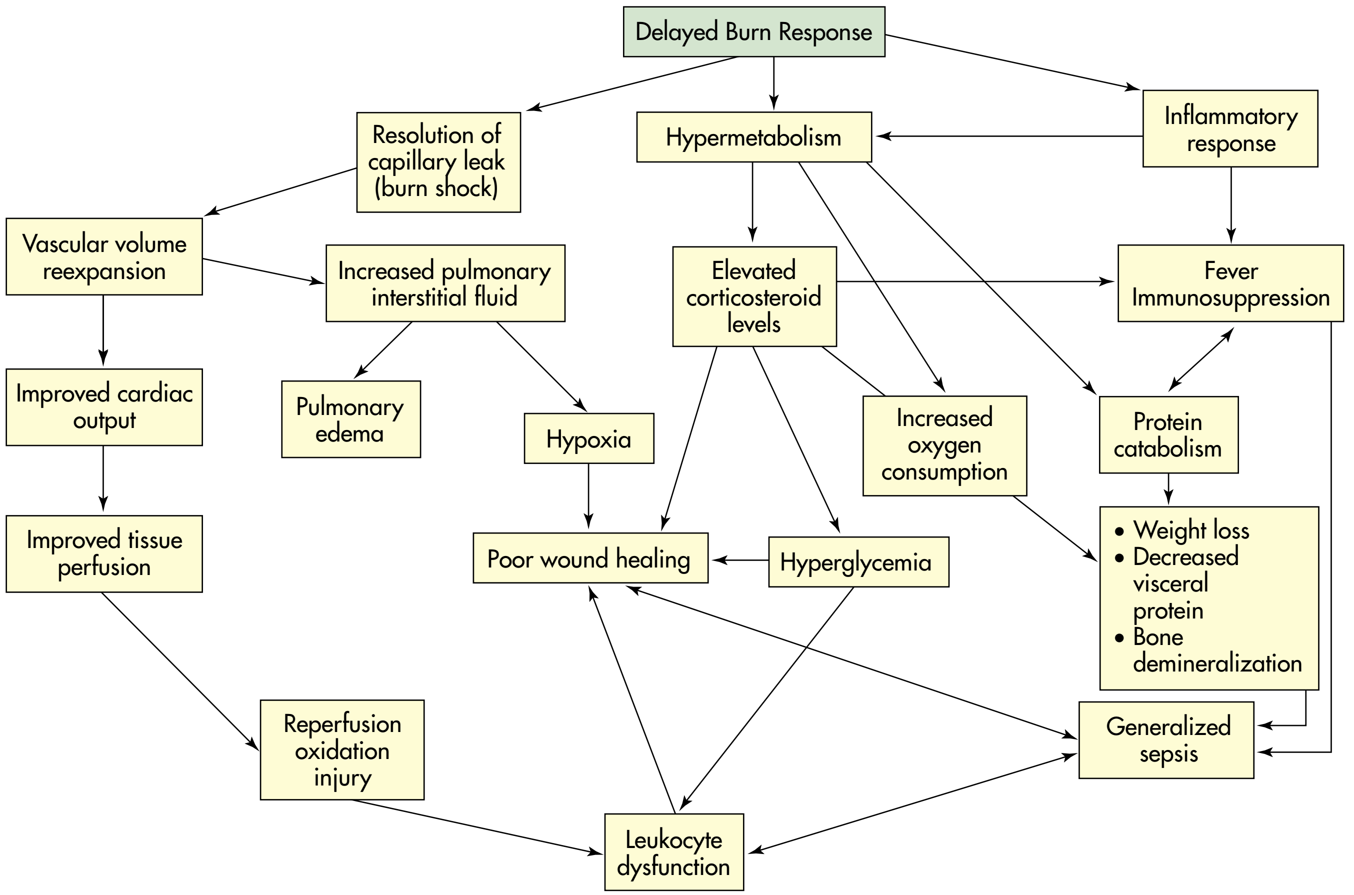

FIGURE 48-18 Physiologic Alterations in Inflammatory Burn Injury Response.

in normal states.[114] Further, the hypermetabolic rate is not decreased during rest, sleep, or warmth.

Evidence of hepatic response to burn injury is characterized by alterations in the clotting factors.[118] A hypercoagulable state develops as manifested by an elevated plasma fibrinogen concentration in the presence of shortened prothrombin time (PT) and activated partial thromboplastin time (PTT).[119]

In summary, extensive burn injury initiates the most marked alterations in body metabolism associated with any illness (Figure 48-18). Much of the work explaining this response has been conducted by Wilmore,[120,121] who reported that the persistent tachycardia, hyperpnea, hyperpyrexia, and marked body wasting seen in burn injury reflect heightened metabolic activity and accelerated body catabolism. The development of decreased bone density can last long after discharge from the hospital.[122] These system alterations occur as a result of the cutaneous inflammatory process and are thought to facilitate wound repair. The neural component of this alteration is in response to a sympathetic reaction that releases catecholamines in large amounts.

Immunologic Response. The immunologic response to burn injury is immediate, prolonged, and severe. The result in individuals surviving burn shock is immunosuppression with increased susceptibility to potentially fatal systemic burn wound sepsis.

Several cytokines have been identified in the immediate postburn period. IL-1 (interkeukin-1) is detected in the serum of burned individuals. The level of IL-1 correlates inversely with burn survival; low levels may be associated with a higher mortality.[123] Fatal burn injury has often shown decreased levels of IL-2, which may result in decreased T helper 1 (Th-1) lymphocytes. Th-1 cells produce IL-2, interferon-gamma, and TNF, which help to initiate cellular immunity and immunoglobulin G (IgG) production. IL-4 is elevated after burn injuries and causes a shift in the T helper cell production from Th-1 to Th-2 lymphocytes. Th-2 cells secrete IL-4 which promotes further conversion of nonspecific Th cells to Th-2 cells. Th-2 cells also produce other cytokines and antibodies.[124] IL-6 levels increase quickly after burn injury and remain elevated for several weeks. The level of IL-6 correlates with the extent of burn injury.[125] IL-6 and platelet-activating factor (PAF) activates polymorphonuclear neutrophils (PMNs) causing infiltration of neutrophils into burned tissue and adhesion to vascular endothelial surfaces.[126,127] IL-8 levels are elevated after burn injury, with significantly greater elevations in individuals with a TBSA burn of 40% or higher. IL-8 activity may play a role in the strong and persistent activation of neutrophils noted in people with large burns.[128] Burn blister fluid contains large amounts of IL-6 and IL-8 in addition to substances such as epidermal growth factor, platelet-derived growth factor, and TGF.[129]

Macrophages, platelets, neutrophils, and vascular endothelial cells release prostaglandins and leukotrienes, which are the byproducts of arachidonic acid metabolism. These chemical

mediators cause peripheral vasodilation, pulmonary vasoconstriction, increased capillary permeability, and local tissue ischemia in the burn wound.

A host of chemicals found in burn plasma in altered concentrations also may play a role in burn shock. These include vasoactive amines (histamine, serotonin), products of complement activation (C3a, C5a), prostaglandins, kinins, endotoxin, and metabolic hormones (catecholamines, glucocorticoids). A decrease in complement components C3a and C5a in the circulation after burn injury suggests a nonspecific activation of the complement system.[130] Activation of the complement system in injured tissue results in an inflammatory response caused by release of histamine and serotonin by C3a and C5a, because histamine and serotonin alter capillary permeability and participate in the mechanism of burn shock along with kinin polypeptides and other chemical mediators. Prostaglandins function in the inflammatory process by regulating metabolism of cells of inflammation (see Chapter 7).

Burn shock can induce changes in the integrity of the intestinal wall, facilitating bacterial translocation and endotoxemia.[131] Bacterial translocation from the gut may be a mechanism of infection leading to septic shock after burn injury and other major trauma.[132] Circulating endotoxin is correlated with the development of MODS and death after major burn injury.[133]

White blood cells are also altered at this time, when their need to inhibit sepsis is vital. Natural resistance to infection in burn wounds is a function of the nonspecific immune system; that is, resistance to microorganisms that infect wounds rests almost solely on the ability of phagocytic cells (i.e., granulocytes, macrophages) to leave the bloodstream, migrate to the site of infection, and ingest and kill microorganisms.[134] Opsonins normally render bacteria susceptible to phagocytosis but the burn injury triggers a consumptive opsoninopathy. Burn serum contains an inhibitor of C3 conversion that leads to decreased opsonization and polymorphonuclear (PMN) dysfunction.[135,136]

Individuals with altered immunocompetence before burn injury are at additional risk for complications. Opportunistic infections, such as fungal sepsis, can increase a hospital stay and ICU costs.[137] Included in this group are individuals at the extremes of age and those with cardiac disease, malnutrition, immunodeficiency disease, and a history of alcohol or drug abuse.[138,139] Additional risk factors include diabetes mellitus and pulmonary or renal dysfunction.

Evaporative Water Loss

One of the major purposes of intact skin is to serve as a barrier to evaporative water loss (EWL) from the body. With major burn injury, this ability of the skin to regulate evaporative water loss is totally disrupted. In a classic 1962 study, Moncrief and Mason[140] attempted to determine the magnitude of such a loss and determined that daily evaporative water loss was in the range of 20 times normal in the early phase of injury, with gradual decreases as wound closure is achieved. Further studies indicated that insensible water loss through burned skin is not from evaporation of water from sweat glands but rather from water vapor formed within the body and lost through the skin.[141,142]

Calculation of the amount of fluid lost by evaporative water loss includes losses from all sources. Normally the skin is the

FIGURE 48-19 **Hypertrophic Scarring.** Deep partial-thickness thermal injury can result in extensive hypertrophic scarring. (Courtesy Intermountain Burn Center, University of Utah.)

major source of insensible loss (75%) and the lungs are minor sources (25%), with a total loss of only approximately 600 to 800 ml/day. This changes dramatically with burns, because not only does skin loss increase but also lung loss increases by hypermetabolism and hyperventilation, especially in an intubated individual. Total evaporative losses exceed many liters per day in an adult with large burn wounds. Replacement of the loss is mandatory to prevent volume deficit.

EVALUATION AND TREATMENT. Burn recovery can be long and difficult, with complications often the rule rather than the exception. The goal of burn management is wound closure in a manner that promotes survival. Scar formation with contractures is often a consequence of healing in deep partial-thickness and full-thickness burns (Figure 48-19; see also Figure 48-10). Assessment of tissue viability can be difficult in complex extremity injury; pyrophosphate nuclear scanning can assist in evaluation.[143] Early intervention may have effects on tissue survival as is evident in the zone of stasis and application of cerium nitrate.[144] The advancement in survival and outcome can be as simple as using antibiotic catheters to reduce catheter-associated bloodstream infections[145] or better glycemic management during ICU treatment.[146] Advances in care systems have shown the value of advanced practice nurses in a collaborative role in the burn ICU and emergency departments.[147]

The three essential elements of survival of major burn injury are: (1) meticulous wound management, (2) adequate fluids and nutrition, and (3) early surgical excision and grafting. Current therapy for deep partial- and full-thickness burn injury includes surgical removal of the burn tissue (excision) followed by grafting of the person's unburned skin (autograft) onto the excised wound. Techniques of early wound care, such as the use of amniotic membrane,[148] may well affect the nature of burn scarring. Satisfactory wound closure with cultured epithelial autograft (Figure 48-20) has been inconsistent and costly.[149,150] Early enthusiasm for synthetic dermal replacement has been tempered by a high rate of dermal graft loss and slow epidermal engraftment.[151,152] Such advancements in skin replacement technology include sheets of acellular dermal matrix that can be used with thin, meshed autografts or cultured epithelial autografts.[153,154] This concept also is being used on the donor site; glycosaminoglycan hydrogels, and even topical gene therapy or stem-cell applications,[155-157] may supplement donor site wound

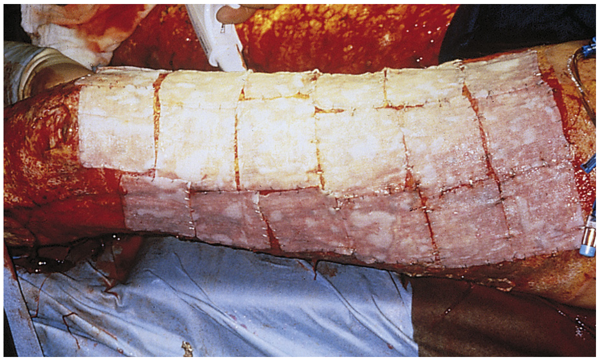

FIGURE 48-20 **Application of Cultured Epithelial Autografts.** The thin sheets of keratinocytes are attached to gauze backing to allow application onto the clean, excised thigh. (Courtesy Intermountain Burn Center, University of Utah.)

dressings.[158] Scar reduction or prevention is a challenging problem that is being addressed with pulsed-dye laser treatment.[159] Current research also is directed toward therapies to modulate hypermetabolic and inflammatory responses. Nutritional therapy is focused on early enteral feeding to reduce the potential of gut-mediated sepsis. Ongoing clinical trials using anabolic agents (e.g., recombinant human growth hormone) and pharmacologic agents that modulate inflammatory and endocrine mediators (e.g., ibuprofen, propranolol) show promise in the treatment of severe burn injuries.[99] Altered body image is a significant hurdle to those with facial burns. A supportive framework to aid individuals is essential to integrate them back into the community.[160] Burn pain is almost always acute and treatment strategies usually differ from strategies for chronic pain. The understanding and management of burn pain is key to recovery.[161,162] In addition to opioid-based agents, newer treatment approaches may include antianxiety agents, hypnosis, and relaxation techniques,[163] as well as virtual reality systems.[69,164]

SUMMARY REVIEW

Shock

1. Shock occurs when the cardiovascular system fails to perfuse tissue, cells, and organs adequately, causing a widespread impairment of cellular metabolism and tissue function. It is a downward physiologic spiral that, if not reversed, can lead to MODS.
2. Types of shock are cardiogenic, hypovolemic, neurogenic or vasogenic, anaphylactic, and septic.
3. The final common pathway in all types of shock is impaired cellular metabolism and cells switch from aerobic to anaerobic metabolism. Energy stores drop, and cellular mechanisms relative to membrane permeability, action potentials, and lysozyme release fail.
4. Anaerobic metabolism results in activation of the inflammatory response, decreased circulatory volume, and decreasing pH.
5. Impaired cellular metabolism results in cellular inability to use glucose because of impaired glucose delivery or impaired glucose intake, resulting in a shift of glycogenolysis, gluconeogenesis, and lipolysis for fuel generation.
6. Glycogenolysis is affected for up to 10 hours. Gluconeogenesis results in the use of proteins necessary for structure, function, repair, and replication that leads to more impaired cellular metabolism. Lipolysis is ineffective because of a lack of transport serum proteins.
7. Gluconeogenesis contributes to lactic acid, uric acid, and ammonia buildup; interstitial edema; and impairment of the immune system, as well as general muscle weakness leading to decreased respiratory function and cardiac output.
8. Cardiogenic shock results from persistent hypotension and tissue hypoperfusion caused by cardiac dysfunction in the presence of adequate intravascular volume and left ventricular filling pressure.
9. Hypovolemic shock is caused by loss of whole blood, plasma, or interstitial fluid in large amounts. The use of compensatory mechanisms may be vigorous, but tissue perfusion ultimately decreases and results in impaired cellular metabolism.
10. Neurogenic (vasogenic) shock results from massive vasodilation that results from an imbalance between parasympathetic and sympathetic stimulation of vascular smooth muscle. It causes a relative hypovolemia (even though cardiac output may be high), and results in impaired cellular metabolism.
11. Anaphylactic shock is the outcome of a widespread hypersensitivity to an allergen that triggers anaphylaxis. The inflammatory response is triggered, and a massive vasodilation with fluid shift into the interstitium follows. The relative hypovolemia leads to impaired cellular metabolism.
12. Septic shock begins with impaired cellular metabolism caused by uncontrolled septicemia. The infecting agent triggers the inflammatory and immune responses. It is part of a continuum known as SIRS. Mortality for septic shock is very high.

Multiple Organ Dysfunction Syndrome

1. MODS is the progressive dysfunction of two or more organ systems resulting from a systemic inflammatory response after a severe illness or injury. The inflammatory response can be triggered by sepsis, necrotic tissue, trauma, burns, ARDS, acute pancreatitis, major surgery, circulatory shock, DIC, acute renal failure, blood transfusion, heat stroke, liver failure, mesenteric ischemia, propofol infusion syndrome, persistent inflammatory foci, and other severe injuries.
2. Primary MODS is the immediate local or mild systemic response to the triggering event or illness. It primes the inflammatory system.

SUMMARY REVIEW—cont'd

3. Secondary MODS is the uncontrollable, excessive systemic inflammatory response that develops after a latent period and results in organ dysfunction.
4. People at greatest risk for developing MODS are older adults, those with significant tissue injury or preexisting disease, and those in whom resuscitation from the initiating illness or injury has been delayed or inadequate.
5. MODS is a leading cause of mortality in surgical intensive care units (ICUs). Mortality for individuals with MODS increases progressively from 54% with two failing organ systems to 100% with five failing organ systems.
6. Multiple organ dysfunction involves the stress response; release of complement, coagulation, and kinin proteins; changes in the vascular endothelium; and numerous inflammatory processes mediated by substances released by activated neutrophils and macrophages. The accumulation of activated neutrophils in organs is thought to play a key role in the pathogenesis of MODS, as well as macrophages.
7. The consequences of the release of inflammatory mediators in MODS are vasodilation, increased vasopermeability, and selective vasoconstriction resulting in maldistribution of blood flow; hypermetabolism; myocardial depression; and hypoxic injury to cells. Cellular hypoxia and acidosis impair cellular metabolism, leading to organ dysfunction.
8. Clinical manifestations of the development of MODS are general during the first 24 hours: low-grade fever, tachycardia, tachypnea, dyspnea, and altered mental status. Over the next several days, beginning with the lungs, individual organ systems show signs of failure.
9. Because there is no specific therapy for MODS, early detection is extremely important so that supportive measures can be initiated as soon as possible.
10. At present the therapeutic management of MODS consists of prevention or removal of triggering mechanisms and support of individual organs. Recent scientific knowledge about inflammatory mediators has led to many promising future therapies for MODS.

Burns

1. Burns are classified according to depth and extent of injury.
2. First-degree burns involve the superficial skin without loss of protective function.
3. Second-degree burns are superficial (blister formation) or superficial involving partial skin thickness with a waxy white appearance and no involvement of dermal appendages.
4. Third-degree burns involve full skin thickness and often underlying tissues. They are painless and can be life threatening as a result of hypovolemic shock and metabolic and immunologic responses.
5. The TBSA burned is estimated using either the rule of nines or the Lund and Browder chart.
6. Hypovolemia associated with burn shock is caused by increased capillary permeability with massive fluid losses from blood volume.
7. Altered cell membrane permeability and loss of electrolyte homeostasis contribute to burn shock.
8. Cardiac contractility is decreased during the first 24 hours with shunting of blood away from the liver, kidney, and gut.
9. Fluid resuscitation, such as with lactated Ringer solution, involves infusion of fluid at a rate faster than the loss of circulating volume.
10. The most reliable criterion for adequate resuscitation of burn shock is urine output.
11. Capillary seal is the term used to indicate the end of burn shock.
12. Transmembrane potentials are altered in cells not directly damaged by heat, with impairment of the sodium-potassium pump and loss of magnesium and phosphate.
13. The stress of a major burn activates the sympathetic nervous system with release of catecholamines, cortisol, glucagon, and insulin.
14. Burn injury produces a hypermetabolic state that persists until wound closure and is related to a higher thermal regulatory set point.
15. The local inflammatory response at the burn site releases cytokines, oxygen-free radicals, chemotactic factors, and eicosanoids, which lead to a systemic inflammatory response and contributes to hypermetabolism.
16. A posttraumatic hypermetabolic response is associated with increased visceral heat production.
17. Alterations in clotting factors produce a hypercoagulable state following major burns.
18. The immune response following a burn is immediate, prolonged, and severe.
19. Numerous alterations in inflammatory cytokines are evident in the immediate burn period, affecting cellular immunity, antibody production, and attraction of neutrophils and contributing to the vasodilation and increased capillary permeability associated with burn shock.
20. White blood cells are altered, and there is decreased opsonization and phagocytosis, contributing to the development of sepsis.
21. Changes in intestinal wall integrity lead to translocation of bacteria, endotoxemia, and septic shock.
22. Loss of intact skin with a major burn results in significant evaporative water loss contributing to hypovolemia.
23. Treatment of major burns involves meticulous wound management, adequate fluids and nutrition, early surgical excision and grafting, modulation of the hypermetabolic state, and pain management.

- Review Questions and Answers

CHAPTER OUTLINE

This chapter reviews shock, multiple organ dysfunction syndrome, and burns in children. It focuses on the assessment and care of children but also notes many of the differences between these conditions in children and adults.

SHOCK AND MULTIPLE ORGAN DYSFUNCTION SYNDROME

Shock is a condition of acute and progressive circulatory dysfunction that results in inadequate delivery of oxygen and nutrients to the tissues. Shock in children most often results from hemorrhage, severe dehydration, progressive heart failure, or sepsis. It may also complicate the care of the child with congenital heart disease, pulmonary hypertension (cor pulmonale), drug toxicity, electrolyte or acid-base imbalance, dysrhythmias, or multiple organ failure.

Shock in children is present when there are signs of poor systemic perfusion, regardless of the blood pressure—shock may be present with normal, high, or low blood pressure. When the systolic blood pressure is adequate for age, but there are signs of inadequate tissue perfusion, the child is in **compensated shock.** In this child, although the systolic blood pressure may be normal, the diastolic or mean blood pressure is typically low. If systolic hypotension is associated with inadequate tissue perfusion, the child is in **hypotensive** (formerly called decompensated) **shock.**[1-3]

Shock causes tissue **ischemia** (inadequate blood flow) and **hypoxia** (inadequate oxygen delivery) that leads to acidosis and cell dysfunction. Oxygen delivery may be inadequate because arterial oxygen content or cardiac output is low, or because there are increased metabolic requirements or impaired cellular use of oxygen. Ischemia and hypoxia are primary insults to cells. Restoration of adequate blood flow and oxygen delivery may trigger the development of *reperfusion injury,* a secondary problem characterized by an exaggerated inflammatory response that may produce cellular death and organ failure.

Multiple organ dysfunction syndrome (MODS) is the simultaneous failure of at least two organs resulting from a single cause.

MODS may be either primary or secondary. Primary MODS is directly attributable to the insult and typically occurs soon (3 to 7 days) after an insult. Secondary MODS typically occurs later and may be associated with more sequential development of organ dysfunction. Risk factors for MODS include severe or prolonged shock, sepsis, trauma, cardiopulmonary arrest, congenital heart disease, and liver and bone marrow transplantation.[3-5] Children with chronic diseases have an increased risk for MODS and increased mortality.[5]

Types of Shock

Shock is categorized by type as follows:[2,3]

1. *Hypovolemic shock:* caused by inadequate intravascular volume relative to the vascular space
2. *Cardiogenic shock:* results from impairment of myocardial function
3. *Distributive shock* (including septic, anaphylactic, and neurogenic): results from inappropriate distribution of blood flow, increased capillary permeability, and myocardial dysfunction (e.g., septic or anaphylactic shock) or central nervous system injury (e.g., neurogenic or spinal shock)
4. *Obstructive shock:* caused by a mechanical obstruction to blood flow into and through the heart and great vessels (e.g., cardiac tamponade, pulmonary embolus, obstructive congenital heart lesions such as critical aortic stenosis) resulting in low cardiac output

With **hypovolemic** or **cardiogenic shock** blood flow distribution is reduced to skin, gut, and kidney to maintain blood flow to the heart and brain. With **distributive (septic, anaphylactic, and neurogenic) shock,** blood flow is unregulated throughout the skin and organ systems and vasodilation and increased capillary permeability are typically present, so a normal cardiac output is likely to be inadequate to maintain sufficient perfusion of all tissue beds. Volume administration is necessary to ensure that the intravascular volume is adequate relative to the vascular space, and vasoactive drugs are needed to support adequate cardiac output and oxygen delivery. **Neurogenic shock** is a form of hypovolemic and vasogenic (maldistributive) shock. It is caused by a loss of vasomotor tone after severe head or spinal cord injury. Massive vasodilation and loss of sympathomimetic tone result in a relative hypovolemia and hypotension. The loss of sympathetic tone prevents compensatory tachycardia.

In **obstructive shock,** low cardiac output is caused by mechanical obstruction to blood flow, such as cardiac tamponade, tension pneumothorax, critical left heart or aortic obstruction, or pulmonary embolus.[2] Obstructive shock is difficult to distinguish from cardiogenic shock because both may present with signs of low cardiac output and evidence of systemic or pulmonary venous congestion. Prompt detection and treatment are critical to survival.[2,3]

An etiologic classification of shock is helpful because it indicates the initial therapy required. However, any child with late or progressive shock is likely to demonstrate widespread cardiovascular dysfunction that may include inappropriate intravascular volume relative to the vascular space, poor myocardial function, and maldistribution of blood flow so the etiologic classification of shock is oversimplified for such children.

BOX 49-1 CLINICAL MANIFESTATIONS OF SHOCK IN NEWBORNS, INFANTS, AND CHILDREN

Signs of Shock in Infants and Children

- Change in responsiveness (initial irritability followed by lethargy)
- Tachypnea
- Mottled color, pallor (distributive shock may be associated with flushed skin)
- Tachycardia
- Cool skin, prolonged capillary refill (distributive shock may cause "flash" [instantaneous] refill)
- Diminished intensity of peripheral pulses (may also vary in intensity)
- Metabolic (lactic) acidosis (serum lactate >4 mmol/L is typically well above normal for arterial or venous blood)
- Decreased central venous oxygen saturation (more than 25% to 30% below arterial oxygen saturation)
- LATE: Hypotension, bradycardia

Nonspecific Signs of Distress in Newborns

- Jitteriness or lethargy with decreased tone
- Change in oxygen requirements
- Apnea
- Bradycardia or decreased heart rate variability
- Temperature instability, hypothermia
- Glucose instability, hypoglycemia
- Feeding intolerance (e.g., increased residual volume)

Severe shock of any kind may be followed by complications such as reperfusion injury or MODS. An etiologic classification is also incomplete for children with septic shock, because sepsis produces elements of hypovolemic and cardiogenic shock in addition to the complications of infection and maldistribution of blood flow. Thus, healthcare providers must assess and support all aspects of cardiovascular function and oxygen delivery during the treatment of any form of shock.

Clinical Manifestations of Shock

The child with inadequate cardiac output demonstrates signs of inadequate blood flow to some tissue beds and evidence of organ system dysfunction (Box 49-1). Critical parameters to evaluate when approaching the child include assessment of consciousness, breathing, and color. This initial assessment is described in the Pediatric Advanced Life Support course.[2] Through this assessment the provider determines if the child "looks good" (appears stable, in no acute distress) or "looks bad" (in need of immediate intervention).[6] More detailed assessment of organ function and acid-base status will detect evidence of inadequate organ perfusion.

The child's level of *consciousness* and *responsiveness* often provides valuable information about the severity of illness. The healthy infant should orient to faces, make eye contact, and track bright objects across a visual field. The healthy toddler is reluctant to be separated from parents or examined by strangers, and the healthy child is alert and responds to questions. By comparison, the critically ill infant or child is often extremely irritable; lethargy indicates severe deterioration in the child's level of consciousness. A decreased response to painful

stimulation is abnormal and usually indicates severe cardiorespiratory or neurologic compromise.[2,6]

The infant or child normally *breathes* without evidence of distress or increased effort, such as retractions or nasal flaring. An extremely rapid respiratory rate (tachypnea), increased depth of respirations (hyperpnea), or evidence of increased respiratory effort (e.g., retractions, grunting) may indicate the presence of heart failure or shock. The development of apnea or inadequate respiratory rate or effort may indicate deterioration and need for immediate support of airway, oxygenation, and ventilation.

If perfusion is adequate and the ambient temperature is warm, the child's *color* will be consistent over the surface of the skin, with pink lips and mucous membranes. Children who are in a cold environment, those who have undergone hypothermic surgery or a procedure in a cold room, and children in shock often demonstrate mottling (a marbled or "blotchy" appearance to the skin).[2,3,6] Pallor also may be observed when perfusion is poor (Figure 49-1). Children with sepsis occasionally demonstrate flushed, bright red skin.[2,3,6]

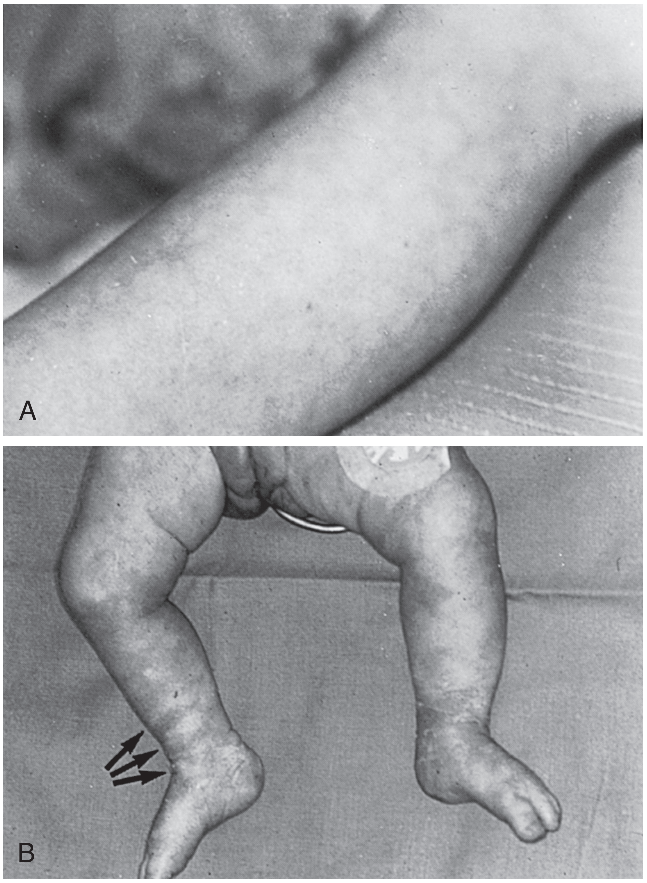

FIGURE 49-1 Mottling of Skin Caused by Poor Systemic Perfusion. **A,** Mottling of skin color often indicates inadequate tissue oxygenation; this may result from hypoxemia or poor systemic perfusion. This child developed myocardial dysfunction and signs of cardiogenic shock. **B,** Mottled skin color is often associated with other signs of compromise of skin perfusion, including delayed capillary refill. The skin over this infant's right ankle was blanched using three fingers (arrows), and the skin failed to perfuse for more than 5 seconds. This infant suffered from septic shock. (From Hazinski MF: Cardiovascular disorders. In Hazinski MF, editor: *Nursing care of the critically ill child,* ed 2, St Louis, 1992, Mosby.)

If perfusion is adequate and the ambient temperature is warm, the child's capillary refill is normally brisk (<2 seconds). A prolonged capillary refill time (>2 seconds) may indicate a compromise in systemic perfusion (see Figure 49-1, *B*) and the development of shock.[2,3,6] However, evaluation of capillary refill time is subjective and gradual changes may be difficult to detect.[7]

The child's *vital signs* must be evaluated in light of the child's clinical condition. Normal vital signs are not always appropriate in the seriously ill or injured child[6] (Box 49-2 and Table 49-1).

The child's heart rate should be appropriate for age and clinical condition. The child in shock is often tachycardic. The **tachycardia** may be primary (i.e., associated with a tachydysrhythmia) or secondary to stress (i.e., sinus tachycardia). If the heart rate is extremely rapid or if it is present in the child with decreased myocardial function, tachycardia may be the cause rather than the symptom of shock. In general, if the ventricular rate exceeds 200 to 220/min in the infant or 160 to 180/min in the child, ventricular diastolic filling time and coronary artery perfusion time are significantly reduced and stroke volume falls. As a result, cardiac output falls and signs of heart failure or shock develop. Once supraventricular or ventricular tachycardia produces signs of shock, urgent treatment is required.[8]

Bradycardia, an abnormally low heart rate, can cause a fall in cardiac output or it can be a symptom of deterioration. In young animal models, a fall in heart rate produces a commensurate fall in cardiac output.[9] The most common cause of bradycardia in young children is hypoxia.[2,10] Therefore, if the infant or child develops bradycardia with poor perfusion, the provider must immediately assess and support the child's airway, oxygenation, and ventilation, and be prepared to initiate chest compressions if the heart rate and systemic perfusion do not improve.[2,6,10]

BOX 49-2 ESTIMATING BLOOD PRESSURE IN CHILDREN 1 TO 10 YEARS OF AGE

Typical systolic BP for 1-10 years of age: The typical "normal" (i.e., median, or 50th percentile) systolic blood pressure for a child 1 to 10 years of age of normal height may be estimated by adding 90 mmHg to twice the child's age in years (90 mmHg + [2 × age in years]); this corresponds to the 50th percentile systolic blood pressure for the child's age.

Hypotensive systolic BP for 1-10 years of age: A systolic pressure less than 70 mmHg plus twice the child's age in years (<70 mmHg + [2 × age in years]) is considered hypotensive for children 1 to 10 years of age because this blood pressure corresponds to the 5th percentile systolic blood pressure for age (i.e., only 5% of normal, healthy children of average height demonstrate a systolic blood pressure lower than that number).

Hypotensive mean arterial pressure for 1-10 years of age: A mean arterial pressure less than 40 mmHg + (1.5 × age in years) is consistent with hypotension because this mean arterial pressure corresponds to the 5th percentile mean arterial pressure in children of average height.

Data from Chameides L et al, editors: Systematic approach to the seriously ill or injured child. In *Textbook of pediatric advanced life support,* Dallas, 2011, American Heart Association; Hacque IU, Zaritsky AL: *Pediatr Crit Care* 8:138–144; 2007.

TABLE 49-1 NORMAL PEDIATRIC VITAL SIGNS

AGE	HEART RATES: AWAKE HEART RATE (Per min)	HEART RATES: SLEEPING HEART RATE (Per min)	RESPIRATORY RATE* (Breaths Per min)
Newborn	100-205	90-160	
Infant (6 mo)	100-180	90-160	30-53
Toddler	98-140	80-120	27-37
Preschooler	80-120	65-100	20-28
School-age child	75-118	58-90	18-25
Adolescent	60-100	50-90	12-20

AGE	BLOOD PRESSURES: SYSTOLIC BLOOD PRESSURE (mmHg)†	DIASTOLIC BLOOD PRESSURE (mmHg)†	MEAN ARTERIAL PRESSURE (mmHg)‡	SYSTOLIC HYPOTENSION (mmHg)§
Birth (12 hr, <1000 g)	39-59	16-36	28-42¶	<40-50
Birth (12 hr, 3-kg weight)	60-76	31-45	48-57	<50
Newborn (96 hr)	67-84	35-53	45-60	<60
Infant (1-12 mo)	72-104	37-56	50-62	<70
Toddler (1-2 yr)	86-106	42-63	49-62	<70 + (2 × age in years)
Preschool (3-5 yr)	89-112	46-72	58-69	<70 + (2 × age in years)
School-age child (6-7 yr)	97-115	57-76	66-72	<70 + (2 × age in years)
Preadolescent (10-12 yr)	102-120	61-80	71-79	<90
Adolescent (12-15 yr)	110-131	64-83	73-84	<90

Note: Always consider patient's normal range and clinical condition. Heart and respiratory rates normally increase with fever or stress.

‡Mean arterial pressures (Diastolic pressure + [Difference between systolic and diastolic pressures ÷ 3]) for 1 year and older, assuming 50th percentile for height.
§Threshold for hypotension in children 1 to 10 years old from Pediatric Advanced Life Support course (Chameides L et al: *Pediatric advanced life support provider manual*, Dallas, 2011, American Heart Association).
¶Approximately equal to postconception age in weeks (may add 5 mmHg).
Blood pressure ranges from the following sources: Gemelli M et al: *Eur J Pediatr* 149:318–320, 1990; Versmold H et al: *Pediatrics* 67:107, 1981; Haque IU, Zaritsky AL: *Pediatr Crit Care* 8:138–144, 2007; National Heart, Lung and Blood Institute: *Fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents*, Bethesda, MD, 2004, National Heart, Lung and Blood Institute. Available at www.nhlbi.nih.gov/guidelines/hypertension/child.tbl.htm. Accessed July 10, 2013.

Bradycardia often indicates impending cardiovascular collapse and is the most common terminal cardiac rhythm observed in children.[2,3,6,10] The child's stroke volume may be altered by conditions affecting ventricular preload, compliance, contractility, and afterload (Table 49-2). Evaluate and optimize each of these variables in the treatment of shock (see Chapter 48).

Evaluate the child's *blood pressure* in light of age and clinical condition; note that shock may be present despite a systolic blood pressure within the normal range for age. When hypovolemic or cardiogenic shock is present, compensatory vasoconstriction may initially maintain the systolic blood pressure, although the mean and diastolic arterial pressures may fall. The development of systolic hypotension in the child with hypovolemic or cardiogenic shock indicates severe shock, and rapid deterioration may follow. In septic shock, by comparison, mild systolic hypotension may develop early in the clinical course. However, in all children, the development of systolic hypotension or a fall in mean arterial pressure indicates hypotensive shock, and urgent treatment is needed.[2,3,6]

The central venous pressure (CVP) is normally 0 to 5 mmHg and the pulmonary artery wedge pressure (PAWP, also called pulmonary artery occlusion pressure [PAOP]) is normally 5 to 8 mmHg or less. Inadequate CVP or PAWP may indicate hypovolemia, whereas high measurements typically result from heart failure or cardiogenic shock. Note that in the absence of tricuspid valve disease, tension pneumothorax, or influence from positive pressure ventilation, the CVP reflects the right ventricular end-diastolic pressure, whereas the PAWP should, in the absence of mitral valve disease, reflect the left ventricular end-diastolic pressure (if the catheter is appropriately placed and calibrated). The cardiac silhouette is normally less than 50% of the width of the chest on chest radiograph.

If a central venous catheter is in place, the superior vena cava (SVC) oxygen saturation is monitored to evaluate the balance of oxygen delivery versus consumption. The SVC saturation is central venous oxygen saturation ($S_{CV}O_2$) that is used as a surrogate for mixed venous oxygen saturation that would require a sampling of blood from the pulmonary artery. Normally, the

TABLE 49-2 FACTORS AFFECTING CARDIOVASCULAR PERFORMANCE IN CHILDREN

FACTOR	COMMENTS
Heart rate	Major factor affecting cardiac output in children. Normally more rapid in children than in adults. Because the *stroke volume* is smaller than in adults, the *cardiac output* of the child is more closely related to heart rate than stroke volume. *Tachycardia* is expected in the seriously ill or injured child. The most common cause of *bradycardia* in young children is hypoxia; bradycardia is an ominous sign if present in association with poor perfusion. Urgent treatment is required once bradycardia or supraventricular or ventricular tachycardia produces signs of shock.
Stroke volume	Averages 1.5 ml/kg; affected by conditions altering ventricular preload, compliance, contractility, and afterload
Ventricular end-diastolic pressure (VEDP)	Optimal pressure for children in shock is unknown. Aggressive fluid administration is linked to improved survival in children with *septic* shock.
Ventricular compliance or distensibility	Can be affected by congenital heart defects such as atrial septal defects (ASDs) and complex congenital heart defects. If compliance is low, such as in newborns and infants, volume administration may increase VEDP. Hypoplastic ventricles are often noncompliant. Hypertrophied ventricles, present in children with severe pulmonary stenosis or aortic stenosis, may become fibrotic and noncompliant. Increased compliance may be present in early septic shock.
Contractility	Contractility probably similar in normal newborns, infants, children, and adults. Newborn myocardium does have fewer contractile proteins and higher water content than adult myocardium, but the clinical significance of this is probably minimal.
Afterload	Newborn myocardium *can* adapt to mild, nonacute increases in afterload. Afterload may be increased in children with systemic vasoconstriction or pulmonary hypertension (constrictors include alveolar hypoxia, acidosis, hypothermia, and alveolar distention). Some uncorrected congenital heart defects may increase afterload. Coarctation of the aorta and aortic stenosis increase left ventricular afterload. Pulmonary stenosis increases right ventricular afterload. Afterload may be decreased in septic shock.
Oxygen delivery and consumption	Highest per kilogram body weight during the neonatal period and infancy. The young child requires a higher cardiac output and oxygen delivery per kilogram than the adult. Increased oxygen consumption occurs in critically ill newborns exposed to cold because they cannot shiver to generate heat. Other causes of increased oxygen consumption in children and infants include fever, sepsis, trauma, pain, and seizures.

VEDP, Ventricular end-diastolic pressure.

$S_{CV}O_2$ is 25% to 30% below the arterial oxygen saturation. A fall in $S_{CV}O_2$ can indicate a fall in oxygen delivery (caused by decreased arterial oxygen content or decreased cardiac output), an uncompensated rise in oxygen consumption, or both.[3]

Shock compromises renal perfusion, so urine volume decreases, typically to less than 2 ml/kg/hr in infants, less than 1 ml/kg/hr in children, and less than 0.5 ml/kg/hr in adolescents, despite adequate fluid intake. Liver enzymes may be elevated if hepatic perfusion is reduced. The development of metabolic acidosis and a rise in serum lactate to greater than 4 mg/dl indicate that blood flow to some tissues is inadequate to support aerobic metabolism.

Infants have high glucose needs and low glycogen stores that may be rapidly depleted during stress. For this reason, *hypoglycemia* (glucose ≤60 mg/dl) may be observed in seriously ill or injured infants and may be associated with cardiovascular or neurologic deterioration.[2,11] *Hyperglycemia* (>150 mg/dl) may develop in critically ill or injured children as the result of a relative insulin-resistant state associated with high levels of endogenous catecholamines and hydrocortisone secretion.[3,11] Such hyperglycemia in children is often observed in the first 12 to 18 hours after initial injury or development of shock, then falls to normal levels; persistent hyperglycemia (>180 mg/dl or 10 mmol/L) has been linked with poor survival in critically ill children,[12,13] and hypo-, hyperglycemia, and glucose instability (episodes of both hypo- and hyperglycemia in same child) have been linked with development of multiple organ dysfunction.[13]

Hypovolemic Shock

Hypovolemic shock, the most common type of shock in children, is associated with a reduction in the intravascular volume relative to the vascular space. Dehydration and trauma are the most common causes of hypovolemic shock in children. A relative hypovolemia also may result from vasodilation and a redistribution of blood volume or from increased capillary permeability, such as may develop following burns or with sepsis.

When hypovolemia is mild or moderate, such as with 5% to 10% dehydration or mild hemorrhage, compensatory adrenergic vasoconstriction redistributes blood from the skin, the mesenteric (gut), and renal circulations to maintain blood flow to the heart and brain. The child with mild hypovolemic shock typically maintains systolic blood pressure with this vasoconstriction.

Hypotension is a sign of severe, decompensated hypovolemic shock and may not develop unless intravascular volume loss is rapid or severe.[2,3] Hypotension typically develops with greater than 10% isotonic or hypotonic dehydration in the infant or child (or greater than 6% to 7% dehydration in the adolescent).[11] Hypotension may not be observed in the child with trauma unless hemorrhage totals about 20% to 25% of circulating blood volume.[14,15]

Relative hypovolemia may be caused by a decrease in the intravascular volume relative to the vascular space. This may be associated with the vasodilation of sepsis, anaphylaxis, or neurogenic shock (see following text) or with β_2-adrenergic drug toxicity. A relative hypovolemia also may be caused by

increased capillary permeability with a redistribution of intravascular volume, such as with burns, anaphylaxis, or sepsis. The translocation of extravascular fluid to a location that is neither intravascular nor intracellular, as in edema, is termed **"third spacing" of fluids.**[11]

Compensatory Responses. Significant dehydration, hypovolemia, and low cardiac output stimulate adrenergic and renal compensatory mechanisms characterized by the "fight-or-flight" response. These include tachycardia and redistribution of blood from the skin, gut, and kidney to the brain and heart. Reduced renal perfusion stimulates the renin-angiotensin-aldosterone system, resulting in renal sodium and water retention. Decreased atrial stretch stimulates the secretion of antidiuretic hormone (ADH, also known as arginine vasopressin [AVP]) and produces free water retention by the kidneys.[3] These mechanisms are similar in adults and children and may help restore or maintain intravascular volume over time. Neonatal and young infant kidneys, however, are incapable of excreting concentrated urine, so these compensatory mechanisms are relatively ineffective during the first weeks of life.[11]

Compensatory mechanisms cannot be maintained indefinitely. Systemic vasoconstriction increases left ventricular afterload and myocardial oxygen consumption and may produce tissue ischemia. Prolonged tachycardia may impair subendocardial blood flow and increase myocardial oxygen consumption; both may ultimately contribute to myocardial ischemia.[3] Extreme tachypnea increases oxygen demand and reduces effective ventilation. A severe compromise in blood flow and systemic perfusion contributes to cerebral, renal, or hepatic ischemia and possible organ failure.

CLINICAL MANIFESTATIONS. The child with hypovolemic shock demonstrates signs of inadequate blood flow to some tissue beds and some evidence of organ system dysfunction (see Box 49-1). The infant or child may be irritable or lethargic. Respirations will be rapid and may be labored if shock is severe or associated with myocardial failure. The skin will be mottled, although pallor also may be observed. A prolonged capillary refill time (>2 seconds) is consistent with the development of shock.[2,3,6,16]

The child in hypovolemic shock is often tachycardic. Bradycardia often indicates impending cardiovascular collapse or cardiac arrest and is the most common terminal cardiac rhythm observed in children.[2,3,10] When hypovolemic shock is present, compensatory vasoconstriction may initially maintain the systolic blood pressure, although the mean arterial pressure may fall. The development of systolic hypotension often indicates severe shock, and rapid deterioration may follow. The CVP is less than 5 to 8 mmHg, unless heart failure or pulmonary hypertension is present.

Hypovolemic shock compromises renal perfusion so urine volume decreases despite adequate fluid intake. Liver enzymes may be elevated if hepatic perfusion is reduced. The development of metabolic acidosis and a rise in serum lactate indicate that blood flow to some tissues is inadequate to support aerobic metabolism.

Hypoglycemia (glucose ≤60 mg/dl) may be observed in seriously ill or injured infants, especially if intake has been compromised, and may be associated with cardiovascular or neurologic deterioration. *Hyperglycemia* (>150 mg/dl) may develop in critically ill or injured children.

Clinically significant dehydration is associated with weight loss (Table 49-3). Fluid intake and output records (or reports

TABLE 49-3 DEHYDRATION AND HYPOVOLEMIA

TYPE OF DEHYDRATION	CLINICAL INDICATORS
Isotonic dehydration	Fluid output exceeds intake. Loss of free water is proportional to loss of sodium, so serum sodium concentration remains normal. Fluid loss is from intravascular and extravascular compartments. Compromises peripheral perfusion when the young child has lost approximately 10% (100 ml/kg) of body weight. Compromises systemic perfusion in the adolescent with acute fluid loss equivalent to 5% to 6% of body weight.
	Produces hypotension (decompensated shock) when the young child has lost 15% (150 ml/kg) of body weight. Produces hypotension in the adolescent with a fluid loss equivalent to 7% to 9% of body weight because body water constitutes a smaller percentage of body weight in older children and adults than in young children.
Hypotonic/hyponatremic dehydration	Associated with a proportionately greater loss of sodium than free water; thus the serum sodium falls. Resultant acute fall in serum osmolality produces an acute extravascular fluid shift and further loss of extravascular volume. Fluid loss in hypotonic dehydration is primarily from the intravascular compartment; thus a compromise in systemic perfusion will be observed after even small quantities of fluid loss.
	Poor peripheral perfusion occurs in a child with a fluid loss equivalent to 5% (50 ml/kg) of body weight. Adolescents with hyponatremic dehydration may demonstrate a compromise in peripheral perfusion with a fluid loss equivalent to approximately 3% of body weight.
	Hypotension often is observed when fluid loss is equal to approximately 10% (100 ml/kg) of body weight. Hypotension in an adolescent is observed when the fluid loss equals approximately 5% to 6% of body weight.
Hypertonic/hypernatremic dehydration	Free water deficit is proportionately greater than the deficit of sodium, so serum sodium concentration rises, increasing serum osmolality and producing an intravascular shift of free water. For this reason the child with hypernatremic dehydration is likely to maintain intravascular volume and systemic perfusion until relatively large quantities of fluid are lost.
	Compromise in systemic perfusion is not likely to be observed in the *child* with hypernatremic dehydration until *severe* dehydration is present with a fluid loss equivalent to 10% of body weight (or 5% to 6% of body weight in the adolescent).
	Hypotension may not be observed until the fluid loss approximates 15% or more of body weight (7% to 9% or more of body weight in the adolescent).
	Hypotension in the child with hypertonic/hypernatremic dehydration indicates a substantial fluid deficit. However, the deficit must be replaced carefully to correct shock and avoid rapid lowering of serum sodium concentrations.

Data in part from Roberts KE: *Pediatr Rev* 22:380–386, 2001; Roberts KE: Fluid, electrolyte and endocrine problems. In Hazinski MF, editor: *Nursing care of the critically ill child*, ed 3, St Louis, 2013, Mosby.

TABLE 49-4 SEVERITY OF (ISOTONIC) DEHYDRATION BASED ON CLINICAL EXAM*

CLINICAL PARAMETERS	MILD	MODERATE	SEVERE
Body weight loss			
Infant	5% (50 ml/kg)	10% (100 ml/kg)	15% (150 ml/kg)
Adolescent	3% (30 ml/kg)	5%-6% (50-60 ml/kg)	7%-9% (70-90 ml/kg)
General appearance	Alert, restless, thirsty	Lethargic, postural dizziness	Limp, coma, cold and cyanotic extremities
Radial pulse	Full	Thready, weak, rapid	Feeble, not palpable
Respiration	Normal	Deep	Deep, rapid
Skin elasticity	Pinch retracts immediately	Pinch retracts slowly	Pinch retracts very slowly (>2 seconds)
Eyes	Normal	Sunken	Very sunken
Tears	Present	Diminished	Absent
Mucous membranes	Moist	Dry	Very dry (parched)
Urine output	Normal	↓	↓ or absent
Capillary refill time	<2 seconds	>2 seconds	Prolonged
Heart rate	Varies with age	Varies with age	Varies with age
Blood pressure	Normal	Normal	Reduced

Modified from Perkin RM et al: Shock, cardiac arrest and resuscitation. In Hazinski MF, editor: *Nursing care of the critically ill child,* ed 3, St Louis, 2013, Mosby.
*The interpretation of the assessments must be appropriately modified for age and type of dehydration (hypotonic or hypertonic).

TABLE 49-5 ESTIMATION OF PEDIATRIC CIRCULATING BLOOD VOLUME

AGE OF CHILD	BLOOD VOLUME (ml/kg body weight)
Newborn	80-85
Infant	75-80
Child	70-75
Adolescent	65-70

From Hazinski MF: Children are different. In Hazinski MF, editor: *Nursing care of the critically ill child,* ed 3, St Louis, 2013, Mosby.

from parents or primary caretakers) reveal a history of inadequate fluid intake or excessive fluid losses. The child with significant dehydration demonstrates dry mucous membranes, a sunken fontanel (in infants), and poor skin turgor[11] (Table 49-4). Moderate isotonic dehydration produces signs of peripheral circulatory compromise, and severe isotonic dehydration will produce hypotension. The blood urea nitrogen (BUN) and urine specific gravity are usually elevated. The serum sodium concentration and osmolality are affected by the type and severity of dehydration present.

Hemorrhage is another potential cause of hypovolemic shock. To appreciate the significance of any blood lost or drawn for laboratory analysis, the total blood loss should be considered as a percentage of the child's circulating blood volume (Table 49-5).

Tachycardia, peripheral vasoconstriction, and altered level of consciousness may be the only early evidence of hemorrhage in the child with trauma (Table 49-6). Acute blood loss (hemorrhage) may not compromise a child's peripheral perfusion until an estimated 25% to 30% of intravascular volume is lost (i.e., an acute intravascular or blood loss of 16 to 24 ml/kg).[14-16] Once hypotension develops, cardiovascular collapse is imminent and immediate, rapid intravascular volume expansion is required and surgical intervention may be needed.

Redistribution of blood volume associated with systemic vasodilation, high capillary pressure or transudative fluid losses, or capillary leak may produce a relative hypovolemia and signs of poor systemic perfusion in the absence of evidence of absolute volume loss. For example, children with end-stage hepatic failure may demonstrate a relative hypovolemia associated with ascites and hepatorenal syndrome. Children demonstrate increased capillary permeability and loss of intravascular volume immediately after a burn. The septic child also may demonstrate systemic edema associated with capillary leak and intravascular volume loss. In these children some evidence of extravascular fluid movement (ascites, systemic edema, or fluid loss to dressings over burns) is usually observed.

Signs of neurogenic shock in the child with a recent, severe spinal cord injury include warm skin and hypotension with a low diastolic blood pressure. Signs of poor systemic perfusion also are observed (see Clinical Manifestations of Shock, previously), although loss of sympathetic nervous system tone prevents the typical tachycardic response.

Cardiogenic Shock

Cardiogenic shock is present when impaired myocardial function compromises cardiac output. This form of shock is observed:

1. Following cardiovascular surgery or with inflammatory disease of the heart, such as cardiomyopathy and myocarditis
2. With drug toxicity or severe electrolyte or acid-base imbalances
3. As a complication of any form of shock and early in septic shock

Compensatory Responses. In the early stages of cardiogenic shock, adrenergic compensatory mechanisms produce tachycardia, peripheral vasoconstriction, and constriction of the splanchnic arteries to divert blood flow from the skin, gut, and kidneys to maintain flow to the heart and brain.[2,3,16] These compensatory mechanisms may be sufficient to maintain the

TABLE 49-6 CLASSIFICATION OF PEDIATRIC HEMORRHAGIC SHOCK IN TRAUMA PATIENTS BASED ON CLINICAL EVALUATION

SYSTEM	MILD HEMORRHAGE, COMPENSATED SHOCK, SIMPLE HYPOVOLEMIA (<30%)	MODERATE HEMORRHAGE, DECOMPENSATED SHOCK, MARKED HYPOVOLEMIA (30%-45%)	SEVERE HEMORRHAGE, CARDIOPULMONARY FAILURE, PROFOUND HYPOVOLEMIA (>45%)
Cardiovascular	Tachycardia Weak peripheral pulses, strong central pulses Low to normal blood pressure (systolic BP >70 mmHg + [2 × (age in years)]) Mild acidosis	Moderate tachycardia Thready peripheral pulses, weak central pulses Frank hypotension (systolic BP <70 mmHg + [2 × (age in years)]) Moderate acidosis	Severe tachycardia Absent peripheral pulses, thready central pulses Profound hypotension (systolic BP <50 mmHg) Severe acidosis
Respiratory	Mild tachypnea	Moderate tachypnea	Severe tachypnea
Central nervous system	Irritable, confused	Agitated or lethargic	Obtunded, comatose
Skin	Cool extremities, mottling Poor capillary refill (72 sec)	Cool extremities, pallor Delayed capillary refill (72 sec)	Cool extremities, cyanosis Prolonged (>5 sec) capillary refill
Kidneys	Mild oliguria, increased specific gravity	Marked oliguria, increased blood urea nitrogen (BUN)	Anuria

From Soud T, Pieper P, Hazinski MF: Pediatric trauma. In Hazinski MF, editor: *Nursing care of the critically ill child,* ed 2, St Louis, 1992, Mosby.

child's systolic blood pressure and effective coronary artery and cerebral blood flow. However, tachycardia and systemic arterial constriction increase myocardial oxygen consumption. In addition, reduction in gut and kidney blood flow may produce hepatic, mesenteric, or renal ischemia or failure. Decreased renal perfusion stimulates the renin-angiotensin-aldosterone system, as described for hypovolemic shock.

If the mean arterial pressure or pulse pressure falls, stimulation of the baroreceptors in the carotid sinuses and aortic arch is reduced. This reduced baroreceptor activity removes inhibition from the vasomotor center in the medulla, resulting in increased adrenergic stimulation.[3] If myocardial dysfunction progresses, cardiac output and systemic blood pressure ultimately fall. Myocardial ischemia then exacerbates myocardial dysfunction, and multisystem organ failure may result from persistent or severe organ ischemia.

CLINICAL MANIFESTATIONS. The child with cardiogenic shock demonstrates signs of inadequate systemic perfusion despite adequate intravascular volume or even relative hypervolemia. This form of shock is generally associated with low cardiac output. The child's extremities are cool to touch (will cool peripherally to proximally), with delayed capillary refill despite a warm, ambient temperature.[2,6,16] The skin may be mottled (see Figure 49-1).

Evidence of an adequate or high central venous pressure, including hepatomegaly and periorbital edema, is typically present in uncomplicated cardiogenic shock, particularly if right ventricular failure is involved. Evidence of pulmonary edema may be noted on a chest radiograph or clinical assessment (including signs of respiratory distress, reduced lung compliance during hand ventilation, or frothy pink sputum suctioned from the endotracheal tube) if left ventricular failure is present. The cardiac silhouette is usually enlarged on the chest radiograph, unless concurrent hypovolemia is present. If myocardial function is severely compromised, peripheral pulses may be diminished in intensity (dampened) or they may vary in intensity (pulsus alternans).

A low cardiac output may be documented by invasive or noninvasive devices. If a pulmonary artery catheter is in place, the cardiac output may be calculated through a thermodilution technique or continuous monitoring of the mixed venous oxygen saturation.

Signs of low cardiac output and cardiogenic shock may be identical to signs of cardiac tamponade. Although some classic signs of tamponade, including muffled heart tones or pulsus paradoxus may be observed, these signs may be difficult to appreciate if cardiac output and blood pressure are severely compromised. Therefore, if cardiogenic shock is suspected in a child after cardiovascular surgery or in any child at risk for the development of pericardial effusion, tamponade should be ruled out through an echocardiogram.

Septic Shock

Sepsis and its complications result from activation of biochemical and physiologic cascades that lead to the formation or activation of cytokines and other mediators that produce vasodilation, increased capillary permeability, maldistribution of blood flow, and cardiovascular dysfunction.[3] Sepsis and its complications may result in organ system dysfunction and are leading causes of death in noncoronary intensive care units. An estimated 42,000 pediatric cases of sepsis are reported annually in the United States and result in approximately 4400 deaths per year.[17]

Much information about the pathophysiology and clinical signs of sepsis has been extrapolated from adult studies and adult animal models of sepsis. Some information gleaned from adult experience is applicable to children, whereas other information is not. More research is needed to better understand pediatric sepsis and septic shock.

Watson's 2003 hospital data from seven states[17] still provides the most detailed information regarding causes of pediatric sepsis in the United States. The most common sites of infection from these data were primary bloodstream (25%) and

respiratory tract (37%) infections;[17] about half of children with sepsis had an underlying disease and more than one fifth were low–birth-weight neonates.[17,18]

Many bloodstream and respiratory infections may be prevented with proper handwashing by healthcare providers before and after contact with children, appropriate sterile and aseptic technique during catheter insertion and tubing changes, and use of protocols to reduce central venous catheter infections and ventilator-associated pneumonias.[19,20] More pediatric data are needed to develop evidence-based recommendations to reduce hospital-acquired infections and sepsis.

The microorganisms that cause sepsis vary according to age, immune function, and location (e.g., in the hospital versus in the community).[21] Approximately 40% of all hospital-acquired infections in adults and children are linked to gram-negative infections; 40% to gram-positive infections; and 20% to viruses, fungi, or rickettsial microorganisms.[18] Prevention of hospital-acquired infections can substantially reduce the risk of sepsis and its complications.[19,20] Clinicians must be aware of the common pathogens in various populations.

Factors associated with risk for the development of sepsis include extremes of age (infants, young children and older adults)[3,17]; invasive catheters, surgical incisions, or wounds or burns; immunocompromise; and long-term antibiotic therapy.[17,18] Many of these risk factors are present in seriously ill or injured children and children with a chronic disease.

It is now clear that genetic variations among children and among invading microorganisms can alter the outcome of infections, sepsis, and septic shock.[21] Genetic variation in any of several genes that affect host responses to invading microorganisms can influence outcomes of infections.[22] Certainly, infectious diseases, such as meningococcal disease, can vary widely in their invasiveness and in the severity of effects on the host.[23] It is anticipated that genetic information will ultimately influence identification of a child's susceptibility to infection and sepsis, risk modification, early detection of sepsis, tailoring of therapy, and prognostication.[22]

Both proinflammatory and anti-inflammatory cytokines serve essential protective functions in fighting infection and modulating the immune response. Sepsis is caused by the effects of the invading microorganism and its toxins, but most effects that contribute to shock result from a disruption in the balance between *proinflammatory* mediators (including tumor necrosis factor-alpha [TNF-α], interleukin [IL]-1, IL-6, and IL-8; platelet-activating factor; arachidonic acid metabolites; nitric oxide; and many kinins) and *anti-inflammatory* mediators (IL-4, IL-10, IL-11, and IL-13; transforming growth factor-beta; colony-stimulating factors; soluble tumor necrosis factor receptor; IL-1 receptor antagonist; and activated protein C).[3] Extremely high levels of proinflammatory mediators, such as TNF, nitric oxide, and platelet-activating factor can become destructive, even after the triggering microorganism is eradicated.[3,21]

High proinflammatory cytokine levels have been implicated in the development of sepsis-induced disseminated intravascular coagulation, pulmonary injury, and microcirculatory disruptions, such as are observed in burns, severe trauma, shock reperfusion syndromes, and MODS.[21] Tumor necrosis factor levels have been directly related to mortality in newborns and children with meningitis and sepsis,[24] and interleukin-8 levels have been shown to be reliable predictors of pediatric sepsis mortality.[22]

Increased nitric oxide concentrations are thought to contribute to vasodilation, hypotension, and decreased myocardial function that develop during adult sepsis. In comparison, infants with sepsis often demonstrate pulmonary vasoconstriction resulting from shock-induced acidosis and hypoxia, and may benefit from administration of inhaled nitric oxide or other vasodilators.[25]

During sepsis, endotoxin stimulates the endothelium to become a secretory organ. The endothelium changes from the normal profibrinolytic and anticoagulant state to an antifibrinolytic and precoagulant one.[25] This change can lead to the development of microthrombin in some areas of the microcirculation, further contributing to maldistribution of blood flow. Mediators (e.g., activated protein C) that regulate coagulation pathways have been implicated in the sepsis process.[25-27] Activated protein C also regulates inflammation and activated protein C deficiency is a marker for severe sepsis in all ages.[27] Although administration of activated protein C improved survival in adults with severe sepsis,[28] it has not been shown to improve outcome in children and may produce excessive bleeding complications.[25]

There is clear interaction among catecholamines, adrenoreceptors, and glucocorticoids. Endogenous glucocorticoids have an anti-inflammatory effect (they decrease activation of proinflammatory mediators), and they modulate vasomotor tone by enhancing cardiovascular and vasomotor response to catecholamines.[29]

Critically ill children may have adrenal insufficiency (caused by adrenal hemorrhage, decreased renal perfusion, inhibition of corticosteroid production by TNF, or actual adrenal disease) or a relative adrenal insufficiency, with inadequate adrenal stress response or decreased response to circulating glucocorticoids.[30,31] When sepsis is present and the child fails to respond to initial fluid therapy and vasoactive support, providers should rule out adrenal insufficiency and consider hydrocortisone administration, especially if risk of adrenal insufficiency is present.[32]

CLINICAL MANIFESTATIONS. Sepsis and its complications produce a cascade of physiologic and biochemical changes. The clinical progression of sepsis in children has been described and defined by a consensus panel of international physicians[4] (Box 49-3).

Systemic inflammatory response syndrome (SIRS) represents a nonspecific response to a variety of insults, including trauma, burns, pancreatitis, or infection. SIRS is present when the child demonstrates two or more of the following as an acute change from baseline: change in temperature, specifically fever (greater than 38.5° C [101.3° F]) or hypothermia (less than 36° C [96.8° F]), change in heart rate (tachypnea or, in infants, bradycardia), change in respiratory rate (or need for mechanical ventilation), or change in white blood cell (WBC) count (including leukocytes, leukopenia, or an increase in the percentage of immature or band forms of WBCs).[4] These clinical signs must be interpreted in light of the child's baseline function.

BOX 49-3 INTERNATIONAL CONSENSUS DEFINITIONS OF SYSTEMIC INFLAMMATORY RESPONSE SYNDROME, SEPSIS, SEVERE SEPSIS, AND SEPTIC SHOCK IN CHILDREN

Systemic Inflammatory Response Syndrome (SIRS)

The presence of at least two of the following four large bulleted criteria, one of which must be abnormal temperature or leukocyte count:

- ALTERATION IN TEMPERATURE: Core body temperature of >38.5° or <36°C
- ALTERATION IN HEART RATE (characterized by any of the three open bullets, below):
  - Tachycardia in the absence of external stimulus, chronic drugs, or painful stimuli, defined as follows:
    - Newborn to 1 year: HR >180/min
    - 2-5 years: >140/min
    - 6-12 years: >130/min
    - 13 to <18 years: >110/min
  - Otherwise unexplained persistent elevation over a 0.5 to 4-hour time period
  - For children younger than 1 yr: bradycardia, in the absence of external vagal stimulus, β-blocker drugs, or congenital heart disease, defined by one of the three dashes below:
    - Newborn to 1 month: <100/min
    - 1 month to 1 year: <90/min
    - Otherwise unexplained persistent depression over a 30-minute time period
- ALTERATION IN RESPIRATORY RATE (characterized by either of the open bullets, below):
  - Mean respiratory rate >95th percentile normal for age, defined as follows:
    - Newborn to 1 week: >50/min
    - 1 week to 1 month: >40/min
    - 1 month to 1 year: >34/min
    - 2-5 years: >22/min
    - 6-12 years: >18/min
    - 13 to <18 years: >14/min
  - Mechanical ventilation for an acute process not related to underlying neuromuscular disease or the receipt of general anesthesia
- ALTERATION IN WHITE BLOOD CELL COUNT:
  - Leukocyte count elevated or depressed for age (not secondary to chemotherapy-induced leukopenia) or >10% immature neutrophils

Infection (one of the following)

- A suspected or proven (by positive culture, tissue stain, or polymerase chain reaction test) infection caused by any pathogen
- A clinical syndrome associated with a high probability of infection

Note: Evidence of infection includes positive findings on clinical examination, imaging, or laboratory tests (e.g., white blood cells in a normally sterile body fluid, perforated viscus, chest radiograph consistent with pneumonia, petechial or purpuric rash, purpura fulminans)

Sepsis

- SIRS in the presence of or as a result of suspected or proven infection

Severe Sepsis

- Sepsis plus one of the following:
  - Cardiovascular organ dysfunction
  - Acute respiratory distress syndrome
  - Two or more other organ dysfunctions (organ dysfunctions are defined in Box 49-4)

Septic Shock

- Sepsis and cardiovascular organ dysfunction as defined in Box 49-4

From Perkin RM et al: Shock, cardiac arrest and resuscitation. In Hazinski MF, editor: *Nursing care of the critically ill child,* ed 3, St Louis, 2013, Mosby; Modified from Goldstein B et al: *Pediatr Crit Care Med* 6:2–8, 2005.

Sepsis is a systemic response to infection. It is present when manifestations of SIRS are observed in conjunction with suspected infection. Positive blood or other cultures are not necessary for the diagnosis, but suspicion of infection is required.[4] For example, if the child with trauma develops a high fever or pulmonary congestion several days after injury, it is highly likely that an infection is present.

Severe sepsis is present when the child demonstrates evidence of sepsis (SIRS with suspected infection) and signs of cardiovascular or pulmonary dysfunction, or if the child has sepsis and evidence of two or more other organ dysfunctions (Box 49-4).[4] Altered organ perfusion is signaled by signs of organ system dysfunction. The dysfunctional organ system should be separate from the site of suspected infection and not explained by effects of drug therapy or other acute effects.[4] This important distinction will enable separation of signs of severe sepsis from signs of simple pneumonia and associated respiratory failure.

Septic shock is heralded in the child with sepsis by the development of cardiovascular dysfunction. This may be characterized by hypotension despite adequate fluid resuscitation or by the need for vasopressors to maintain blood pressure.[4] Because children tend to develop hypotension only late in the course of any shock, septic shock should be identified when the child develops more subtle signs of poor perfusion despite adequate fluid resuscitation. When the child with sepsis does develop hypotension plus signs of poor perfusion, hypotensive/decompensated septic shock is present, and mortality may be as high as 30%.[33]

Kissoon, Orr, and Carcillo[34] have proposed simplified diagnostic criteria for pediatric septic shock. They note that fever, tachycardia, and vasodilation are signs of inflammation. They propose that if the child with this triad of inflammatory signs also develops altered level of consciousness, the diagnosis of septic shock should be considered. Carcillo[25,34] has distilled the international consensus definitions of septic shock to include suspected infection with hypo- or hyperthermia and clinical signs of inadequate perfusion. Carcillo defines signs of inadequate perfusion as including any one of the following: decreased level of conscious or change in mental status; prolonged (>2 seconds) capillary refill; abnormal pulses (either diminished or bounding with wide pulse pressure); mottled, cool extremities; or decreased urine output. Carcillo also notes that hypotension is not required for the diagnosis but, if present, is confirmatory.[25,34]

Children with septic shock may have a high, normal, or low cardiac output. Unlike adults, who typically present with

BOX 49-4 CRITERIA FOR ORGAN DYSFUNCTION IN CHILDREN WITH SEVERE SEPSIS OR SEPTIC SHOCK

Cardiovascular

Despite administration of isotonic intravenous fluid boluses of more than 40 ml/kg in 1 hour, is described by the characteristics in one or more of the three bullets below:

- Decrease in blood pressure (BP) (hypotension) to <5th percentile for age, estimated for children 1-10 years of age as follows:
  - Mean arterial pressure: <40 mmHg + (1.5 × age in years)
  - Systolic BP <70 mmHg + (2 × age in years)
- Need for vasoactive drug to maintain BP in normal range (dopamine >5 mcg/kg/min; or dobutamine, epinephrine, or norepinephrine at any dose)
- Two of the following:
  - Unexplained metabolic acidosis: base deficit more severe than –5 mEq/L
  - Increased arterial lactate >2 times upper limit of normal
  - Oliguria: urine output <0.5 ml/kg/hr
  - Prolonged capillary refill: >5 seconds
  - Core to peripheral temperature gap >3°C

Respiratory (one of the following)*

- $PaCO_2/FiO_2$ <300 in absence of cyanotic heart disease or pre-existing lung disease
- $PaCO_2$ >65 torr or 20 mmHg over baseline $PaCO_2$
- Proven need† or >50% inspired oxygen to maintain saturation >92%
- Need for nonelective invasive or noninvasive mechanical ventilation‡

Neurologic (either of the following)

- Glasgow Coma Scale score ≤11
- Acute change in mental status with a decrease in Glasgow score ≥3 points from abnormal baseline

Hematologic (one of the following)

- Platelet count <80,000/mm^3
- A decline of 50% in platelet count from highest value recorded over the past 3 days (for chronic hematology/oncology)
- International normalized ratio >2

Renal

- Serum creatinine ≥twofold upper limit of normal for age or twofold increase in baseline creatinine

Hepatic (either of the following)

- Total bilirubin ≥4 mg/dl (not applicable for newborn)
- ALT twofold upper limit of normal for age

From Perkin RM et al: Shock, cardiac arrest and resuscitation. In Hazinski MF, editor: *Nursing care of the critically ill child*, ed 3, St Louis, 2013, Mosby. Modified from Goldstein B et al: *Pediatr Crit Care Med* 6:2–8, 2005.

*Acute respiratory distress syndrome must include a PaO_2/FiO_2 ratio <200 mm Hg, bilateral infiltrates, acute onset, and no evidence of left heart failure. Acute lung injury is defined identically except the PaO_2/FiO_2 ratio must be <300 mmHg.

†Proven need assumes oxygen requirement was tested by decreasing flow with subsequent increase in flow if required.

‡In postoperative patients this requirement can be met if the patient has developed an acute inflammatory or infectious process in the lungs that prevents the patient from being extubated.

ALT, Alanine transaminase.

vasodilation, hypotension, and normal or high cardiac output, approximately half of children with septic shock present with severe peripheral vasoconstriction, high systemic vascular resistance, and low cardiac output.[25,34]

The child with septic shock has significant hypovolemia and maldistribution of blood flow that typically respond to aggressive fluid administration, antibiotics and titration of inotropes, vasopressors, and vasodilators. Therapeutic goals include restoring blood pressure, normalizing heart rate and capillary refill, and maintaining high cardiac index (3.3 to 6 L/min/m^2 body surface area [BSA]) and high oxygen delivery (more than 200 ml/min/m^2) BSA.[32-37] In fact, in a small but seminal report of outcomes of septic shock in children,[35] Carcillo, Davis, and Zaritsky showed that aggressive fluid resuscitation (more than 40 ml/kg administered within the first hour of therapy and more than 200 ml/kg administered during the first 8 hours of therapy) was associated with significantly higher survival than less aggressive fluid resuscitation. In the most recent consensus recommendations for hemodynamic support of children with septic shock,[32] the experts noted the reduction in mortality (from initial 35% to 40% mortality to about 2% to 8% mortality) associated with the implementation of their consensus therapy recommendations.[32,34] In fact, for every hour delay in the restoration of normal blood pressure for age and restoration of capillary refill less than 3 seconds, the child's mortality doubled.[25,32-34]

The ultimate goal of treatment of septic shock is to support adequate systemic oxygen delivery and organ perfusion and function. This requires careful titration of fluid administration, inotropic support, and vasoconstrictors or vasodilators to maximize systemic oxygen delivery and organ perfusion and function.

The terms *warm* and *cold septic shock* are imprecise terms and should be used only in conjunction with other descriptions of systemic perfusion and cardiovascular function. **Warm shock** is characterized by peripheral vasodilation, warm skin with flash capillary refill, bounding pulses, and wide pulse pressure. Warm shock was thought to be associated with hyperdynamic cardiovascular function and high cardiac output. These characteristics are most commonly seen in adults with septic shock.[25] **Cold shock** is characterized by peripheral vasoconstriction, cold skin with prolonged capillary refill, and decreased peripheral pulses. Cold shock is often associated with low cardiac output; these characteristics are present in almost half of children who present with septic shock.[25] However, cardiac output may be low, normal, or high regardless of skin temperature, perfusion, and pulses; these characteristics alone will not identify the cardiovascular support required. When inadequate systemic perfusion persists, the child likely needs more aggressive fluid administration and titration of vasoactive drug therapy.

Many adults and some children with sepsis generate a cardiac output that is higher than normal despite a fall in ventricular

ejection fraction. This high cardiac output may be associated with temporary adaptive ventricular dilation and an increase in ventricular end-diastolic volume, an increase in heart rate, and a fall in systemic vascular resistance. This low ejection fraction and ventricular dilation has not been documented in most children with septic shock. Most demonstrate severe hypovolemia, and cardiac function may be maintained or restored if fluid resuscitation is adequate.[25]

Kissoon, Orr, and Carcillo[34] describe the calculation of a *shock index* for children with septic shock. This shock index (heart rate ÷ systolic blood pressure) is high (2.4 or higher) with untreated or inadequately treated septic shock but falls with effective treatment of septic shock.

Obstructive Shock

Obstructive shock is inadequate cardiac output caused by an impediment to blood flow to or from the heart into the pulmonary or systemic circulation. Causes of obstructive shock in children include congenital heart defects (such as critical aortic stenosis and those with ductal-dependent pulmonary or systemic blood flow), tension pneumothorax, and pulmonary embolus. Obstruction to blood flow results in low cardiac output and circulatory collapse, typically with signs of peripheral vasoconstriction as adrenergic stimulation attempts to reduce blood flow to the skin, gut, and kidney and maintain adequate blood flow to the heart and brain. Signs of systemic or pulmonary venous obstruction are observed.

Additional clinical manifestations of obstructive shock are based on the cause of the obstruction. For example, the newborn with ductal-dependent pulmonary blood flow develops profound hypoxemia when the ductus arteriosus begins to constrict. If a newborn has ductal-dependent systemic blood flow, systemic pulses become faint or absent, extremities become cold and pale, and signs of pulmonary venous congestion develop when the ductus arteriosus begins to close. Tension pneumothorax produces signs of systemic venous obstruction and congestion, decreased breath sounds and chest expansion on the side of the pneumothorax, and shift of the mediastinum to the contralateral chest. Significant hypoxemia is present. When cardiac tamponade is the cause of the obstruction, signs of systemic or pulmonary edema, or both, develop with low cardiac output. When pulmonary embolus is the cause of the obstruction, hypoxemia, severe respiratory distress (or shortness of breath), and signs of right ventricular failure are observed.[3,16]

Treatment of obstructive shock focuses on restoration of systemic oxygenation and perfusion, and elimination of the obstruction to flow. To support systemic oxygenation and perfusion, providers must establish and maintain an adequate airway and support oxygenation and ventilation. Following establishment of vascular access, administration of a fluid bolus of 10 to 20 ml/kg of isotonic crystalloid may improve systemic perfusion; repeat if it is effective.[3,37] Diagnostic studies are limited to those essential to establishment of the diagnosis. Elimination of the cause of obstruction may require administration of prostaglandin E_1 (to reopen a constricted ductus arteriosus in newborns with ductal-dependent congenital heart disease), interventional cardiac catheterization for treatment of other defects causing obstruction, needle decompression of a tension pneumothorax or cardiac tamponade, and fibrinolytic therapy and anticoagulation (and possible embolectomy) for treatment of massive pulmonary embolus.[3,37]

Reperfusion and Inflammatory Injury

Reperfusion (reoxygenation) injury is cell damage caused by the restoration of blood flow and physiologic concentrations of oxygen to cells that have been exposed to injurious but nonlethal hypoxic conditions.[38] Ischemia causes changes in transmembrane permeability to sodium and calcium, and damage to intracellular organelles.[39] This damage triggers a proinflammatory and procoagulant response that can be very similar to that described for septic shock (described previously).

Restoration of oxygen delivery to extremely ischemic tissues produces highly reactive oxygen intermediates (e.g., free oxygen radicals and superoxide) that damage cell membranes, denature proteins, and disrupt chromosomes (see Chapter 2).[39] The amount of free oxygen radical produced is directly related to the severity and duration of the ischemic period. The reperfusion process is most likely to affect endothelial cells of the microvasculature, compromising organ perfusion after shock resuscitation.[38,39]

An ischemic insult activates white blood cells, priming monocytes and macrophages and contributing to the release of inflammatory mediators or cytokines, including TNF, IL-1, IL-6, IL-8, and platelet-activating factor. These cytokines in turn contribute to vasodilation, increased capillary permeability, and altered platelet function. The ultimate result is a maldistribution of blood flow and a compromise in organ perfusion.[38,39] The role of these mediators is summarized in Table 7-5. Chapter 48 includes a more comprehensive discussion of MODS.

Signs of organ dysfunction include but are not limited to lactic acidosis, oliguria, and an acute alteration in level of consciousness (e.g., decrease in Glasgow Coma Scale score of 1 point or more); hypoxemia, hypotension, poor capillary refill, or shock plus signs of coagulopathy, respiratory, renal, or hepatic dysfunction, or neurologic dysfunction. Gut injury and inflammation may enable translocation of gram-negative bacteria or endotoxin into the bloodstream, and may contribute to gastrointestinal bleeding.[5] Box 49-4 contains information on other potential signs of organ system failure in children.

Several scoring systems are available to characterize the severity of illness in critically ill children with organ dysfunction. These include the Pediatric Logistic Organ Dysfunction (PELOD) scoring system[40] and the Pediatric Multiple Organ Dysfunction Score (P-MODS).[40-42] These scoring systems may be useful as prognostic indicators when they are used for several days. Important differences exist between neonates and children in terms of mortality associated with specific organ failures and with specific PELOD scores.[41]

Evaluation and Treatment of Shock

The goals of treatment of shock are maximization of oxygen delivery and minimization of oxygen demand. The airway, oxygenation, ventilation, and perfusion must be supported. Reduction of oxygen demand requires treatment of fever and pain. In

addition, the child should be kept warm and shivering should be prevented. Blood components and, perhaps, intravenous fluids should be warmed before administration to young infants and children with hypothermia. Fear and pain increase oxygen consumption, so care must be taken to reassure the child and treat pain as indicated.

As noted, all children in shock require support of airway, oxygenation, and ventilation. Specific treatment of hypovolemic shock is volume resuscitation. Treatment targeting cardiogenic shock requires titration of fluid administration to optimize cardiac preload, but vasoactive drugs are needed to improve myocardial function and vasodilators or vasoconstrictors may be needed to support systemic perfusion. Specific management of septic shock includes administration of antimicrobial therapy, fluid resuscitation, and initiation of vasoactive support within the first hour of care following initial medical contact. Treatment specific to obstructive shock includes elimination of the cause of the obstruction to blood flow.

To evaluate and support airway patency and ventilation the child is positioned in a manner that supports maximal airway patency, and the provider then assesses airway and ventilation. Humidified supplementary oxygen is given as needed at up to 10 to 15 L/min by nonrebreathing mask or bag-mask ventilation. An advanced airway is placed in children *before* respiratory deterioration or arrest complicates shock management. Oxygenation is monitored continuously through pulse oximetry.

The child's heart rate must be adequate to support effective cardiac output and systemic perfusion. The most common pediatric dysrhythmias are listed in Box 49-5. Treat bradydysrhythmias and extreme tachydysrhythmias promptly. Pharmacologic therapy, pacing, or synchronized direct current (DC) cardioversion may be required.

The rhythms associated with loss of pulses ("arrest" rhythms) include asystole, electromechanical dissociation (EMD), pulseless ventricular tachycardia, and ventricular fibrillation. Regardless of electrocardiogram (ECG) findings, provide cardiopulmonary resuscitation—including cardiac compression—when pulses are lost or if, despite support of oxygenation and ventilation, the child demonstrates a heart rate less than 60/min with poor perfusion.

Adequate vascular access is needed to establish hemodynamic monitoring and to provide volume and inotropic support as needed. Once systemic perfusion is restored, transfer to a pediatric intensive care unit is advised.

Volume resuscitation is designed to restore intravascular volume relative to the vascular space and to optimize ventricular preload. The specific fluid selected and route of administration are determined by the child's clinical condition. In general, isotonic **crystalloids** (isotonic salt-containing solutions, such as normal saline or lactated Ringer's solution) or **colloids** (protein-containing fluids, such as albumin or blood) are administered in boluses of 20 ml/kg (or 10 ml/kg of packed red blood cells) given over 5 to 20 minutes for hypovolemic and septic shock. If cardiogenic shock (myocardial dysfunction) is present, smaller fluid boluses (5 to 10 ml/kg) are administered over about 10 to 20 minutes. Hypotonic fluids should not be administered.[3,37] After each bolus, reassess systemic perfusion and administer additional fluids if indicated.

Children in septic shock require a large volume of intravenous fluid to restore and maintain systemic perfusion. More than 40 ml/kg in fluid boluses will likely be required during the first hour of volume resuscitation, and a total of 200 ml/kg or more may be required during the first several hours of therapy.[3,32,34,35,37] In fact, rapid volume administration, particularly during the first hour of therapy, has been linked with improved survival in hypotensive children in septic shock.[33] An algorithm for the treatment of septic shock, based on the recommendations of the American College of Critical Care Medicine and the Pediatric Advanced Life Support course, is presented in Figure 49-2.

Unless shock is mild or responds immediately to volume therapy, insertion of a central venous (monitoring) catheter is advisable. Several multilumen catheters are available in pediatric sizes that enable simultaneous monitoring of central venous pressure and administration of fluids. Continuous or intermittent monitoring of the superior vena cava $S_{CV}O_2$ will enable evaluation of the balance between the child's oxygen delivery and oxygen consumption. If cardiac output is adequate, oxygen saturation in the SVC will be approximately 25% to 30% lower than the arterial oxygen saturation. A larger arterial venous oxygen saturation difference suggests inadequate oxygen delivery (caused by inadequate arterial oxygen content or inadequate cardiac output or both) or excessive oxygen demand.[3]

Monitoring of the volume of urine output and specific gravity is useful in determining the child's response to fluid therapy. A urinary catheter should be inserted if shock is present unless the child has sustained pelvic trauma or a urethral tear is suspected. All sources of fluid intake and output should be monitored and recorded hourly or more frequently if needed.

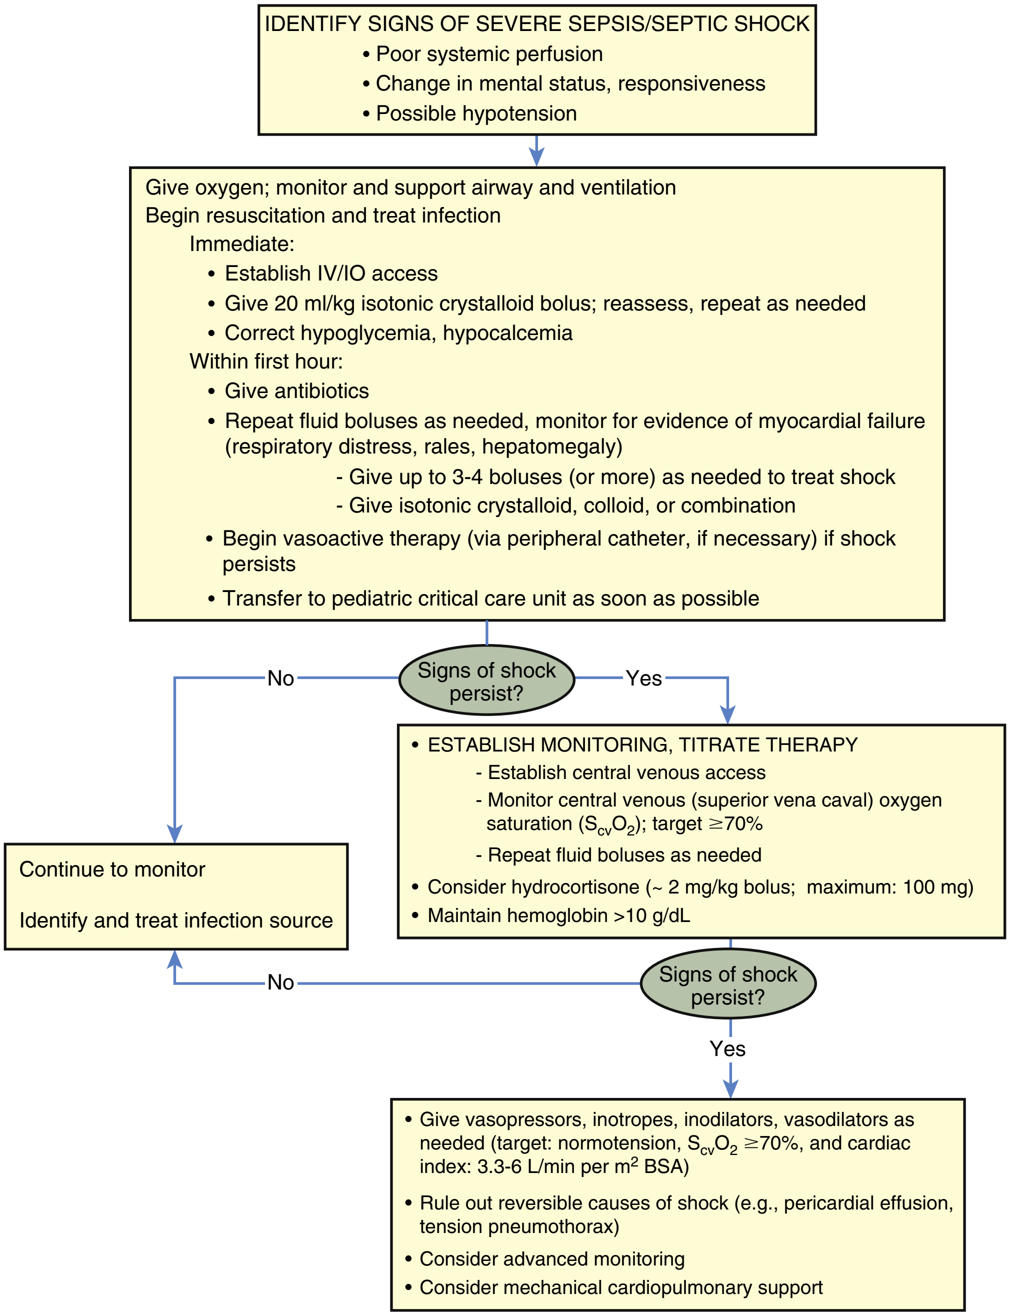

FIGURE 49-2 Hemodynamic Support in Pediatric Septic Shock. *BSA,* body surface area; *IO,* intake/output; *IV,* intravenous. (From Perkin RM et al: Shock, cardiac arrest and resuscitation. In Hazinski MF, editor: *Nursing care of the critically ill child*, ed 3, p 126, St Louis, 2013, Mosby; data from Brierley J et al: *Crit Care Med* 37:666–688, 2009.)

An intra-arterial line should be inserted if shock persists. This enables reliable, continuous evaluation of arterial pressure. Noninvasive oscillometric blood pressure–monitoring devices may not accurately measure low or rapidly falling blood pressures and may *overestimate* the blood pressure,[43] particularly in trauma patients.[44]

Insertion of a pulmonary artery catheter may be considered if the child demonstrates shock that is unresponsive to volume and vasoactive drug support. A pulmonary artery catheter with thermodilution cardiac output thermistor, a fiberoptic pulmonary artery catheter, or both can enable continuous monitoring of mixed venous oxygen saturation or continuous monitoring of cardiac output. Quantification of these variables can be particularly helpful if precise tracking of hemodynamic measurements is desired. This may be necessary in the care of the child with septic shock or MODS.

The optimal hemoglobin threshold for transfusion in critically ill children is unknown. In a multicenter trial of critically ill children, a hemoglobin red-cell transfusion threshold of 7 g/dl decreased transfusion requirements without increasing adverse outcomes.[45] However, that study excluded premature infants and children with severe hypoxemia, hemodynamic

instability, active blood loss, and cyanotic heart disease. A more recent publication from the same researchers[46] recommends higher transfusion thresholds (9 to 12 g/dl) for children with cardiac or respiratory disease, with the highest thresholds for children with cyanotic congenital heart disease and those with hemodynamic instability.

Administration of blood or blood component therapy is needed to treat hemorrhage or severe coagulopathies. A "normal" hematocrit does not rule out the possibility of hemorrhage; the hematocrit typically falls in a person who has sustained whole blood loss after the blood loss is replaced with crystalloids or colloids. In general, 10 ml/kg boluses of packed red blood cells are used for every second or third fluid bolus needed to treat significant blood loss.[14,15,37]

Transfusion for the child with chronic anemia and shock must be accomplished slowly to prevent hypervolemia and further deterioration in myocardial function. Administration of packed red blood cells at a rate averaging 3 to 5 ml/kg/hr over several hours may be well tolerated, particularly if it is preceded and followed by administration of diuretics.[47] If severe anemia is associated with severe hypervolemia and myocardial dysfunction, an exchange transfusion may be required. If a coagulopathy is present, administer specific blood component therapy necessary to prevent or treat hemorrhage.

Hypoxemia, metabolic acidosis, and electrolyte imbalances depress myocardial function and must be corrected when shock is present. Administer oxygen during resuscitation of the child in shock and be prepared to institute noninvasive pressure support ventilation or mechanical ventilation when needed.

The child's serum glucose concentration should be monitored using rapid bedside testing. Hypoglycemia requires glucose administration; continuous infusion is preferred to repeated intermittent bolus therapy. If severe hyperglycemia develops, insulin administration may be indicated to reduce the serum glucose concentration to less than 150 to 180 mg/dl. Although tight glycemic control has been linked with improved survival in critically ill children,[48] it also caused frequent episodes of hypoglycemia. The relative risks of severe hyperglycemia versus unintentional hypoglycemia have not been established.[49] In a recent survey, pediatric intensivists reported management of hyperglycemia with insulin therapy; the preferred blood glucose target range was 90 to 140 mg/dl.[50] A randomized clinical trial of pediatric glycemic control is needed.

During resuscitation, providers must avoid acute or severe alterations in the serum sodium concentration.[3,11,37] Acute changes in serum sodium alter the serum osmolality and result in fluid shifts into and out of the vascular spaces. Such fluid shifts can be associated with neurologic complications including seizures, cerebral edema, and intracranial hemorrhage.[11]

Alterations in serum potassium concentration may affect myocardial contractility and conduction. However, children are far less sensitive than adults to minor changes in serum potassium concentration. Hypokalemia may result from inadequate potassium administration during volume therapy or from excessive potassium losses caused by drug therapy (e.g., furosemide). The serum potassium concentration falls in the presence of alkalosis; this represents an intracellular shift of potassium and is corrected when the pH is normalized. Treat true hypokalemia with an infusion of potassium chloride at a dose equivalent to 0.5 to 1 mEq/kg administered over several hours.[11]

Hyperkalemia may result from excessive potassium administration, reduced potassium excretion (e.g., in renal failure), or massive cell lysis (e.g., tumor lysis syndrome). Serum potassium concentration also rises when acidosis develops; the rise in serum potassium is caused by a shift of potassium from the intracellular to the vascular space (i.e., exchanged for vascular H^+) and falls when the serum pH is corrected.[11]

Both ionized and total calcium concentration should be monitored, and documented hypocalcemia must be treated. Note that the ionized serum calcium falls with alkalosis and rises with acidosis. Serum ionized calcium concentration is often low (less than 4.5 mEq/L) in children with septic shock.[11]

Hypercalcemia may be observed in children with some malignancies, including acute lymphocytic leukemia, lymphomas, and soft tissue sarcomas. Malignant cells often secrete a parathormone-like substance that stimulates bone reabsorption, release of calcium, and rapid cell turnover. Although mild hypercalcemia is not life threatening, extreme hypercalcemia (total serum calcium approaching 19 to 20 mEq/L) may produce renal and cardiovascular complications.[47]

Table 49-7 summarizes drug therapy for children in shock. If oxygenation, ventilation, heart rate, and intravascular volume are appropriate and myocardial function and systemic perfusion remain poor, vasoactive drug therapy with inotropes is indicated.

Emerging Therapies for Shock and Sepsis

Prevention of shock is important. Prevention of trauma (injury prevention) and treatment of dehydration can eliminate the two leading causes of hypovolemic shock in children. *Haemophilus influenzae* sepsis and meningitis have been nearly eradicated in the United States since the introduction and widespread use of *H. influenzae* vaccine for infants, and immunization against *Neisseria meningitidis* (the causative microorganism of meningococcal sepsis and meningitis); pneumococcus vaccine may similarly reduce the incidence of pneumococcal infection and sepsis. The incidence of septic shock from hospital-acquired infections, such as ventilator-associated pneumonia or catheter-related bloodstream infections, is decreasing with the use of quality improvement approaches.[20]

Advances in shock therapy have been made in recent years, and several show promise for continued improvement in treatment. First, there is a better understanding of resuscitation goals with an appreciation of the need to target high, rather than normal, cardiac output and oxygen delivery during resuscitation.

Trauma resuscitation has become more targeted in adults and children. In the prehospital setting, prehospital fluid resuscitation is reserved for children with signs of shock. If penetrating trauma is associated with hypovolemic shock, the child requires urgent surgical intervention, so delays during transport are minimized.

Because massive transfusions can produce immunologic and coagulation complications, the surgical approach to trauma has changed to include staged surgical repair of significant

TABLE 49-7 PEDIATRIC VASOACTIVE DRUGS FOR THE TREATMENT OF SHOCK*

DOSE	EFFECTS	CAUTIONS
Sympathomimetics		
Dobutamine: 2-20 mcg/kg/min	Selective β-adrenergic effects, increases cardiac contractility and also increases heart rate (this latter effect is variable); β_2 effects produce peripheral vasodilation; no dopaminergic or α-adrenergic effects	Extreme tachyarrhythmias have been reported, particularly in infants; hypotension may develop; may produce pulmonary vasoconstriction
Dopamine: 1-5 mcg/kg/min	Dopaminergic effects predominate, including increase in glomerular filtration rate and urine volume	Can produce extreme tachyarrhythmias; can result in increase in pulmonary artery pressure; inhibits thyroid-stimulating hormone and aldosterone secretion
Dopamine: 2-10 mcg/kg/min	Dopaminergic effects persist and β_1 effects are seen, especially an increase in heart rate	As above
Dopamine: 8-20 mcg/kg/min	α-Adrenergic effects dominate	As above
Epinephrine: 0.05-0.15 mcg/kg/min	Endogenous catecholamine, which produces α, β_1, and β_2 adrenergic effects; at low doses, β_1 effects dominate	Will increase myocardial work and oxygen consumption at any dose; splanchnic constriction will occur at even low doses
Epinephrine: 0.2-0.3 mcg/kg/min	α-Adrenergic (vasoconstrictive) effects dominate	As above
Isoproterenol: 0.05-0.1 mcg/kg/min	β-Adrenergic effects; β_1 effects may result in rapid increase in heart rate; β_2 effects may produce peripheral vasodilation and also may effectively treat bronchoconstriction	Monitor for tachyarrhythmias, hypotension; will increase myocardial oxygen consumption
Norepinephrine: 0.05-1 mcg/kg/min	Endogenous catecholamine with α- and β-adrenergic effects; produces potent peripheral and renal vasoconstriction; can increase blood pressure	May cause tachyarrhythmias, increased myocardial work, and increased oxygen consumption; may result in hepatic and mesenteric ischemia
Vasopressin		
Vasopressin: 0.2 to 2 milliunits/kg/min (0.0002 to 0.002 unit/kg/min)	Antidiuretic hormone analog that acts on vasopressin receptors; produces peripheral and splanchnic vasoconstriction; also used to treat GI hemorrhage for this reason	May cause hypertension, bradycardia
Phosphodiesterase Inhibitors and Inodilators		
Inamrinone: Loading dose 0.075 to 0.1 mg/kg (75 to 100 mcg/kg) slowly; Infusion: 5-10 mcg/kg/min	Nonadrenergic inotropic agent that produces phosphodiesterase inhibition and increase in intracellular cyclic adenosine monophosphate (cAMP); intracellular calcium uptake also is delayed; these effects result in improved cardiac contractility and vasodilation	Monitor for arrhythmias (especially accelerated junctional rhythm, junctional tachycardia, and ventricular ectopy); may produce hypotension (especially if patient is hypovolemic), liver and GI dysfunction, thrombocytopenia, and abdominal pain; experience in children is limited and recent
Milrinone: Loading dose: 0.05 mg/kg (50 mcg/kg) over 10-60 min; Infusion: 0.25-0.75 mcg/kg/min	As above	Reduce dose when renal dysfunction present
Vasodilators		
Nitroglycerin: 0.25-0.5 mcg/kg/min; increase as tolerated to maximum 10 mcg/kg/min (adolescents, 5 mcg/min; *note* **not** per kg per min)	Arterial and venodilator	Is absorbed by polyvinyl chloride tubing; use special infusion set
Nitroprusside: 0.3-0.5 mcg/kg/min; titrate up to 8 mcg/kg/min (max. infusion dose: 8-10 mcg/kg/min)	Arterial and venodilator	Light sensitive; use special infusion set or cover tubing when infusion slow; may produce thiocyanate and cyanide toxicity, particularly for higher doses or prolonged infusion

Modified from Perkin RM et al: Shock, cardiac arrest and resuscitation. In Hazinski MF, editor: *Nursing care of the critically ill child,* ed 3, p 120, St Louis, 2013, Mosby.

*Infusion rate = ml/hr = Weight (kg) × Dose (mcg/kg per min) × 60 min/hr ÷ concentration (mcg/ml).

GI, Gastrointestinal.

injuries (e.g., liver and bowel injuries). The initial surgery is performed to stabilize the child, and, if needed, subsequent procedures repair the injury. This multistage approach, based on battlefield experiences, reduces the volume of blood products administered and has been linked with reduced morbidity and mortality.[15]

We now have a better understanding of the pathophysiology of septic shock in children,[32] appreciating the critical role that immediate antibiotics, early and aggressive fluid resuscitation, and vasoactive therapy play in the outcome of pediatric sepsis.[32-36] Such resuscitation should be provided during the first hour of therapy; every hour of delay has been reported to result in a 40% increase in mortality.[33]

Goals for management of pediatric septic shock are to restore the child's heart rate and blood pressure to normal for age, to achieve targeted perfusion pressure (mean arterial pressure – CVP) of about 55 to 65 mmHg, to reduce capillary refill to less than 2 seconds, and to support a cardiac index of 3.3 to 6 $L/min/m^2$ body surface area, and to maintain the SVC's $S_{CV}O_2$ at 70% or higher.[32,33-37] This goal-directed therapy, targeting an $S_{CV}O_2$ of 70% or higher in children, has been shown to substantially reduce mortality (by two thirds in one study) and organ failure.[36]

In an excellent and very concise summary of the management of the child in septic shock, Kissoon, Ort, and Carcillo suggest calculation of a *shock index,* dividing the child's heart rate by the child's systolic blood pressure (heart rate [HR] ÷ systolic BP). This shock index can serve as an indicator of left ventricular ejection, and should fall (e.g., from 2.25 to 1.75) in the first hour of effective management.[34]

Therapeutic hypothermia suppresses proinflammatory mediators and may enhance anti-inflammatory mediators.[51,52] Mild to moderate induced hypothermia (to 32° to 34° C [89.6° to 93.2° F]) has been shown to increase survival in neurologic outcome in neonates with hypoxic-ischemic encephalopathy[53] and in comatose, hemodynamically stable adults following resuscitation from cardiac arrest.[54] It is possible that such therapy may be helpful for victims of shock, particularly those with MODS. However, it is important to note that the control groups in these neonatal and adult hypothermia studies were all febrile. We know that fever develops following resuscitation from cardiac arrest and that fever is associated with unfavorable neurologic outcome.[55] While we await the results of multicentered clinical trials of therapeutic hypothermia in children, it is important to treat fever following resuscitation.

It soon may be possible to tailor sepsis and other critical therapies through the use of genetic profiling of the microorganism[23] and of the child.[22] Prospective identification of genetic markers for risk of sepsis and responsiveness to therapy may enable individual tailoring of surveillance and interventions to maximize survival and minimize risks from those therapies that are unlikely to be effective.

Finally, several devices are available that enable noninvasive or minimally invasive calculation of cardiac output and index, stroke volume, and circulating blood volume in children.[3] As providers gain experience with the use of such devices and more published data are available about their reliability, we will have more tools to confirm clinical assessment and monitor response to therapy.

BURNS

Management of pediatric burn injuries requires an understanding of the differences that exist in this population related to etiology of injury, growth and development, physiology, and clinical course. In 1988 the American Burn Association established criteria to guide transfer of a patient to a specialized burn center. These criteria remain a standard in burn care and are based on complex management issues related to treatment of acute burns and the long-term rehabilitation needs of children.[56]

Burn injuries in children often are preventable and often are the result of inadequate supervision, curiosity, inability to escape the burning agent, or intentional abuse. **Scald injuries** (i.e., hot water, grease, other) are most common among young children, whereas flame burns are more prevalent among older children.[57] A child exposed to hot tap water at 60° C (140° F) for 3 seconds will sustain a third-degree burn.[58]

A child's skin is thinner and thus more susceptible to injury than an adult's. The extent of injury is determined by the temperature of the burning agent and the duration of exposure. Because very young children may be unable to escape the heat source, the depth of the injury is likely to be greater. The kitchen also is a common site for burn injury and often involves pulling over dishes or appliances containing hot liquids. These are common burn injury sources for children 2 years of age and younger.

Although **child abuse** can occur at any age, young children are particularly vulnerable to serious injury. Approximately 10% of all forms of abuse cases in the United States are caused by burning.[59] Burns that may suggest physical maltreatment include: (1) patterned burns, (2) classic forced immersion burn pattern with sharp stocking or glove demarcation and sparing of flexed protected areas, (3) splash/spill burn patterns not consistent with history or developmental level, and (4) cigarette burns. Abuse is suggested with: (1) incompatible history and physical examination; (2) incompatible burn and developmental level; (3) bilateral or mirror image burns; (4) localized burns to genitals, buttocks, and perineum (especially at toilet-training stage); (5) evidence of excessive delay in seeking treatment; and (6) presence of other forms of injury.[60] Forced immersion in hot water typically presents with deep symmetric injuries lacking any evidence of splash wounds (Figure 49-3). By contrast, a pull-down splash burn usually has a triangular pattern with immediate skin contact reflected as the area of greatest burn injury. The burn injury then forms an arrow pointing downward. **Contact burns** also may be intentionally inflicted by contact with cigarettes or other hot objects such as curling irons. Young children may inadvertently grasp a hot object. However, the pattern of injury will be confined to the palm. Burns to the dorsum of the hand are viewed with suspicion.[59,60]

Children 3 to 8 years of age are most often injured by flame during fire play. Lighters and matches ignite clothing and cause house fires. Young children may run when clothing ignites and increase the severity of injury. Approximately 50% of all deaths

FIGURE 49-3 Burn Pattern Typically Seen After Forced Emersion in Hot Water.

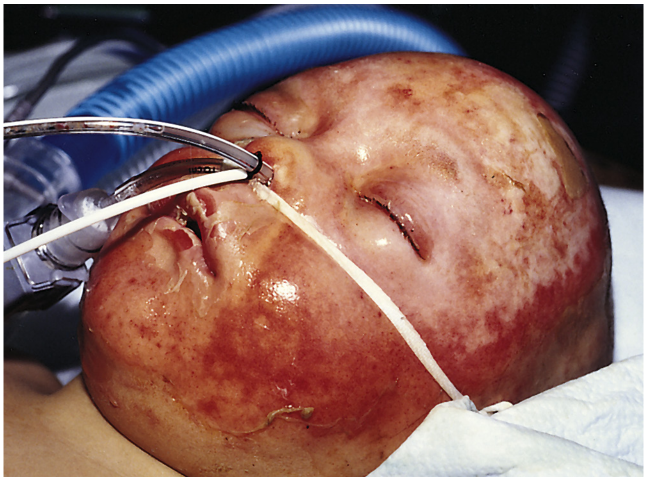

FIGURE 49-5 Areas of Indeterminate Depth of Injury in a Young Child.

FIGURE 49-4 Commissure Burn Resulting from Biting an Electrical Wire.

in burn children are caused by inhalation injury.[61] Escape from a burning residence or motor vehicle is often delayed because young children cannot cognitively comprehend the circumstances or physically remove themselves from the danger. **Flame burns** involving flammable liquids, especially gasoline, are more common in older children.

Although flame and scald burns account for the majority of thermal injuries in children, **electrical burns** result from direct contact with high- or low-voltage current. Most commonly these injuries occur as a result of risk-taking behavior on the part of young males. Trauma from contact with electrical energy results from the passage of current through vital organs, muscle compartments, and nerve or vascular pathways. Very young children are at risk for injury from chewing on electrical cords or inserting objects into electrical outlets (Figure 49-4). Lightning strikes also account for some electrical burns. **Chemical burns** occur most often in an industrial setting for the adult. At home, children may be burned by swallowing corrosive agents. The type of causative agent has important implications for the evaluation, treatment, and prognosis of the child.

Severity of Injury

The severity of burn injury is assessed based on the percentage of the total body surface area (TBSA) involved. Use of the standard Rule of Nines results in inaccurate calculation of the percentage of TBSA involved in children. Although the infant's trunk and arms are of roughly the same proportion as the adult's, the head and neck make up 18% of TBSA and each lower extremity is 14% of TBSA. A modified Rule of Nines deducts 1% from the head and adds 0.5% to each leg for each year of life after 2 years.[58] Various charts are available that assign body proportions to children of different ages. These are generally used in pediatric burn facilities and do accurately compute the extent of burn injury.

Because burn trauma represents a three-dimensional wound, the severity of injury is assessed also in relation to the **depth of injury.** The etiology of the burn and the duration of contact with the burning agent are important considerations in determining the depth of injury. In general, the more intense the heat source and longer the contact, the deeper the resulting injury; however, infant skin is extremely fragile and more likely to sustain a deeper burn. This makes the estimation of the depth of burn difficult in very young children, especially following scald injuries (Figure 49-5). Intentionally inflicted burns tend to be more severe because contact with the burning agent is prolonged. Electrical injuries also may mask the extent of damage on initial assessment. Visible tissue damage may appear minimal despite severe injury to underlying structures.

Another important factor in assessing the severity of injury is the victim's age. Children younger than 2 years have a significantly higher risk for associated morbidity and mortality after sustaining a burn injury. They have not achieved maturity of the immune system and are at increased risk for infection and sepsis. In addition, very young children are intolerant of rapid fluid shifts and demonstrate immature renal function, which negatively affects their ability to retain sodium and water (see Shock).

The areas of the body injured are another consideration when assessing the severity of the burn. Burns of the hands, feet, and perineum and across joints carry the potential for scar formation and contracture that may interfere with function as well as growth and development. Specialized care is required to preserve maximal function. In addition, burns to the face and neck may result in airway compromise as well as deformity caused by damage to delicate cartilage of the nose and ears.

Concomitant injuries may be suggested by the circumstances of the burn and should always be investigated; for example, initially burns do not bleed. Bloody drainage suggests another source of trauma. Fractures may result from jumping from a window to escape a house fire. Electrical injuries and motor vehicle accidents often result in associated trauma. Any suspicion of intentionally inflicted burns should alert the burn team to assess for other injuries.

PATHOPHYSIOLOGY, CLINICAL MANIFESTATIONS, AND TREATMENT. Major burn trauma involves all body systems, and the consequences of injury include shock, infection, hypermetabolism, organ failure, and functional limitations. These effects can be magnified in the pediatric population as a result of physiologic immaturity and age-related variation in treatment modalities. Along with recognition of changes in the pathophysiology with a burn injury, clinical manifestations are apparent in all organ systems. Although the cutaneous trauma is the initiator of the chain of responses, it is important to consider all of the likely consequences of the injury. An awareness of the changing patterns of convalescence and the development of complications assists in the identification and early treatment of potential sequelae.

Integument

The local response manifested in the area of trauma includes cellular destruction and damage. Progressive injury caused by **dermal ischemia** may result from ineffective initial management, especially inadequate or delayed resuscitation. An increase in the permeability and hydrostatic pressure of the capillaries results in the loss of fluid, proteins, and electrolytes into the interstitial spaces. A diminishing intravascular oncotic pressure further enhances these losses and results in edema formation. Marked edema can result not only in the area of injury but also in unburned areas. Loss of substantial areas of skin has immediate and profound physiologic effects. Direct and evaporative fluid losses are seen immediately.[62] Although these losses are maximal in the immediate postburn period, they persist until wound closure.

Circulatory alterations also occur in the area of injury. Reduced blood flow and capillary stasis result from **hemoconcentration,** the release of thromboplastin and clot-activating factors from heat-damaged cells, reduced cardiac output, and edema formation. Circulation in the area of partial-thickness wounds ceases for 24 to 48 hours after injury, after which it is usually restored. Vascular supply in the area of full-thickness injuries is completely occluded and is not restored until granulation tissue forms or the wound is surgically repaired. The dry, leathery **eschar** provides an ideal environment for bacterial growth. Infection, trauma, or applying ice to the burn area may convert a partial-thickness injury to a full-thickness one, especially in young children, who have thinner, more delicate skin.

Vitamin D, an essential factor for proper formation of bone during growth and development, is an important nutrient in children to facilitate intestinal absorption of calcium. Vitamin D deficiency has been associated with adverse effects on the skeletal system, as well as the immune system. Vitamin D production may be compromised in burned children demonstrated by a high incidence of low-serum vitamin D levels. Burn wound scarring and lack of sunlight may limit cutaneous vitamin D biosynthesis.[63]

FIGURE 49-6 Escharotomy/Fasciotomy in a Severely Burned Arm.

Cardiovascular System

The marked reduction in cardiac output immediately following injury is accompanied by an initial increase in systemic vascular resistance. As fluid is lost into the interstitial spaces, a further reduction in cardiac output occurs, accompanied by vasodilation. Because the infant maintains cardiac output by increasing heart rate preferentially to stroke volume, extremely elevated heart rates result in a decreased filling time and a further reduction in cardiac output.[64] Adequate resuscitation returns cardiac output to normal levels in approximately 24 to 36 hours. Without fluid replacement, cardiac output continues to decrease and results in organ failure and death.

The inefficient and labile peripheral circulation of the infant further complicates management of the burn shock phase of treatment. The rapid fluid shift to the interstitial space and drying of the eschar results in compromised circulation and a resultant tourniquet effect in the extremities. Blood vessels and nerves become entrapped because the fascia cannot expand to accommodate the massive edema. Release of pressure is required to restore blood flow and preserve nerve function (Figure 49-6).

Constriction of the chest and impairment of respiratory excursion also may result, especially in the very young child, because of the increased pliability of the rib cage. Excessive fluid volume can contribute to a serious complication (increased intra-abdominal pressure) that may have an underestimated incidence in burned individuals. Although children with increased intra-abdominal pressure readings tended to be younger, larger TBSA injuries and full-thickness components were significantly associated with elevated pressures.[65] Increased **intra-abdominal pressure** has the potential to impair hemodynamics, renal function, hepatic malperfusion, and pulmonary dysfunction. Despite maintaining cardiac output with fluid replacement, renal function remains impaired in the presence of increased intra-abdominal pressure. Intra-abdominal pressure, as a stressor, can stimulate the neuroendrocrine system and elicit stress reactions directed at neutralizing the initial insult of the burn. Increases in the production and release of catecholamines, glucocorticoids, and beta-endorphins support the clinical finding of profoundly altered cardiovascular, pulmonary, and renal function.[66]

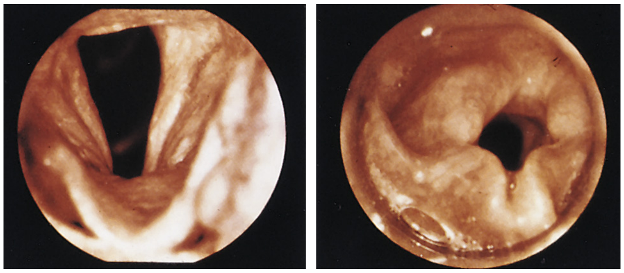

FIGURE 49-7 Airways. Adult airway *(left);* smaller pediatric airway *(right).*

Pulmonary System

The clinical manifestations of burn injury related to the pulmonary system include a variety of complications ranging from inhalation injury, pulmonary edema, and respiratory failure to aspiration of gastric contents and pneumonia. Inhalation injury has a negative, prolonged effect on pulmonary function that is associated with and remains a major determinant of increased morbidity and mortality.[67]

Anatomic differences in the pediatric airway affect the response to pulmonary complications, as well as therapeutic interventions. The infant airway is positioned anteriorly, making visualization of the cords more difficult. The difficult visualization is further compounded by the relatively large tongue and slanting vocal cords. A small degree of edema results in greatly increased work of breathing in the child (Figure 49-7). These considerations are particularly important during the resuscitation phase when progressive edema threatens to obstruct the airway. Significant edema results in impairment of respiratory function unless an artificial airway is inserted (Figure 49-8). Malposition of an endotracheal tube may result in inadvertent extubation, intubation of the bronchi, and atelectasis. Because of the relatively short length of the infant trachea, alterations of the position of the head and neck can affect tube position despite maintenance of the tube position at the teeth.[68-70]

Infants compensate for pulmonary compromise by increasing the respiratory rate. However, because the child possesses fewer type I muscle fibers, fatigue related to the increased work of breathing results in more rapid desaturation than in adults. The soft cartilage of the pediatric airway is prone to collapse in the presence of partial obstruction. Children with burns are at increased risk for these events because of underlying respiratory disease or injury.

Mechanical ventilation of severe inhalation injury is a dynamic and complex task.[71] Therapeutic interventions required for maintenance of pulmonary function have been implicated in postextubation stridor and barotrauma. Evidence suggests that barotrauma from mechanical ventilation may be minimized by protocols based on permissive hypercapnia. Moderate respiratory acidosis was well tolerated and ventilating pressures maintained below 40 cm.[72] The low incidence of mortality associated with this strategy suggests a reduction in ventilator-induced lung injury. In addition, high-frequency oscillatory ventilation (HFOV) in severe pediatric burn patients has significant, early, and sustained improvement in oxygenation. When HFOV is begun early in burn care, barotrauma is significantly reduced.[73]

FIGURE 49-8 Severe Facial Edema During Burn Shock.

The consequences of metabolic and physiologic changes occurring during the acute phase of injury remain apparent during convalescence. Severe burns result in a decrease in pulmonary function from restrictive and obstructive pulmonary disease evidenced by a reduction in pulmonary volumes and maximum voluntary ventilation lasting up to 8 years. At times, chest wall scarring in children caused by burns severely limits thoracic cage excursion.

Burn Shock

The pathophysiologic responses of burn injury result in **hypovolemia** and extracellular sodium depletion in the burn-injured individual. Manifestations for adults are discussed in Chapter 48. Hypotension is a late sign of shock in the child. A complete circulatory assessment, including heart rate and peripheral parameters, is a more reliable measure. Urine output is a reflection of end-organ perfusion and is therefore the most accurate monitor of the adequacy of fluid resuscitation. A urine output of 30 to 50 ml/hr in adults and 1 ml/kg/hr in children weighing less than 30 kg are the suggested endpoints associated with many resuscitation formulas. Fluid is titrated to maintain the output within the parameters.[58]

The fluid of choice for burn shock resuscitation should approximate the fluid lost from the circulating volume, for example, lactated Ringer's solution. Children require fluid resuscitation for smaller burns than do adults as a result of their limited physiologic reserves. The child's relatively greater ratio of body surface area to weight results in increased evaporative water losses and proportionately more fluid during resuscitation. Although **colloid replacement** during burn shock

resuscitation remains controversial, colloids may be required in the very young child who fails to respond to fluid replacement.[74] A component for **maintenance fluid** *must* be included in the calculation of fluid needs during resuscitation. Maintenance fluids represent the body requirements in the absence of burn injury.

Successful resuscitation depends on establishment of intravenous access. Although this is usually accomplished by peripheral or central venous cannulation, circulatory collapse may preclude timely administration of fluid replacement. Cannulation of veins in the pediatric population is further complicated by small vessels and increased subcutaneous fat. Children are good candidates for **intraosseous cannulation** when traditional venous access techniques fail. Blood, drugs, and fluid are readily absorbed by red marrow that drains into medullary venous channels and thus to the systemic circulation. This technique is most effective in children younger than 5 years, because red marrow is steadily replaced by yellow marrow in the limbs, making infusion more difficult, hence decreasing the infusion rate.[75] With proper care and removal as soon as other access is available, complications are minimal.

Fluid Resuscitation

Fluid resuscitation is generally required for children after thermal injuries in excess of 10% to 15% of the TBSA. Fluid is administered to compensate for fluid and electrolytes extravasating into the interstitial spaces. This replacement restores circulating volume, improves perfusion, and alleviates organ dysfunction associated with impaired circulation.

Various protocols have been proposed as guidelines for fluid administration. It is important to remember that any regimen serves merely as a guideline and will require adjustment based on the individual response of each child. Because the linear relationship between weight and surface area does not exist in children (surface area varies to weight as a two-thirds function), use of adult formulas result in under- or over-resuscitation.[76] A commonly used protocol is a modification of the Parkland formula. Children also tend to require relatively more fluids than adults because they have higher evaporative losses because of their body surface area-to-weight ratio. **Evaporative fluid loss** can be a significant contributor to hypovolemia in the burned child. This evaporative fluid loss continues until the burn wounds are closed. As in adults, inhalation injury also continues until burn wounds are closed. And as in adults, inhalation injury increases the magnitude of total body surface area injury; therefore, children with burn injuries require more fluids.[74]

Research suggests that in the acute phase of the burn injury children receive far more fluid resuscitation than calculated by the modified Parkland (Baxter) formula guidelines. This syndrome has been termed “fluid creep.”[77] Onset maybe caused by higher fluid limits and increased use of opiates resulting in an increased abdominal pressure. The method to control fluid creep includes strict adherence to the modified Parkland formula. In children who have developed increased abdominal pressure, decompressive laparotomy may resolve the increased intra-abdominal pressure.[74]

Renal System

Loss of circulating volume into the interstitial spaces results in reduced renal blood flow and decreased glomerular filtration. An important measure of the adequacy of volume replacement is urine excretion. Sufficient volume replacement maintains urine output during resuscitation. Approximately 36 hours after injury, edema fluid begins to mobilize and output increases.

Children younger than 2 years of age lack the ability to concentrate urine because of the immaturity of the renal system and are, therefore, at increased risk for dehydration. In addition, the child has a relatively larger TBSA in relation to weight than the adult. Combined with limited physiologic reserves, increased fluid requirements are necessary for children during burn shock resuscitation and to compensate for evaporative water losses.[76]

Evidence of pigment in the urine results from the hemolysis of red blood cells. This is especially common after extensive electrical injuries and destroyed muscle from deep thermal injury. The release of **myoglobin** may occlude the kidney tubules and result in renal failure.

Gastrointestinal System

The gastrointestinal (GI) system plays an important role in the pathophysiology of burns. Alterations in blood flow result in decreased perfusion to the GI tract. Ischemia may cause erosion and necrosis of GI tissue. The GI response to a burn injury often includes mucosal atrophy, changes in digestive absorption, and increased intestinal permeability. Depending on the proportion of burn size, atrophy of the GI tract mucosa can occur immediately after injury. The atrophy results in gut barrier dysfunction leading to increased bacterial translocation and ultimately sepsis.[78]

Paralytic ileus occurs often after major burn injuries. Although digestion ceases in the stomach and the large bowel, the small intestine maintains motility and absorptive capacity. Intestinal motility returns as fluid losses are replaced unless irreversible necrosis of the bowel has occurred as a result of insufficient perfusion.

Immune Function

Burn trauma–induced immunosuppression results in increased susceptibility to infection and sepsis. Although the exact mechanisms responsible for this immunosuppression remain obscure, it is clear that complex interactions of the hypermetabolic response, nutritional support, bacterial translocation, and defects in both innate and acquired immune function are involved (Figure 49-9). In addition, young children are at increased risk for microbial invasion caused by an immature immune system and limited antibody production.

Deitch reported that wound- or gut-derived endotoxemia may be one of the mediators of the hypermetabolic response observed after thermal injury, and this finding remains undisputed.[79] When bacteria translocate from the gut or from the burn wound, endotoxin may affect immunologic response as inflammatory mediators are released. A further complication in the activation of inflammatory mediators is the release of toxic metabolites, such as oxygen free radicals.[80]

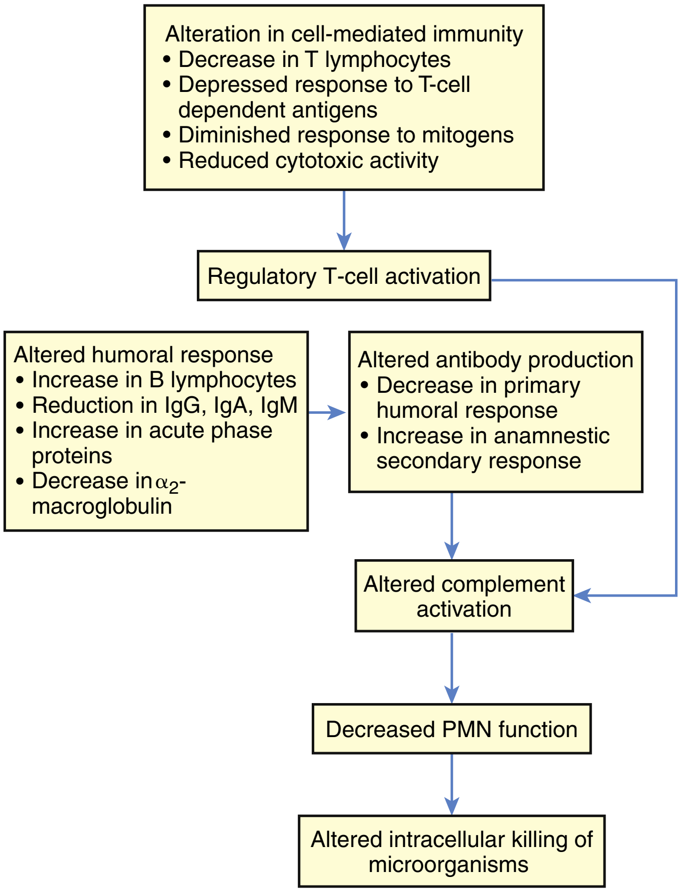

FIGURE 49-9 **Altered Immune Function After Thermal Injury.** Cell-mediated immunity, antibody production, humoral response. *PMN,* Polymorphonuclear leukocyte.

Circulating immunoglobulins may be affected by several factors, including age and the severity of injury.[81] Therapeutic interventions such as multiple transfusions, surgical procedures, and antibiotic and anesthetic administration also introduce elements that confound the evaluation of immunosuppressive effects. The immune system is activated systemically after a large burn injury with extensive tissue necrosis and may become ineffective or even self-destructive. Infections in burns may result in the loss of some components of innate immune function.[82]

An additional aspect of the immunopathologic consequence of a burn is the role of immunomodulatory cytokines that are suggested to regulate innate regulatory lymphocytes. Research regarding four cell types—NK (natural killer), natural killer T (NKT), gamma-delta T (γδ), and regulatory T (Treg)—indicates their central role in protective immunity.[83] In children with moderate to severe burn injury, cytokines have been found to increase inflammation by enhancing catabolism and hypermetabolism. In this immunomodulatory process the proinflammatory function of cytokines enhances protection from sepsis, and the anti-inflammatory function supports anabolism (i.e., tissue repair).[84]

Infection

Whereas shock and pulmonary compromise present the most immediate threat after burn trauma, local and systemic infections become the primary complication during healing. The burn wound initially is relatively free of pathogens; however, dead, avascular tissue and wound exudate provide a fertile environment for bacterial growth. Colonization of the wound is apparent by the fifth postburn day. Gram-positive microorganisms are usually recovered from cultures first, followed by opportunistic gram-negative bacteria. The impaired vascular supply to burned tissue enhances the proliferation of pathogenic microorganisms. Bacterial invasion results in thrombosis and a further impairment of circulation sufficient to convert a partial-thickness injury to a full-thickness wound.

Improvements in treatment have resulted in a reduction in wound infection. Aggressive excision and grafting of the wounds, improved nutritional support, and the development of microorganism-specific topical antimicrobials have contributed to this trend. However, the incidence of septicemia remains relatively constant. This is perhaps explained by the survival of children with burns of increasingly large body surface area. The burn wound serves as the site of primary invasion for the majority of instances of local or generalized infection. Because the burned child is immunosuppressed for many weeks after injury, maintaining wounds at low contamination levels by meticulous wound care decreases the frequency and duration of septic episodes caused by wound flora.[85]

Metabolism

Complex metabolic alterations are observed after burn injury. The extent of metabolic derangement is proportional to the magnitude of TBSA burn sustained. Wilmore demonstrated the linear increase in metabolic rate up to 2½ times normal resting energy expenditure.[86] As burn injury approaches 50% of TBSA, a plateau is reached, limiting further physiologic response to the trauma or other challenges such as infection.

A biphasic pattern of physiologic response is evident in thermally injured children. The initial **ebb phase** occurs during the immediate postburn period and continues for 3 to 5 days. This phase is characterized by reduced oxygen consumption, impaired circulation, and cellular shock. After the resolution of the shock and the restoration of circulating volume, the metabolic response shifts to a **catabolic (flow) phase** (Table 49-8). A state of **hypermetabolism** ensues, characterized by increased oxygen consumption and elevation of catecholamines, glucocorticoids, and glucagon.

Increased blood flow to the wound supplies additional glucose necessary for tissue repair. Insulin levels are usually normal or even elevated but are inappropriately low in relation to glucagon. Catecholamines and glucocorticoids act as antagonists to insulin. This effect combined with a tissue resistance to insulin stimulates glycogenolysis and gluconeogenesis, thus increasing glucose flow from the liver.[65] In the child, glycogen stores for meeting the increased energy demands of the burn are limited. The initiation of protein and lipid catabolism for glycogenesis is accelerated. This prolonged metabolic dysfunction may lead to loss of lean body mass and increased morbidity.[87]

Metabolic rates slowly return to normal with wound closure. However, a reactivation of the hypermetabolic response may occur with sepsis or organ failure.

TABLE 49-8 METABOLIC ALTERATIONS FOLLOWING INJURY

RESPONSE	DOMINANT FACTORS	CLINICAL FINDINGS
Ebb response	Loss of plasma volume Shock Low plasma insulin levels	Hyperglycemia Decreased oxygen consumption Depressed resting energy expenditure Decreased blood pressure Cardiac output below normal Decreased body temperature
Flow response		
Acute phase	Elevated catecholamines Elevated glucagons Elevated glucocorticoids Normal or elevated insulin levels High glucagon/insulin ratio	Catabolic Hyperglycemia Increased respiratory rate Increased oxygen consumption Increased body temperature Redistribution of polyvalent cations such as zinc and iron Mobilization of metabolic reserves Increased urinary excretion of nitrogen, sulfur, magnesium, phosphorus, potassium Accelerated gluconeogenesis
Adaptive phase	Stress hormone response subsiding	Anabolic Normoglycemia Energy turnover diminished Convalescence

From Gottschlich M, Alexander JW, Bower RH. In Rombeau JL, Caldwell MD, editors: *Enteral and tube feeding,* Philadelphia, 1990, Saunders.

Hypermetabolism

The hypermetabolic response after burn injury profoundly alters the production and use of nutrients. As a consequence of these phenomena, caloric requirements increase dramatically. Advances in burn care have allowed the performance of indirect calorimetry and assessment of metabolic rate at the bedside. Nutritional support must have an increased metabolic rate factored in (increased by 10% to 20%) because of fluctuations in energy use associated with activity. Current recommendations suggest 1.5 to 2 g protein/kg/day for adults and up to 2.5 to 4 g protein/kg/day for children.[87]

In addition to age, body composition has been found to significantly affect the postburn course. Preexisting obesity in burn children has been associated with longer hospital stay and associated morbidity.[88] However, the heightened nutrient requirements of the burned child preclude a reduction in nutritional support during the acute phase of recovery. Aggressive nutritional therapy is critical to the recovery of these children, and programs designed to achieve ideal body weight should not be instituted until wound healing is achieved.

Metabolism of many micronutrients is greatly affected by burn injury. Micronutrient supplementation is necessary because vitamin and mineral requirements increase with the severity of the burn related to heightened protein synthesis, enhanced caloric expenditure, and increased micronutrient losses. Pre-burn status also indicates individual vitamin and mineral needs.[63] Hypermetabolism results in a rapid turnover in vitamins and trace minerals important in the wound healing and immune response. A deficiency of specific nutrients interferes with carbohydrate and nucleic acid metabolism, collagen formation, and immune function.

The **thermoregulatory response** after burn injury results in an elevation in core body temperature. Burned individuals strive for temperatures of about 38° C (100.4° F). Depressed or "normal" temperature may be indicative of overwhelming sepsis, or an exhausted physiologic capability to maintain temperature, and should be viewed as an ominous sign. Routine methods of heat conservation after a major burn injury are inadequate because of excessive heat loss through convection and evaporation.[88] Therapeutic intervention, such as operative procedures and dressing changes, and transport present situations requiring increased diligence to prevent inadvertent cooling. Infants are at increased risk for a precipitous drop in core body temperature caused by an inability to regulate heat loss by shivering. Heat is also lost because of evaporation of water from damaged skin surfaces. Infants and children are especially vulnerable because of the large surface area relative to metabolically active tissue.[77]

Nutritional Support

The heightened metabolic demands after burn injury combined with a poor appetite often necessitate supplementation of oral intake. Children with burns in excess of 20% of TBSA often require supplementation with tube feeding. Feeding does not need to be delayed pending resolution of paralytic ileus and the resumption of bowel sounds because the small bowel maintains motility and absorptive capability. A small-bore feeding tube placed in the duodenum provides a safe route for the delivery of essential nutrients. Parenteral hyperalimentation is reserved for those children who are unable to tolerate enteral support because of attendant risks of catheter sepsis and loss of intestinal integrity. Early enteral supplementation preserves gut

WHAT'S NEW?

Advances in Burn Wound Care

Ongoing research and development continues to focus on the burn wound dressing, providing more therapeutic options with major wounds. Impregnated silver dressings kill bacteria but because most are processed with a special layer, they are less painful to remove. Some of these products can be left on the wound for up to 2 weeks allowing less frequent dressing changes and more comfort for the individual. A new extracellular matrix (ECM) product is being researched for repair and remodeling of damaged tissues in a burn injury and other therapeutic wound care situations. Derived from porcine urinary bladder, this ECM technology contains a bimodal surface technology with naturally occurring collagens and proteins and maintains an epithelial basement membrane surface. An in vitro study demonstrated that urinary bladder ECM is the best basement membrane as compared to small intestine or liver ECM. Another study suggested that antibacterial activity exists within ECM and these low-molecular-weight peptides may help explain resistance to bacterial infection.

Data from Brennan A et al: *Tissue Eng* 12(10):2949–2955, 2006; Brown B et al: *Tissue Eng* 12(3):519–526, 2006.

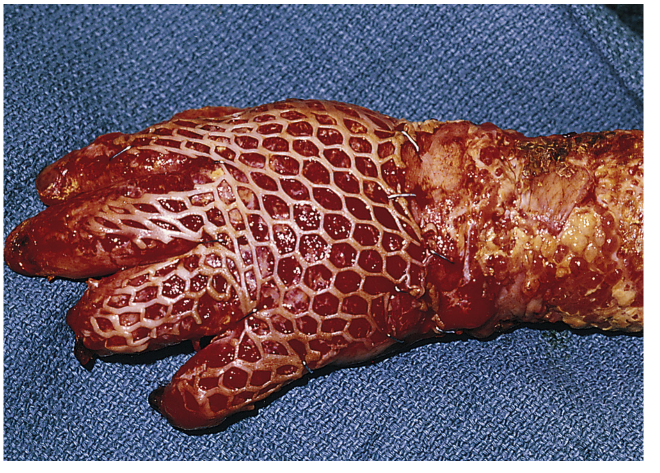

FIGURE 49-11 Meshed Autograft.

mucosal integrity and improves intestinal blood flow, as well as motility.[63] Early initiation of enteral supplementation along with aggressive management of complications permits successful enteral alimentation in most burned children.

Severe burn injury causes exaggerated muscle protein catabolism, contributing to weakness and delayed healing. Many therapeutic strategies have been used to avert the hypermetabolic response and improve clinical outcomes. Pharmacologic agents, such as recombinant growth hormone, low-dose insulin, and testosterone, have been shown to improve muscle kinetics and wound healing. However, these can cause serious side effects. Investigators have found that anabolic steroid agents, along with nutritional support, improve muscle protein metabolism through enhanced protein synthesis efficiency in children and adults.[89] Outpatient follow-up should include regular weighing of the child and nutritional assessment to identify children at risk for further weight loss.

Wound Management

The goals of wound management include prevention of infection, removal of devitalized tissue, and closure of the wound (see What's New? Advances in Burn Wound Care). Burns that are clearly deep dermal or full-thickness injuries are surgically excised as soon as the child is hemodynamically stable after resuscitation. Early excision reduces the incidence of wound infection and systemic sepsis.[90-92] Coverage of the excised wound is necessary to achieve wound closure. The choice of a coverage technique depends on the availability of donor skin.

Split-thickness sheet grafts are selected for areas of maximal functional and cosmetic results (Figure 49-10). Children with very large burn injuries often do not have sufficient unburned skin available to facilitate use of the sheet graft. In these cases the surgeon uses a meshing technique to expand the available skin and increase the size of the graft. The pattern created heals by migration of epithelium from the meshed edges. Scar formation is increased, and the mesh pattern remains clearly visible (Figure 49-11). The color, texture, vascularity, thickness, and hair-bearing nature of the skin vary from one area to another. Site selection and depth of donor sites require careful consideration. Skin grafts for the face should be taken, if possible, from above the nipple line for best color match and "blush" ability.[91]

Scar Maturation

In normal epidermal healing, minimal disruption in skin color, texture, and thickness occurs. However, burn wounds that extend into the dermis are repaired through **scar formation** and may result in an overgrowth of dermal constituents (Figure 49-12, *A*). Accelerated collagen synthesis most likely begins with high levels of activity in granulation tissue. The **hypertrophic scar** consists of hypercellular and disorganized connective tissue that is erythematous, raised, and pruritic. Normal dermis contains thick fibers and fiber bundles running parallel to the surface. In the hypertrophic scar, the collagen is arranged in whorls and nodules that account for its inelasticity and increased turgor.[92] As the hypertrophic scar matures, collagen begins to orient in a more parallel fashion, and vascularity decreases (see Figure 49-12, *B*). Collagen synthesis is very active soon after wound closure, and alteration of the scar can be accomplished before strong cross-linking of the collagen is established.

FIGURE 49-12 Scar Maturation. **A,** Immature hypertrophic scar. **B,** Flat, mature scar after pressure therapy.

Although duration of wound healing varies among individuals, the length of time required to achieve wound closure is the most reliable predictor of hypertrophic scarring. Deeper burns demonstrate increased scarring caused by the formation of granulation tissue and prolonged healing time. Generally, darker-pigmented races are more susceptible to hypertrophic scarring.[92,93] Although age has not been found to be a predictor of hypertrophic scar formation, younger individuals are more susceptible to trauma and have greater skin tension and an accelerated rate of collagen synthesis. Increased tension with resultant trauma stimulates inflammation, which in turn results in the formation of additional collagen.

Scar tissue is metabolically active and highly vascular. Collagen is deposited in random patterns, and contraction of the scar can result in disabling deformities. The scar is active as long as it is raised, red, and firm. **Scar maturation** requires 1 to 2 years and depends on individual differences and compliance with the rehabilitation program. The mature scar is characterized by increased suppleness, flattening, and pigmented color.

Scar tissue does not grow and expand like normal tissue. Although massage therapy offers some benefit in stretching, functional limitation may develop as the child grows. This is particularly evident over joints. Reconstructive surgery is often necessary to restore anatomic integrity and to promote independent function.

Itching may occur at any time during burn wound healing. As a complication, healed skin may be scratched away in an effort to obtain relief. The combination of H_1 and H_2 antagonists may be used to control itching.[94]

Comfort Management

Pain management presents a significant challenge in the pediatric population. In addition to procedural pain, there is a component of background pain that is present without activity. Pain perception is also affected by the degree of emotional overlay or affective experience.[95] The measurement of pain is particularly challenging in young infants, who lack the language skills to express pain. A variety of tools, from physiologic monitors to behavioral analyses and analog scales, have been developed to measure pediatric pain. The quality of pain control in burn centers has improved along with the ability to assess pain in the pediatric population. Studies have documented pharmacologic as well as nonpharmacologic interventions that have improved the quality of pain control.[95]

Recovery from Burn Injury

Rehabilitation becomes the major focus of care once wound coverage has been achieved and continues until all reconstructive procedures have been completed. This phase may extend over many years in the pediatric population. Children require specialized management to ensure optimal functional and cosmetic results. Scar and contracture management is necessary for prolonged periods because of changes in body composition as the child grows and matures. Very young children present unique challenges because the small body size can be difficult to fit with pressure garments and splints, growth is rapid, and cooperation with the rehabilitation program is limited.

Infant skin is thinner, and the epidermis is more loosely connected to the dermis. This increases the risk of blistering, chafing, and rash formation. The infant also produces less sebum and sweat, which further exacerbates the propensity to skin irritation. Because scar tissue contains no sweat glands, these characteristics of the skin in growing children compound the difficulty in maintaining pressure on maturing scars while cooling the body.

Positioning and splinting to prevent contracture formation, as well as rehabilitative aspects of therapy, are instituted on admission and continue throughout the hospitalization. Physical therapy and occupational therapy provide exercise to maintain range of motion and function. Psychosocial support is very important for the child and the family. The information provided should be consistent and honest to allow clarification of concerns. In addition to the functional aspects of rehabilitation, attention must be directed to psychosocial needs and community reintegration.

A method to facilitate the transition from the hospital to the community is the school reentry program offered by many burn centers. These programs provide education for teachers and peers about the injury, appearance, and abilities of the returning child.

SUMMARY REVIEW

Shock and Multiple Organ Dysfunction Syndrome

1. Shock in children is present when there are signs of poor systemic perfusion, regardless of blood pressure.
2. Hypovolemic shock is the most common type of shock in children and it most frequently results from dehydration and trauma. Hypovolemic shock also may result from expansion of the vascular space, producing inadequate intravascular volume relative to the vascular space.
3. Hypotension is a sign of severe (preterminal), decompensated shock, referred to as "hypotensive shock."
4. Clinical manifestations of hypovolemic shock include inadequate systemic perfusion associated with intravascular fluid loss. Adrenergic compensatory mechanisms can produce tachycardia, redistribution of blood flow, peripheral vasoconstriction, cool extremities, delayed capillary refill, and oliguria.
5. Neurogenic shock is caused by a loss of vasomotor tone after severe injury to the spinal cord.
6. Clinical manifestations of neurogenic shock include warm skin, hypotension with a low diastolic blood pressure, and poor systemic perfusion. Tachycardia is not present.
7. Cardiogenic shock, with decreased cardiac output, is observed most commonly after cardiovascular surgery or with inflammatory diseases of the heart, such as cardiomyopathy and myocarditis. It is also found in children with obstructive congenital heart disease and those with drug toxicity or severe electrolyte or acid-base imbalances.
8. Clinical manifestations of cardiogenic shock include inadequate systemic perfusion despite adequate intravascular volume. Cardiac output is typically low. Adrenergic compensatory mechanisms, including peripheral vasoconstriction and decreased urine volume, are similar to those found in hypovolemic shock.
9. Once septic shock is present, immediate treatment is urgently needed. Therapy in the first hour includes aggressive fluid resuscitation (typically 60 to 80 ml/kg administered in first hour of therapy, and approximately 200 to 240 ml/kg in the first 8 hours of therapy). If the child does not respond to volume administration alone, vasoactive support must be initiated within the first hour of treatment. Antibiotics also must be administered within the first hour. Goals of therapy are to rapidly normalize the heart rate and blood pressure for age and to normalize capillary refill to less than 2 seconds. The child's shock index (heart rate/systolic blood pressure) should fall during the first hour of management if therapy is effective. Fluid and vasoactive therapy should support high cardiac output and oxygen delivery, maintaining the $S\bar{v}o_2$ at approximately 70%.
10. Sepsis is a systemic response to infection. It is present when manifestations of SIRS are observed. SIRS is present when the child demonstrates two or more of the following as an acute change from baseline values: altered temperature, altered heart rate, altered respiratory rate, and alteration in the WBC count. The newborn often develops hypothermia rather than fever as a sign of infection and may develop bradycardia instead of tachycardia.
11. Severe sepsis is present when there is evidence of SIRS and signs of organ dysfunction, hypoperfusion, or hypotension.
12. The development of septic shock is heralded when the child with severe sepsis develops signs of cardiovascular dysfunction. The child may become hypotensive despite adequate fluid resuscitation or require vasopressors to maintain blood pressure.
13. Reperfusion and inflammatory injury stimulate free oxygen radicals that can damage cell membranes, denature proteins, and disrupt chromosomes. This process likely affects endothelial cells and the microvasculature, causing MODS.
14. Lactic acidosis (i.e., rise in serum lactate) may be the most sensitive indicator of inadequate systemic perfusion in children; effective shock therapy should eliminate lactic acidosis.
15. The general goals of treatment for shock are maximization of oxygen delivery and minimization of oxygen demand. This requires support of airway, oxygenation, and ventilation. Support of cardiovascular function requires support of appropriate heart rate and rhythm, adequate intravascular volume, good myocardial function, and appropriate vascular resistance and distribution of blood flow. The child should be kept warm but fever must be treated promptly.
16. The signs of shock should lessen or disappear if management of shock is effective. The warmth of the child's extremities, briskness of capillary refill, quality of peripheral pulses, level of consciousness and responsiveness, urine volume, oxygenation, ventilation, and acid-base status should improve throughout shock therapy.

Burns

1. Burns in children are often the result of inadequate supervision, curiosity, inability to escape the burning agent, or intentional abuse.
2. Scald injuries are commonly seen in young children and result from exposure to hot water, grease, or other hot liquids, whereas flame burns are more prevalent among older children.
3. A child's skin is thinner and thus more susceptible to injury than adult skin. The kitchen and bathroom are common sites of burn injury.
4. Approximately 10% of all forms of child abuse cases in the United States result from burn injury.
5. Flame burns involving flammable liquids, most notably gasoline, are more common in older children. Risk-taking behaviors in young males can lead to electrical burns. Children may be exposed to chemical injury by swallowing caustic agents at home.
6. Use of the standard Rule of Nines results in inaccurate calculation of the percentage of TBSA in children. A modified Rule of Nines deducts 1% from the head and adds 0.5% to each leg for each year of life after 2 years of age.

SUMMARY REVIEW—cont'd

7. Major burn trauma involves all body systems, and the consequences of injury include shock, infection, hypermetabolism, organ failure, and functional limitations. These effects can be magnified in the pediatric population as a result of physiologic immaturity and age-related variation in treatment modalities.
8. Infection, trauma, or applying ice to the burn area may convert a partial-thickness injury to a full-thickness one, especially in young children, who have thinner, more delicate skin.
9. Marked reduction in cardiac output occurs immediately after injury and is accompanied by an initial increase in systemic vascular resistance. The inefficient and labile peripheral circulation of the infant complicates management of the burn shock phase of treatment. Constriction of the chest and impairment of respiratory excursion may occur in the very young child because of the increased pliability of the rib cage. Younger children are also more susceptible to increased intra-abdominal pressure.
10. The leading cause of death in children after burn injury, as in adults, is inhalation injury.
11. Children require fluid resuscitation for smaller burns than does the adult population as a result of limited physiologic reserves. Colloid replacement may be required in the very young child who fails to respond to fluid replacement.
12. Children younger than 2 years lack the ability to concentrate urine because of the immaturity of the renal system and are therefore at increased risk for dehydration. Because children have a relatively larger body surface area in relation to weight than adults, they require proportionately increased fluid during burn shock resuscitation to compensate for evaporative water losses.
13. Some children exhibit immunosuppression for a prolonged period after wound closure.
14. A biphasic pattern of physiologic responses is evident in the burn-injured child. The initial ebb phase occurs during the immediate postburn period and continues for 3 to 5 days. This phase is characterized by reduced oxygen consumption, impaired circulation, and cellular shock. After this phase and the restoration of volume, the metabolic response shifts to a catabolic, or flow, phase. This phase is characterized by hypermetabolism with an increased oxygen consumption and elevation of catecholamines, glucocorticoids, and glucagon.
15. Glycogen stores are limited in children, making it hard for them to meet the increased energy demands of the burn. This prolonged metabolic dysfunction may lead to loss of lean body mass and increased morbidity.
16. Although age was not found to be a predictor of hypertrophic scarring, children have greater skin tension and an accelerated rate of collagen synthesis.
17. Children require specialized management to ensure optimal functional and cosmetic results. Long-term scar and contracture management is necessary because of changes in body composition as the child grows and matures.

Chapter Summary Review

interactive review

GLOSSARY

Absolute polycythemia excessive red blood cell production; a physiologic response resulting from increased erythropoietin secretion in response to chronic hypoxia or as a symptom of polycythemia vera.

Absorption atelectasis see Atelectasis.

Acid maltase deficiency (glycogen storage disease type II or Pompe disease) an autosomal recessive metabolic disorder that damages muscle and nerve cells throughout the body by an accumulation of glycogen in the lysosome attributable to deficiency of the lysosomal acid α-glucosidase enzyme. The buildup of glycogen causes progressive muscle weakness (myopathy) throughout the body and affects various body tissues, particularly in the heart, skeletal muscles, liver, and nervous system.

Acne a common skin disease characterized by pimples on the face, chest, and back. It occurs when the pores of the skin become clogged with oil, dead skin cells, and bacteria.

- **Acne conglobata** severe cystic acne characterized by cystic lesions, abscesses, communicating sinuses, and thickened, nodular scars; usually does not affect the face.
- **Acne rosacea** a chronic form of dermatitis of the face in which the middle portion of the face appears red with small red lines caused by dilation of capillaries.
- **Acne vulgaris** an inflammatory eruption of the sebaceous follicles usually occurring on the face, upper back, and chest that consists of blackheads, cysts, papules, and pustules.
- **Noninflammatory acne** open comedones caused by the enlargement and dilation of a plug resulting from the accumulation of oil and dead skin cells inside the hair follicle and by closed comedones that form if the hair follicle pore remains closed; they appear as a tiny, sometimes pink bump in the skin.

Acquired immunodeficiency syndrome (AIDS) see Immune deficiency.

Acquired sideroblastic anemia see Anemia.

ACTH deficiency a condition characterized by decreased or absent production of adrenocorticotropic hormone (ACTH) by the pituitary gland, resulting in a reduction in the secretion of adrenal hormones and subsequent weight loss, lack of appetite, weakness, nausea, vomiting, and low blood pressure.

Actinic keratosis a condition in which a premalignant small, reddish, rough spot appears on skin chronically exposed to the sun.

Acute chest syndrome a syndrome occurring in association with sickle cell disease defined by a new infiltrate on chest radiograph; associated with one or more new symptoms: fever, cough, sputum production, dyspnea, or hypoxia. It occurs most commonly in the 2- to 4-year-old age group and declines in incidence with age.

Acute colonic pseudo-obstruction (Ogilvie syndrome) a massive dilation of the large bowel that occurs in critically ill patients and immobilized older adults. It is characterized by significant dilation of the cecum and absence of mechanical obstruction, and is related to excessive sympathetic motor input or decreased parasympathetic motor input.

Acute confusional state (ACS) a form of delirium caused by interference with the metabolic or other biochemical processes essential for normal brain functioning. Symptoms may include disturbances in cognition and levels of awareness, short-term memory deficit, retrograde and anterograde amnesia, and disturbances in orientation, accompanied by restlessness, apprehension, irritability, and apathy. The condition may be associated with an acute physiologic state, delirium, toxic psychosis, or acute brain syndrome.

Acute coronary syndrome a classification encompassing clinical presentations ranging from unstable angina through infarction.

Acute cystitis an inflammation of the bladder, which is the most common site of urinary tract infection.

Acute epiglottitis an infection that causes inflammation of the epiglottis and surrounding tissues and may lead to upper airway blockage.

Acute gastritis an inflammatory disorder of the gastric mucosa, usually caused by injury of the protective mucosal barrier by drugs, chemicals, or *Helicobacter pylori* infection.

Acute glomerulonephritis see Glomerulonephritis.

Acute gouty arthritis an abrupt pain of a joint, most often the great toe, which is swollen, hot, and shiny secondary to an attack of gout.

Acute idiopathic thrombotic thrombocytopenic purpura (TTP) see Thrombocytopenia.

Acute leukemia see Leukemia.

Acute liver failure (fulminant liver failure) a rare clinical syndrome resulting from severe impairment or necrosis of liver cells without pre-existing liver disease or cirrhosis. Acetaminophen overdose is the leading cause.

Acute lung injury (ALI)/acute respiratory distress syndrome (ARDS) a spectrum of acute lung inflammations and diffuse alveolocapillary injury.

Acute lymphoblastic leukemia (ALL) see Leukemia.

Acute mesenteric ischemia caused by acute occlusion of the mesenteric artery that results in a significant reduction in mucosal blood flow to the large and small intestines. Aortic aneurysms, arterial thrombi, or emboli can be causes.

Acute mountain sickness (AMS) the presence of a combination of nonspecific symptoms that appear within a few hours after ascent to altitude, and may include headache, loss of appetite, nausea, vomiting, weakness, lassitude, dizziness, and difficulty sleeping.

Acute myelogenous leukemia (AML) see Leukemia.

Acute otitis media (AOM) an infection of the middle ear space, behind the eardrum (tympanic membrane); characterized by pain, dizziness, and partial loss of hearing.

Acute orthostatic hypotension an abnormal decrease in blood pressure when a person stands. This may lead to fainting.

Acute pancreatitis inflammation of the pancreas resulting from obstruction to the outflow of pancreatic digestive enzymes caused by bile duct or pancreatic duct obstruction (e.g., gallstones). Usually a mild disease and resolves spontaneously.

Acute poststreptococcal glomerulonephritis (PSGN) see Glomerulonephritis.

Acute pyelonephritis acute inflammation of the renal parenchyma and pelvis characterized by small cortical abscesses and yellowish streaks in the medulla resulting from the accumulation of pus in the collecting tubules and interstitial tissue.

Acute renal failure (acute renal injury) a sudden decline in kidney function with a decrease in glomerular filtration and accumulation of nitrogenous waste products in the blood as demonstrated by an elevation in plasma creatinine and blood urea nitrogen levels.

Acute respiratory distress syndrome (ARDS) capillaries or alveoli of the lungs are damaged as a result of infection, injury, blood loss, or inhalation injury causing fluid to leak from the capillaries into the alveoli, resulting in pulmonary edema and collapse of some alveoli.

Acute tubular necrosis (ATN) the kidney undergoes ischemic or nephrotoxic injury because of severe hypotension, aminoglycosides, or radiocontrast agents and produces granular and epithelial cell casts in urine.

Acute urethral syndrome the bladder is irritated and the typical symptoms of a urinary tract infection are present in the absence of an infection.

Adenocarcinoma tumor arising from epithelial cells with a glandular or glandlike pattern.

Adenocystic tumor (cylindroma) rare bronchial gland tumors that arise predominantly in the trachea or large airways and cause obstruction.

Adenomyosis the presence of islands of endometrial glands surrounded by benign endometrial stroma within the uterine myometrium.

Adenosine deaminase (ADA) deficiency see Immune deficiency.

Adrenarche growth of axillary and pubic hair and other physiologic changes induced by hyperactivity of the suprarenal cortex and adrenocortical secretion of androgenic hormones in early puberty.

Agammaglobulinemia see Immune deficiency.

Ageusia loss of the sense of taste.

Agoraphobia a mental disorder characterized by an irrational fear of leaving the familiar setting of home, or venturing into the open, so pervasive that a large number of external life situations are entered into reluctantly or are avoided; often associated with panic attacks.

Agranulocytosis see Immune deficiency.

Akinesia slowness or loss of normal motor function resulting in impaired muscle movement.

Akinetic mutism (AM) a syndrome characterized by the inability to speak, loss of voluntary movement, and apparent loss of emotional feeling. It is related to lesions of the upper brainstem.

Albright syndrome (Albright-McCune-Sternberg syndrome) polyostotic fibrous dysplasia, patchy dermal pigmentation, and endocrine dysfunction.

Alcoholic cirrhosis see Cirrhosis.

Alcoholic fatty liver (steatosis) the mildest form of alcoholic liver disease; can be caused by chronic ingestion of relatively small amounts of alcohol, may be asymptomatic, and is reversible with cessation of drinking.

Alcoholic hepatitis (steatohepatitis) a precursor of cirrhosis characterized by inflammation; degeneration and necrosis of hepatocytes; infiltration of neutrophils, macrophages, and lymphocytes; immunologic alterations; and lipid peroxidation.

Algor mortis postmortem reduction of body temperature.

Alkaline reflux gastritis inflammation of the stomach caused by reflux of bile and alkaline pancreatic secretions that contain proteolytic enzymes and disrupt the mucosal barrier in the remnant stomach.

Allergic contact dermatitis contact dermatitis attributable to allergic sensitization.

Allodynia a condition in which pain arises from a stimulus that would not normally be experienced as painful.

Allostasis long-term or chronic exaggerated responses to stress.

Alogia inability to speak because of mental deficiency, mental confusion, or aphasia.

Alopecia loss of hair.

Alopecia areata an autoimmune T-cell–mediated chronic inflammatory disease directed at hair follicles that results in baldness, usually in round patches.

Alpha-thalassemia major see Anemia.

Alpha-thalassemia minor see Anemia.

Alzheimer disease (dementia of Alzheimer type [DAT], senile disease complex) a degenerative disease characterized by amyloid plaques and fibrillary tangles in the cortex and atrophy and widened sulci in the frontal and temporal lobes.

Amblyopia poor vision caused by abnormal development of visual areas of the brain in response to abnormal visual stimulation during early development.

Amyotrophic lateral sclerosis (ALS) (sporadic motor system disease, sporadic motor neuron disease, motor neuron disease, Lou Gehrig disease) a disease that breaks down tissues in the nervous system (a neurodegenerative disease); it is of unknown cause and affects the nerves responsible for movement.

Anaphylactic shock a state of shock caused by a severe allergic reaction that lowers blood pressure and results in urticaria, breathing difficulties, and possibly death.

Anaphylactoid purpura (allergic purpura, Henoch-Schönlein purpura) nonthrombocytopenic purpura attributable to immune hypersensitivity to foods, drugs, and insect bites.

Anemia hemoglobin concentration is less than normal because of a deficiency in red blood cells, a low level of hemoglobin in cells, or both; it manifests as pallor of the skin and mucous membranes, weakness, dizziness, easy fatigability, and drowsiness caused by oxygen deficiency.

Congenital hemolytic anemias

Alpha-thalassemia major thalassemia in which all four α-chains of hemoglobin are defective, resulting in a fatal condition because oxygen cannot be released to the tissues.

Alpha-thalassemia minor thalassemia in which two α-chains of hemoglobin are defective.

Beta-thalassemia major (Cooley anemia) thalassemia in which α-chain synthesis and β-chain synthesis are uncoupled; β-chain production is depressed moderately in the heterozygous form, **beta-thalassemia minor,** and severely in the homozygous form, **beta-thalassemia major,** resulting in erythrocytes that have a reduced amount of hemoglobin and accumulations of free α-chains.

Beta-thalassemia minor see above.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency an inherited condition that is asymptomatic in the absence of exposure to particular substances such as certain medicines, mothballs, or severe infections; with exposure the red blood cells undergo destruction, producing excessive bilirubin that overloads the liver and causes jaundice.

Hemoglobin H disease a form of alpha-thalassemia in which a hemoglobin H gene is expressed but cannot bind oxygen.

Hereditary spherocytosis (congenital hemolytic anemia, congenital acholuric jaundice) a defect in the cell membrane of red blood cells that causes thickened, fragile red blood cells that are susceptible to spontaneous hemolysis and results in chronic anemia, jaundice, fever, and abdominal pain.

Sickle cell anemia (sickle cell disease [SCD]) an inherited autosomal recessive disorder of the blood caused by abnormal hemoglobin that distorts red blood cells and makes them fragile and prone to rupture and can cause anemia, joint pain, fever, leg ulcers, and jaundice.

Sickle cell–Hb C disease a heterozygous form in which the child simultaneously inherits a hemoglobin C gene from another parent.

Sickle cell–thalassemia disease a heterozygous form in which the child simultaneously inherits a thalassemia gene from another parent.

Sickle cell trait an inherited condition in which an individual carries only one gene for sickle cell disease and is without symptoms.

Thalassemia a potentially fatal genetic disorder in which hemoglobin molecules are abnormal, resulting in severe anemia; enlarged heart, liver, and spleen; and skeletal deformation.

Macrocytic anemia (megaloblastic anemia) a condition characterized by erythrocytes that are larger than normal; associated with deficiency of vitamin B_{12} or folic acid caused by inadequate intake or insufficient absorption secondary to alcoholism or drugs that inhibit DNA replication.

Pernicious anemia an autoimmune disorder that causes a deficiency in intrinsic factor, resulting in the inability to absorb vitamin B_{12} and a subsequent increase in the production of abnormal erythrocytes.

Microcytic-hypochromic anemia a condition in which red blood cells are smaller than normal as a result of iron deficiency.

Acquired sideroblastic anemia a heterogeneous group of disorders characterized by anemia of varying severity caused by a defect in mitochondrial heme synthesis; occurs as a primary disorder with no known cause (idiopathic) or is associated with other myeloproliferative or myeloplastic disorders.

Hereditary sideroblastic anemia heterogeneous group of rare disorders characterized by anemia of varying severity caused by a defect in mitochondrial heme synthesis; occurs almost exclusively in males, suggesting a predominant recessive X-linked transmission.

Hypoplastic anemia a condition in which anemia results from greatly depressed, inadequately functioning bone marrow and smaller-than-normal erythrocytes.

Iron deficiency anemia (IDA) an insufficient dietary intake or absorption of iron, resulting in decreased incorporation of hemoglobin into red blood cells and subsequent feelings of fatigue, weakness, and shortness of breath as well as pale earlobes, palms, and conjunctivae.

Reversible sideroblastic anemia associated with alcoholism; results from nutritional deficiencies of folate.

Sideroblastic anemia (SA) refractory anemia of varying severity that is caused by altered mitochondrial metabolism and is marked by sideroblasts in the bone marrow.

Normocytic-normochromic anemia (NNA) erythrocytes are of normal size and hemoglobin content but of insufficient number; usually caused by hereditary spherocytosis, drug-induced anemia, and anemia secondary to malignancies.

Anemia of chronic disease (ACD) a mild to moderate anemia resulting from decreased erythropoiesis in individuals with conditions of chronic systemic disease or inflammation.

Aplastic anemia decreased bone marrow production of adequate amounts of new red blood cells; results from an

autoimmune disorder or exposure to radiation or substances such as benzene or certain drugs.

Aplastic crisis temporary loss of bone marrow causes erythropoiesis, resulting in an acute fall in hemoglobin levels and subsequent anemia.

Autoimmune hemolytic anemia (AIHA) a form of hemolytic anemia involving autoantibodies against red blood cell antigens.

Cold agglutinin autoimmune hemolytic anemia acquired disorder caused by autoantibodies against antigens normally on the surface of erythrocytes; mediated by immunoglobulin M (IgM) antibodies that optimally bind to and agglutinate erythrocytes in colder portions of the body (e.g., fingers, toes), and occurs less often than warm antibody hemolysis, affecting mostly middle-aged and older adults.

Cold hemolysin autoimmune hemolytic anemia (paroxysmal cold hemoglobinuria) a disorder in which exposure to cold initiates acute and severe intravascular hemolysis that, unlike cold agglutinin anemia, results in hemoglobinuria. The chronic form of this anemia is extremely rare, but an acute form of paroxysmal cold hemoglobinuria is frequently observed in autoimmune hemolytic anemia of childhood.

Drug-induced hemolytic anemia a form of immune hemolytic anemia usually resulting from an allergic reaction against foreign antigens (e.g., antibiotics) that have attached to the surface of red blood cells.

Fanconi anemia a genetic disease affecting bone marrow that is characterized by pancytopenia, hypoplasia of the bone marrow, congenital anomalies, and pigment changes of the skin and that predisposes the individual to myelodysplasia and to acute myeloid leukemia or cancers of the mouth, esophagus, intestinal and urinary tracts, and reproductive organs.

Hemolytic anemia a condition in which red blood cells are destroyed in response to certain toxic or infectious agents or in certain inherited blood disorders and the rate of breakdown exceeds the body's ability to compensate.

Hemolytic disease of the newborn (HDN) (erythroblastosis fetalis) a condition that affects a fetus or newborn in which red blood cells break down because of antibodies made by the mother that are directed against the infant's red cells, potentially resulting in anemia, heart failure, jaundice, and brain damage.

Posthemorrhagic anemia a type of normocytic-normochromic anemia that is caused by sudden blood loss in an individual with normal iron stores and triggers a compensatory response in which water and electrolytes from tissues and interstitial spaces are used to expand plasma volume and accelerate the formation and development of blood cells.

Warm autoimmune hemolytic anemia the most common form of autoimmune hemolytic anemia; caused by IgG that binds to erythrocytes at normal body temperature; often secondary to other diseases, especially lymphomas, chronic lymphocytic leukemia, other neoplastic disorders, or systemic lupus erythematosus (SLE).

Anencephaly anomaly in which the soft, bony component of the skull and much of the brain are missing.

Angelman syndrome (happy puppet syndrome) an inherited syndrome of jerky puppetlike movements, frequent laughter, mental and motor retardation, peculiar open-mouthed facies, and seizures.

Angina pectoris chest pain caused by reduced cardiac blood flow and myocardial ischemia.

Anhedonia absence of pleasure from the performance of acts that would ordinarily be pleasurable.

Ankylosing spondylitis (AS, spondyloarthritis) chronic inflammation of the spine and sacroiliac joints with gradual fusion of the vertebrae that immobilizes the spine.

Anorexia nervosa (AN) a disorder with both psychologic and physiologic components that begins with dieting to lose weight and manifests into an inappropriate self-control behavior; continued restrictive eating may lead to starvation and eventually death.

Anorgasmia (orgasmic dysfunction) the inability of the woman to reach or achieve orgasm.

Anuria urine output less than 50 ml/day.

Anxiety disorder a group of disorders involving various manifestations of anxiety that are grouped together and include panic disorder, specific phobia, social phobia, obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), acute stress disorder, generalized anxiety disorder (GAD), and anxiety disorders secondary to medical conditions or substance-induced or not otherwise specified.

Aplastic anemia see Anemia.

Aplastic crisis see Anemia.

Appendicitis inflammation of the appendix as a result of blockage of the opening from the appendix into the cecum; the appendix wall becomes infected and ruptures, allowing the infection to spread throughout the abdomen and cause pain, anorexia, fever, nausea, vomiting, and diarrhea.

Apraxia a disorder of voluntary movement consisting of impairment of the performance of skilled or purposeful movements; results from acquired cerebral disease.

Arcus senilis a gray to white ring at the periphery of the cornea; caused by deposits of cholesterol in the cornea or hyaline degeneration and occurs primarily in older persons.

Areflexia absence of reflexes.

Arterial ischemic stroke (pediatric arterial ischemic stroke) a rare disorder in children resulting from embolism, arteriopathy, or, rarely, sinovenous thrombosis and leading to a decreased flow of blood and oxygen to areas of the brain.

Asbestosis pulmonary inflammation and fibrosis resulting from inhalation of hydrous silicates of various metals in fibrous form.

Aseptic meningitis a form of inflammation of the meninges and subarachnoid space surrounding the brain and spinal cord without evidence of bacterial infection; may be associated with viral infection, systemic disease, or drugs.

Aspiration pneumonitis a condition caused by the abnormal entry of fluids, particulate matter, or secretions into the lower airways that can lead to chemical pneumonitis from entry of toxic material such as gastric acid, from bacterial infection, or by mechanical obstruction of the lower airways.

Asthma a chronic inflammatory disorder of the airways involving bronchial hyperresponsiveness and airway obstruction marked by periodic attacks of wheezing, shortness of breath, a tight feeling in the chest, and a cough that produces mucus because of an allergic reaction triggered by certain drugs, irritants, viral infection, exercise, or emotional stress.

Asymptomatic bacteriuria the presence of bacteria in the urine without evidence of infection.

Ataxia-telangiectasia (AT) see Immune deficiency.

Ataxic cerebral palsy a form of cerebral palsy associated with damage to the cerebellum and resulting in gait disturbances and instability; at birth the infant may have hypotonia, but develops stiffness of the trunk muscles later in infancy.

Atelectasis a part of or an entire lung collapses and the alveoli deflate as a result of surgery, smoking, or blockage of a bronchiole.

Absorption atelectasis collapse of lung tissue resulting from gradual absorption of air from obstructed or hypoventilated alveoli or from inhalation of concentrated oxygen or anesthetic agents.

Compression atelectasis air pressure in the pleural space pushes against the already recoiled lung, causing compression atelectasis, and against the mediastinum, compressing and displacing the heart and great vessels.

Surfactant impairment decreased production or inactivation of surfactant, which is necessary to reduce surface tension in the alveoli and causes lung collapse during expiration; can occur because of premature birth, acute respiratory distress syndrome, anesthesia, or mechanical ventilation.

Atherosclerosis a type of arteriosclerosis in which the inflammatory changes of thickening and hardening of the walls of large- and medium-sized arteries are caused by an atheroma or plaque of lipids, cells, and connective tissue in the tunica intima.

Atopic dermatitis (AD) (allergic dermatitis) a chronic hereditary skin disease characterized by intense itching and inflamed skin that causes redness, swelling, cracking, crusting, and scaling.

Atrial septal defect (ASD) a congenital heart disease involving the interatrial septum of the heart that separates the right and left atria, which results in misdirected blood flow between the two sides of the heart.

Atrioventricular canal (AVC) defect a large hole is present in the center of the heart where the wall between the atria joins the wall between the ventricles, and the tricuspid and mitral valves are formed into a single large valve that crosses the defect.

Atypical ductal hyperplasia (ADH) abnormal proliferating cells in breast ducts.

Atypical hyperplasia increased number of cells with some variation in cellular structure but without sufficient qualitative or quantitative features of carcinoma.

Atypical lobular hyperplasia (ALH) abnormal proliferating cells in breast lobules.

Autoimmune hemolytic anemia (AIHA) see Anemia.

Autoimmune neonatal thrombocytopenia see Thrombocytopenia.

Autoimmune vascular purpura (allergic purpura) purpura caused by antibody-mediated injury of blood vessel walls, typically arterioles and capillaries. The reaction is directed to foreign proteins or chemicals in the blood (microorganisms, drugs, or other chemicals) that deposit on the vessel walls.

Autonomic hyperreflexia (dysreflexia) a syndrome resulting from afferent stimuli that cause intense sympathetic discharge originating with spinal cord injury above the major splanchnic outflow; characterized by hypertension, bradycardia, sweating of the forehead, severe headache, and piloerection on distention of the bladder and rectum.

Autosomal agammaglobulinemia see Immune deficiency.

Autosomal dominant polycystic kidney disease (ADPKD) a progressive disease characterized by formation of multiple cysts of varying size scattered diffusely throughout both kidneys, resulting in compression and destruction of renal parenchyma, usually with hypertension, gross hematuria, and uremia leading to progressive renal failure.

Autosomal hyper-IgM syndrome see Immune deficiency.

Azotemia kidney dysfunction characterized by increased serum urea levels and frequently associated with increased creatinine levels.

Bacterial pneumonia an acute or chronic disease marked by inflammation of the lungs caused by bacterial infection.

Bacterial tracheitis a condition in which the larynx, trachea, and bronchi are inflamed and present with signs similar to those of epiglottitis and croup; may result in airway obstruction secondary to subglottic edema or sloughing of the epithelial lining or the mucopurulent membrane within the trachea.

Bacterial vaginosis (BV) a condition caused by an overgrowth of normal vaginal bacteria, causing vaginal discharge with a foul odor.

Balanitis inflammation of the glans penis caused by irritation by environmental substances, physical trauma, or infection.

Bare lymphocyte syndrome see Immune deficiency.

Barrett esophagus chronic peptic ulceration of the esophagus; formation of precancerous lesions with possible progression to adenocarcinoma.

Bartholinitis (Bartholin cyst) inflammation of one or both of the ducts that lead from the introitus (vaginal opening) to the Bartholin/greater vestibular glands.

Basal cell carcinoma a surface epithelial tumor of the skin originating from undifferentiated basal or germinative cells.

B-cell neoplasm see Lymphoma.

Becker muscular dystrophy a general term for a number of late-onset X-linked recessive hereditary, progressive degenerative disorders affecting skeletal muscles, and often other organ systems.

Beckwith-Wiedemann syndrome an inherited disorder characterized by exomphalos, macroglossia, and gigantism; often associated with visceromegaly, adrenocortical cytomegaly, and dysplasia of the renal medulla.

Benign breast disease (BBD) a spectrum of noncancerous changes in ducts and lobules of the breast, including irregular lumps, cysts, sensitive nipples, and itching.

Benign prostatic hyperplasia (BPH) enlargement of the prostate gland, which may press against the urethra and bladder, interfering with urine flow.

Beta-thalassemia major (Cooley anemia) see Anemia.

Beta-thalassemia minor see Anemia.

Biliary atresia a condition in newborn children in which the biliary tract is blocked or absent, causing bile accumulation and progressive liver failure.

Biliary cirrhosis see Cirrhosis.

Bipolar disorder psychiatric disorder characterized by alternating mania or hypomania and depression, often with periods of normal mood in between, and changes in energy and behavior according to mood.

Blast injury tissue damage from compressive waves of air against the body followed by waves of decreased pressure.

Blepharitis inflammation of the eyelids.

B-lymphocyte deficiency see Immune deficiency.

Bradykinesia decreased spontaneity and movement; a feature of extrapyramidal disorders, such as Parkinson disease.

Brainstem gliomas a group of tumors located in the brainstem that are usually classified as high grade and result in the sudden onset of symptoms including headaches, vomiting, and visual disturbances.

Bronchial carcinoid tumor an obstructing tumor of the trachea or large bronchi that may cause paraneoplastic symptoms.

Bronchiectasis dilation of the bronchi in response to obstruction, necrotizing pneumonias, cystic fibrosis, or Kartagener syndrome (a hereditary syndrome consisting of dextrocardia, bronchiectasis, and sinusitis).

Bronchiolitis inflammation of the bronchioles usually caused by viral infection.

Bronchiolitis obliterans partial or complete obliteration of bronchioles and some bronchi by granulation and fibrotic tissue masses.

Bronchiolitis obliterans with organizing pneumonia (BOOP) obstruction of the bronchioles and alveolar ducts by fibrous granulation tissue that is further complicated by the development of pneumonia.

Bronchopulmonary dysplasia (BPD) a condition most often found in premature infants in which chronic pulmonary insufficiency occurs because of long-term artificial pulmonary ventilation.

Bruton's agammaglobulinemia see Immune deficiency.

Bulbar palsy a form of palsy resulting from impaired function of the cranial nerves from degeneration of the motor neurons of primarily the brainstem; manifested as weakness and wasting of the various bulbar muscles, resulting in difficulty articulating words (dysarthria) and difficulty swallowing (dysphagia); fluid regurgitation is a major symptom and can cause aspiration.

Bullous pemphigoid (BP) a more benign autoimmune disease than pemphigus vulgaris, with blistering of the subepidermal skin layer.

Burkitt lymphoma see Lymphoma.

Burn shock a phenomenon consisting of both a hypovolemic cardiovascular component and a cellular component; results from massive fluid losses from the circulating blood volume.

C1 deficiency see Immune deficiency.

C2 deficiency see Immune deficiency.

C3 deficiency see Immune deficiency.

C3 receptor deficiency see Immune deficiency.

C4 deficiency see Immune deficiency.

C9 deficiency see Immune deficiency.

Cachexia illness and malnutrition seen in individuals with cancer that results in wasting and eventual death.

Calculi or urinary stone (urolithiasis) masses of crystals, protein, or other substances that are a common cause of urinary tract obstruction in adults.

Candidiasis a fungal infection caused by an overgrowth of normal *Candida albicans* found in the skin and mucous membranes of the mouth, respiratory tract, or vagina.

Caplan syndrome formation in coal workers of intrapulmonary nodules in pneumoconiosis that are histologically similar to subcutaneous rheumatoid nodules associated with rheumatoid arthritis.

Carbuncles a condition in which a bacterial infection of the hair follicle or sebaceous gland ducts becomes painful and discharges pus through various openings.

Carcinoma epithelial cell tumor.

Carcinoma in situ (CIS) preinvasive epithelial malignant tumors of glandular or squamous cell origin.

Cardiogenic shock a condition resulting from decreased cardiac output caused by heart disease in which the heart is unable to pump blood through the body, usually because of myocardial infarction.

Cardiomyopathy(ies) a diverse group of diseases primarily affecting the myocardium and

resulting from tissue remodeling caused by myocardial and neurohumoral responses to ischemic and hypertensive alterations.

Cavernous (congenital) hemangioma a birthmark that is similar to the strawberry hemangioma but is more deeply rooted and may appear as a red-blue spongy mass of tissue filled with blood.

Central core disease (CCD) an autosomal dominant congenital myopathy characterized by hypotonia, delay of motor development in infancy, and nonprogressive or slowly progressive muscle weakness; on biopsy the central core of muscle fibers stains abnormally, myofibrils are abnormally compact, and there is virtual absence of mitochondria and sarcoplasmic reticulum; histochemically, the cores are devoid of oxidative enzyme, phosphorylase, and ATPase activity.

Central precocious puberty condition in which puberty begins prematurely with normal changes in the hypothalamopituitary (HPG) axis with premature development of secondary sexual characteristics and premature closure of the epiphysis of long bones, resulting in lifelong short stature.

Centriacinar emphysema see Emphysema.

Cerebellar astrocytoma brain tumor of the right or left cerebellar hemisphere that causes motor symptoms on the same side as the tumor.

Cerebral palsy (CP) a developmental brain injury that occurs before or shortly after birth and causes muscular impairment affecting motor function and also may alter speech and learning abilities.

Cervical dysplasia (cervical intraepithelial neoplasia [CIN]) a condition characterized by the appearance of abnormal cervical cells that are considered precancerous.

Cervicitis inflammation of the mucous membrane of the uterine cervix caused by infection, typically by chlamydia, genital herpes, or gonorrhea.

Chediak-Higashi syndrome see Immune deficiency.

Cheyne-Stokes respiration an abnormal pattern of breathing in which tidal volume gradually increases followed by a gradual decrease and a period of apnea before returning to a normal respiratory pattern.

Chickenpox an infectious viral disease that is spread by direct contact or through the air by coughing or sneezing; it causes a blister-like rash that first affects the face and trunk and then can spread over the rest of the body; symptoms include severe itching, fatigue, and fever.

Childhood absence epilepsy (petit mal seizures, nonconvulsive epilepsy) a type of generalized epilepsy; age of onset is 4 to 10 years.

Chlamydia a sexually transmitted bacterial infection that can cause infertility and blindness.

Choking asphyxiation obstruction of the internal airways.

Cholangiocellular carcinoma (cholangiocarcinoma) primary carcinomas of the liver that develop in the bile ducts.

Cholecystitis inflammation of the gallbladder commonly caused by impaction of a gallstone that causes right upper quadrant pain and possibly a rupture and abscess in the gallbladder.

Cholelithiasis the presence or formation of gallstones in the gallbladder or bile ducts.

Chondrosarcoma a cancer of the cartilage that usually occurs in the pelvic bones, shoulder bones, and the upper part of the arms and legs.

Chronic active hepatitis the persistence of clinical manifestations and liver inflammation after the acute stages with consistently abnormal liver function tests and persistent HBsAg creating a predisposition to cirrhosis and primary hepatocellular carcinoma.

Chronic bronchitis chronic bronchitis, particularly as a cause of chronic cough in smokers.

Chronic gastritis tends to occur in older adults with chronic inflammation, mucosal atrophy, and epithelial metaplasia; may be immune (fundal) or nonimmune (antral), depending on the pathogenesis and location of the lesions.

Chronic glomerulonephritis see Glomerulonephritis.

Chronic granulomatous disease (CGD) see Immune deficiency.

Chronic kidney disease (CKD) progressive loss of renal function associated with systemic diseases such as hypertension, diabetes mellitus, systemic lupus erythematosus, or intrinsic kidney disease, including kidney stones, acute kidney injury, chronic glomerulonephritis, chronic pyelonephritis, obstructive uropathies, or vascular disorders.

Chronic leukemia see Leukemia.

Chronic lymphocytic leukemia (CLL) see Leukemia.

Chronic mesenteric ischemia development of regions of compromised blood flow in the mesenterium secondary to atherosclerosis (most common), congestive heart failure, dysrhythmias, hemorrhage, thrombus formation, aortic aneurysm, or any condition that decreases arterial blood flow. Chronic occlusion is often accompanied by formation of collateral circulation that may be able to nourish the resting intestine.

Chronic mucocutaneous candidiasis see Immune deficiency.

Chronic myelogenous leukemia (CML) see Leukemia.

Chronic obstructive pulmonary disease (COPD) any of a group of irreversible respiratory diseases (chronic bronchitis, emphysema, α_1-antitrypsin deficiency) that are characterized by airflow obstruction or limitation.

Chronic pancreatitis inflammation of the pancreas resulting from repeated exacerbations of acute pancreatitis that lead to chronic changes; associated with obstruction from gallstones, autoimmune disease, gene mutations, smoking, occupational chemical exposure, and obesity.

Chronic pyelonephritis persistent or recurrent infection of the kidney leading to scarring.

Chronic relapsing thrombotic thrombocytopenic purpura (TTP) see Thrombocytopenia.

Cirrhosis degeneration of liver tissue resulting in fibrosis with nodule and scar formation that compromises liver function.

Alcoholic cirrhosis destructive inflammation of the liver caused by the toxic effects of alcohol metabolism, immunologic processes, oxidative stress from lipid peroxidation, and malnutrition.

Biliary cirrhosis a form of alcoholic cirrhosis in which damage and inflammation leading to cirrhosis begin in bile canaliculi and bile ducts, rather than in the hepatocytes.

Primary biliary cirrhosis a T-lymphocyte- and antibody-mediated destruction of the small intrahepatic bile ducts.

Cloacal exstrophy family of congenital anomalies with two exstrophied bladder units separated by an exstrophied segment of intestine, which is usually cecum, receiving ileum superiorly and continuing distally to blind ending microcolon.

Coal worker pneumoconiosis (coal miner lung, black lung) mild to severe pneumoconiosis (pulmonary fibrosis) caused by coal dust (coal, silica, quartz) deposits in the lung; symptoms initially present as a productive cough and wheezing, but may advance to chronic bronchitis and emphysema.

Coarctation of the aorta (COA) a condition in which the aorta narrows in the area where the ductus arteriosus inserts; narrowing usually occurs preductal in children and postductal in adults.

Cold agglutinin autoimmune hemolytic anemia see Anemia.

Cold hemolysin autoimmune hemolytic anemia (paroxysmal cold hemoglobinuria) see Anemia.

Combined T- and B-lymphocyte deficiency see Immune deficiency.

Common variable immune deficiency see Immune deficiency.

Communicating (extraventricular) hydrocephalus a disorder in which the cerebrospinal fluid pathways are intact but cerebrospinal fluid absorption is impaired.

Complement deficiency see Immune deficiency.

Complete precocious puberty refers to the early onset and progression of all pubertal features (i.e., thelarche, pubarche, and menarche).

Complex febrile seizure seizures with characteristic features similar to those of simple febrile seizure with a longer duration and focal characteristics; occur more than once in a 24-hour period.

Complex regional pain syndrome (CRPS) diffuse persistent pain usually in an extremity often associated with vasomotor disturbances, trophic changes, and limitation or immobility of joints; frequently follows a local injury.

Compression atelectasis see Atelectasis.

Compressive syndrome (sensorimotor syndrome; crush syndrome) a shocklike state that follows release of a limb or limbs or the trunk and pelvis after a prolonged period of compression, such as by a heavy weight; characterized by suppression of renal function, probably the result of damage to the renal tubules by myoglobin from the damaged muscles.

Congenital adrenal hyperplasia a group of autosomal recessively inherited disorders associated with a deficiency of one of the enzymes

involved in cortisol biosynthesis, resulting in elevation of ACTH levels and overproduction and accumulation of cortisol precursors proximal to the block; androgens are produced in excess, causing virilization. The most common disorder is the 21-hydroxylase deficiency, caused by mutation in the cytochrome P450 21-hydroxylase gene *(CYP21)* on chromosome 6p.

Congenital aganglionic megacolon (Hirschsprung disease) a congenital defect in which the nerves that innervate the anus through the wall of the bowel are absent, resulting in enlargement of the bowel superior to the point where the nerves are missing and a subsequent decrease in peristalsis that results in chronic constipation.

Congenital hydrocephalus excessive accumulation of cerebrospinal fluid present at birth and characterized by increased intracranial pressure (ICP). This increase may be caused by a blockage within the ventricular system in which the CSF flows, an imbalance in the production of CSF, or a reduced reabsorption of CSF that results in ventricular enlargement and increased ICP.

Congenital hypothyroidism lack of secretion of thyroid hormone.

Congenital (infantile) nephrotic syndrome (Finnish type) a very rare form of nephrotic syndrome caused by a defect in a kidney protein resulting in excessive amounts of protein excreted in the urine.

Congestive splenomegaly enlargement of the spleen accompanied by ascites, portal hypertension, and esophageal varices; most commonly seen in those with hepatic cirrhosis.

Consumptive thrombohemorrhagic disorders heterogeneous group of conditions that demonstrate the entire range of hemorrhagic and thrombotic pathologic conditions.

Contact dermatitis an allergic response to an environmental antigen binding to specific carrier proteins contained in an individual's skin.

Contrecoup injury brain injury resulting from the brain hitting the inside of the skull on the side opposite the site of blunt force trauma.

Cor pulmonale right-sided heart failure caused by prolonged pulmonary hypertension.

Coronary artery disease (CAD) narrowing of the lumen of one or more of the coronary arteries, usually attributable to atherosclerosis, leading to myocardial ischemia; can cause congestive heart failure, angina pectoris, or myocardial infarction.

Craniopharyngioma a brain tumor that develops in the pituitary gland and most often affects children, causing headache, seizure, diabetes insipidus, early onset of puberty, and delayed growth.

Craniosynostosis (craniostenosis) (see Syndromic craniosynostosis) premature ossification of the skull and closure of the sutures, resulting in abnormal skull expansion and asymmetric skull growth.

Cri du chat syndrome a hereditary congenital syndrome characterized by hypertelorism, microcephaly, severe mental deficiency, and a plaintive catlike cry; caused by deletion of the short arm of chromosome 5.

Crohn disease (CD) an autoimmune condition in which the intestines and possibly other regions of the digestive system are chronically inflamed and ulcerated, causing chronic diarrhea, disrupted digestion, and subsequent difficulty eating and digesting food.

Croup a viral infection that involves the larynx, trachea, and the airways leading to the lungs and that can result in serious breathing difficulties, hoarseness, sore throat, and a hacking cough.

Cryptorchidism the scrotum of one or both testes is absent because of failure of the testis to descend from the abdominal position during fetal development.

Curling ulcer ischemic ulcers of the stomach and duodenal mucosa that develop within hours after an event, such as hemorrhage, multisystem trauma, severe burns, heart failure, or sepsis.

Cushing disease adrenal hyperplasia caused by an ACTH-secreting basophil adenoma of the pituitary.

Cushing syndrome increased synthesis and secretion of cortisol from a tumor of the adrenal cortex; caused by administration of glucocorticoid drugs or by the presence of an ACTH-secreting tumor of the anterior lobe of the pituitary gland (Cushing disease), resulting in weight gain, glucose intolerance, and muscle wasting.

Cushing ulcer a stress ulcer associated with severe head trauma or brain surgery.

Cyclic neutropenia see Immune deficiency.

Cylindrical bronchiectasis reversible bronchial dilation with symmetrically dilated airways, as can be seen after pneumonia.

Cystic fibrosis (CF) a genetic disorder of the exocrine glands caused by a mutation in the CF transmembrane regulator gene, resulting in impairment in chloride transfer across cell membranes and subsequent chloride and water accumulation in organs and in thickened secretions that block ducts and form cysts.

Cystitis a condition characterized by acute or chronic inflammation of the urinary bladder, usually caused by bacterial infection of the urethra; symptoms include frequent burning urination, blood in the urine, pain in the pubic area, chills and fever, back pain, and nausea. See Painful bladder syndrome/interstitial cystitis (PBS/IC) for further information.

Dandy-Walker malformation congenital defect of midline cerebellar structures and the fourth ventricle in which hydrocephalus is caused by atresia of the foramina of Luschka or Magendie, which normally allow the fourth ventricle to empty into the areas surrounding the brain, leading the ventricular flow of CSF into a "blind pouch."

Dawn phenomenon abrupt increases in fasting levels of plasma glucose between 5 and 9 AM, in the absence of antecedent hypoglycemia; occurs in diabetic patients receiving insulin therapy.

Decompression sickness (DCS) (Caisson disease) gas embolism created when a person under water returns to the surface too quickly, resulting in cellular hypoxia, joint and muscle pain, and tissue necrosis.

Deep venous thrombosis (DVT) a blood clot or thrombus in a deep vein, usually of the leg.

Degenerative disk disease (DDD) intervertebral disk tissue is replaced by fibrocartilage during aging; functional capacity is rarely altered.

Demyelinating polyneuropathy a type of polyneuropathy in which the peripheral nerve myelin is primarily affected; can be familial (Charcot-Marie-Tooth disease, type 1) or acquired (Guillain-Barré syndrome); motor nerve conduction is slowed or blocked.

Dermatitis herpetiformis pruritic chronic dermatitis with successive groups of symmetrical, erythematous, papular, vesicular, eczematous, or bullous lesions, usually associated with asymptomatic gluten-sensitive enteropathy.

Detrusor areflexia a lower motor neuron disorder that results in an underactive, hypotonic, or atonic bladder function with retention of urine and distention.

Detrusor hyperreflexia (uninhibited or reflex bladder) upper motor neuron disorders in which the bladder empties automatically when it becomes full and the external sphincter functions normally.

Developmental dysplasia of the hip (DDH) a condition in which the hip joint of babies or young children is malformed, with the ball being completely out of the socket or the socket being too shallow to support the ball.

Diabetes diseases having in common the triad of symptoms of polyuria, weight loss, and significant glucosuria.

- **Diabetes insipidus** a disease caused by a deficiency in or resistance to antidiuretic hormone that is characterized by excretion of large amounts of dilute urine because of a decrease in water reabsorption in the kidney.
- **Gestational diabetes mellitus (GDM)** carbohydrate intolerance of variable severity with onset during pregnancy.
- **Type 1 diabetes mellitus** a disorder of carbohydrate metabolism characterized by a decrease in insulin production, resulting in hyperglycemia, ketoacidosis, and eventually renal failure and coronary artery disease.
- **Type 2 diabetes mellitus** a condition of glucose intolerance that normally appears first in adulthood and is exacerbated by obesity and an inactive lifestyle.

Diabetic nephropathy a progressive kidney disease caused by diabetes-induced angiopathy of capillaries in the glomeruli that causes nodular glomerulosclerosis.

Diabetic neuropathy combined sensory and motor disorder often seen in older diabetic patients as a result of microvascular injury involving small blood vessels that supply nerves.

Diabetic retinopathy damage to the retina caused by an overaccumulation of glucose or fructose that damages the blood vessels in the retina; in advanced stages, lack of oxygen in the retina causes fragile blood vessels to grow along the retina and in the vitreous fluid of the eye that may bleed and cause blurred vision.

Diaper dermatitis a type of dermatitis characterized by inflammation of the skin in the diaper

area in infants caused by exposure of the skin to feces and urine.

Diastolic heart failure a condition in which heart contractions are normal but the ventricle does not relax completely; therefore, less blood enters the heart.

Diffuse brain injury (diffuse axonal injury) injury to neuronal axons in many areas of the brain caused by stretching and shearing forces received during brain injury.

DiGeorge syndrome see Immune deficiency.

Dilated cardiomyopathy (congestive cardiomyopathy) a condition in which all four chambers of the heart are enlarged and weakened, resulting in progressive congestive heart failure and the need for heart transplantation.

Discoid (cutaneous) lupus erythematosus (DLE) see Lupus erythematosus.

Disorders of desire (hypoactive sexual desire, decreased libido) the most common sexual dysfunction in women; prevalence increases with age and may be a biologic manifestation of depression, alcohol or other substance abuse, prolactin-secreting pituitary tumors, or testosterone deficiency.

Distal intestinal obstruction syndrome (DIOS) a syndrome seen in cystic fibrosis secondary to impaction with feces and inspissated mucus.

Diverticulitis inflammation of the herniations or saclike outpouchings of mucosa through the muscle layers of the colon wall.

Diverticulosis presence of multiple bulging sacs pushing outward from the wall of the large intestine that may become infected and rupture, causing abdominal pain, tenderness, and fever.

Down syndrome trisomy or translocation of chromosome 21, resulting in mental retardation; distinctive facial appearance with a low nasal bridge, epicanthal folds, protruding tongue, and flat, low-set ears; poor muscle tone (hypotonia); and short stature. Congenital heart defects, reduced ability to resist respiratory tract infections, and increased risk for leukemia are common.

Drug-induced hemolytic anemia see Anemia.

Duchenne muscular dystrophy an X-linked genetic disorder in which fat and fibrous tissue infiltrate and weaken muscle tissues such as in the legs and pelvis, lungs, and heart; usually results in death before adulthood.

Dumping syndrome rapid emptying of hypertonic chyme from a surgically created residual stomach causing nausea, vomiting, bleeding, and diarrhea about 20 minutes after a meal.

Duodenal ulcer most common type of peptic ulcers; usually associated with altered mucosal defenses, rapid gastric emptying, elevated serum gastrin levels, or acid production stimulated by smoking.

Dysfunctional uterine bleeding (DUB) heavy or irregular bleeding in the absence of organic disease, such as submucous fibroids, endometrial polyps, blood dyscrasias, pregnancy, infection, or systemic disease.

Dyskinetic cerebral palsy extreme difficulty in fine motor coordination and purposeful movements resulting from injury to the basal ganglia or thalamus.

Dysphoric mood mood of general dissatisfaction, restlessness, depression, and anxiety; a feeling of unpleasantness or discomfort.

Dysplasia (atypical hyperplasia) abnormal changes in the size, shape, and organization of mature cells; considered a form of atypical hyperplasia.

Dyssynergia development of lesions in the upper motor neurons of the brain and spinal cord; results in loss of coordinated neuromuscular contraction and overactive or hyperreflexive bladder function.

Eczema most common inflammatory disorder of the skin; generally characterized by pruritus, lesions with indistinct borders, and epidermal changes.

Eisenmenger syndrome a progressively developing condition in which a congenital heart defect such as ventricular septal defect is left untreated and causes a reversed right-to-left shunt secondary to increased pressures on the right side of the heart because of pulmonary hypertension.

Embryonic tumor a tumor originating in the gestational period that contains predominantly immature blast cells that cannot differentiate into mature functional cells.

Emphysema pulmonary inflammation resulting in increased work of breathing or physiologic dead space and abnormal permanent enlargement of gas-exchange airways (acini) accompanied by destruction of alveolar walls without obvious fibrosis.

- **Centriacinar emphysema** diminished pulmonary function resulting from septal destruction in the respiratory bronchioles and alveolar ducts, usually in the upper lobes of the lung.
- **Panacinar emphysema** involves destruction of the entire acinus, with damage more randomly distributed and involving the lower lobes of the lung. It tends to occur in older adults and in those with α_1-antitrypsin deficiency.

Empyema (infected pleural effusion) a condition in which purulent fluid is persistently discharged into the pleural space as a result of complications of bacterial infections.

Encephalitis inflammation of the brain usually caused by a virus.

Endometriosis a condition that is common in women of reproductive age in which the tissue lining the uterus is found outside of the uterus, resulting in pain and infertility.

End-stage kidney disease (ESKD) significant loss of renal function; usually less than 10% of renal function remains.

Eosinophilic esophagitis rare, idiopathic inflammatory disease of the esophagus characterized by infiltration of eosinophils associated with atopic disease, including asthma and food allergies.

Ependymoma intracranial tumor that is most commonly found in children and typically arises from the inner lining of the fourth ventricle and the spinal canal.

Epididymitis a painful condition in which the epididymis becomes inflamed, usually as a result of a secondary bacterial infection that is triggered by a variety of underlying conditions such as urinary tract or sexually transmitted infections.

Epilepsy a group of chronic neurologic disorders with paroxysmal brain dysfunction from excessive neuronal discharge; symptoms vary widely from complex behavioral abnormalities to focal convulsions, to momentary spells of impaired consciousness.

Epispadias a birth defect in which the urethra opens on the upper penile surface.

Erysipelas a highly contagious bacterial infection that produces shiny, red swollen areas and fever and can lead to blood poisoning and pneumonia.

Erythema multiforme a skin disease that is caused by allergies, seasonal changes, or drug sensitivities, resulting in the formation of red macules, papules, or subdermal vesicles on the skin and mucous membranes.

Erythema toxicum neonatorum a temporary eruption of redness of the skin, small papules, and occasionally pustules in newborns that is associated with contact dermatitis or hypersensitivity to milk or other allergens.

Erythrodermic (exfoliative) psoriasis see Psoriasis.

Erythromyalgia chronic disorder characterized by warmth, pain, and redness, occurring primarily in the feet and lower legs.

Essential (primary) thrombocythemia (ET) excessive production of platelets (platelet count greater than 400,000/mm^3 of blood); may be primary or secondary (reactive) and is usually asymptomatic until the count exceeds 1 million/mm^3 of blood when intravascular clot formation (thrombosis), hemorrhage, or other abnormalities can occur.

Ewing sarcoma a malignant neoplasm of bone, primarily those of the extremities, including the shoulder girdle, with a predilection for the metaphysis; histologically presents as conspicuous foci of necrosis in association with irregular masses of small, regular, rounded, or ovoid cells.

Exstrophy of the bladder a congenital defect in which the lower abdominal wall is malformed and ruptures.

Extrapyramidal/nonspecific cerebral palsy any of a group of clinical disorders considered to be due to malfunction in the extrapyramidal system and marked by abnormal involuntary movements; included are parkinsonism, athetosis, and chorea.

Facioscapulohumeral muscular dystrophy (FSHD) an autosomal dominant genetic disorder that begins in childhood and causes muscle wasting and weakness, primarily in the face, shoulder, and arms.

Factor H deficiency see Immune deficiency.

Factor I deficiency see Immune deficiency.

Fanconi anemia see Anemia.

Fetal alcohol syndrome (FAS) a syndrome of altered prenatal growth and morphogenesis that occurs in infants born to women who were chronically alcoholic during pregnancy; it includes maxillary hypoplasia, prominence of the forehead and mandible, short palpebral

fissures, microphthalmia, epicanthal folds, severe growth retardation, mental retardation, and microcephaly.

Fibromyalgia muscles, tendons, and joints are painful, stiff, and tender; often accompanied by restless sleep, fatigue, anxiety, depression, and disturbances in bowel function.

Fibrosarcoma a malignant tumor of fibrous connective tissue that usually is derived from immature proliferating fibroblasts.

Fibrous dysplasia (FD) a genetic disorder in which tumor-like growths or lesions form in one or more bones and replace the medullary bone with fibrous tissue, resulting in expansion and weakening of the bone.

Florid hyperplasia rapid and unexpected cell growth in the lining of the breast ducts.

Focal segmental glomerulosclerosis (FSGS) a condition in which glomerular capillaries with thickened basement membranes and increased mesangial matrix collapse in segments. Usually presents as nephrotic syndrome.

Frontotemporal dementia (FTD) (Pick disease) progressive circumscribed cerebral atrophy; a rare type of cerebrodegenerative disorder manifested primarily as dementia, in which there is striking atrophy of portions of the frontal and temporal lobes.

FSH deficiency a condition characterized by decreased or absent production of follicle-stimulating hormone (FSH), resulting in a decline in spermatogenesis/oogenesis and associated infertility.

Furuncles staphylococcal infection produces painful pus-filled inflamed hair follicles and involves surrounding skin and subcutaneous tissue.

Fusiform aneurysm (giant aneurysm) large aneurysm that stretches to affect the entire circumference of the arterial wall.

Galactorrhea (inappropriate lactation) a condition in which milk-like fluid is secreted from the breast because of hormonal alterations that are not associated with childbirth or nursing.

Ganglioneuroblastoma an embryonal aggressive tumor of intermediate cellular differentiation that originates outside the CNS in the developing sympathetic nervous system.

Ganglioneuroma a benign neoplasm composed of mature ganglionic neurons scattered within a stroma of neurofibrils and collagenous fibers.

Gangliosidosis any disease characterized by abnormal accumulation of specific gangliosides within the nervous system (e.g., Tay-Sachs disease).

Gastroesophageal reflux disease (GERD) the reflux of acid and pepsin from the stomach to the esophagus that causes esophagitis.

General adaptation syndrome (GAS) the sum of all nonspecific reactions of the body to prolonged systemic stress, comprising alarm, resistance, and exhaustion.

Generalized anxiety disorder (GAD) an anxiety disorder characterized by an excessively anxious mood lasting at least 1 month that interferes with daily functioning and may be accompanied by jitteriness, sweating, feelings of catastrophe concerning one's family or self, and irritability.

Generalized neuropathy a functional disturbance or pathologic change in the cell body of one type of peripheral neuron.

Genital herpes a sexually transmitted viral infection that is caused primarily by herpes simplex virus type 2 and is characterized by painful lesions in the genital and anal regions.

Gestational diabetes mellitus (GDM) see Diabetes.

GH deficiency a condition characterized by decreased or absent production of growth hormone (GH), resulting in a decline in insulin-like growth factor 1 and dwarfism if the deficiency is prepubertal.

Glaucoma a disease of the eye characterized by increased intraocular pressure, excavation, and atrophy of the optic nerve; produces defects in the field of vision and eventual blindness.

Glomerulonephritis inflammation of the renal glomeruli that may not produce symptoms or may present with hematuria and proteinuria.

Acute glomerulonephritis an inflammatory disease of both kidneys predominantly affecting children from ages 2 to 12.

Acute poststreptococcal glomerulonephritis (PSGN) kidney disease secondary to infection with *Streptococci* in which bacterial antigens complex with antibodies in the blood, deposit in the kidneys, and initiate an immune complex–mediated hypersensitivity reaction.

Chronic glomerulonephritis a slowly progressive glomerulonephritis most often associated with other systemic disease, including diabetes, malaria, hepatitis, or systemic lupus erythematosus, that generally leads to irreversible renal failure.

Membranoproliferative glomerulonephritis (MPGN) a chronic, slowly progressive glomerulonephritis in which the glomeruli are enlarged as a result of proliferation of mesangial cells and irregular thickening of the capillary walls, which narrows the capillary lumina.

Membranous glomerulonephritis a slowly progressive disease of unknown origin or that occurs secondary to autoimmune conditions, infections, specific drugs, or malignant tumors that is caused by immune complexes formed from the binding of antibodies to antigens of the glomerular basement membrane (GBM) or antigens transported from the systemic circulation and implanted in the GBM.

Membranous nephropathy (membranous glomerulonephritis) membranous nephropathy is caused by subepithelial deposition of antibodies (IgG4 subclass) to antigens (M-type phospholipase A_2 receptor [PLA2R] protein) located on glomerular podocytes and activation of complement-mediated inflammation with injury and release of inflammatory mediators by mesangial and epithelial cells, resulting in increased membrane permeability, thickening of the glomerular membrane, and ultimately glomerular sclerosis.

Mesangial proliferative glomerulonephritis deposition of immune complexes in the mesangium with mesangial cell proliferation and expansion reducing blood flow and altering filtration membrane permeability with development of hematuria, proteinuria, hypertension, and uremia (nephritic syndrome); associated with IgA nephropathy, lupus nephritis, or early diabetic nephropathy.

Rapidly progressive (crescentic) glomerulonephritis (RPGN) (subacute or extracapillary glomerulonephritis) develops over days to weeks, primarily affects adults in their fifties and sixties, and may be idiopathic or associated with a proliferative glomerular disease (diffuse proliferation of extracapillary cells), such as lupus or poststreptococcal glomerulonephritis.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency see Anemia.

Gluten-sensitive enteropathy (celiac sprue) a condition characterized by mucosal inflammation and villous atrophy in the gastrointestinal tract formed in response to a genetic predisposition for an immune response to gluten and similar proteins.

Gonorrhea a sexually transmitted disease caused by the bacteria gonococci that invade the mucous membranes of the genitals and urinary tract and in women the cervix, fallopian tubes, and ovaries, causing chronic pelvic pain or infertility.

Gout a disorder of uric acid metabolism that causes painful inflammation of the joints, commonly the big toe, and arthritic attacks resulting from elevated levels of uric acid in the blood and the deposition of negatively birefringent urate crystals around the joints.

Gouty arthritis inflammation of the joints in gout.

Graft rejection immunologic rejection of transplanted tissue or organs based on antigen differences between the donor and recipient.

Acute graft rejection cell-mediated immune rejection that occurs within days to months after transplantation; immune response is usually against unmatched HLA antigens and develops after transplantation.

Chronic graft rejection slow, progressive organ failure after a period of months or years of normal function by a developing weak cell-mediated immune response against minor histocompatibility antigens on the endothelial cells lining the blood vessels of the grafted tissue.

Hyperacute graft rejection immediate rejection of a graft because of pre-existing antibodies against antigens expressed on the grafted tissue or organ.

Graft-versus-host disease (GVHD) condition in which mature T cells in a transplanted graft (e.g., transfused blood) are capable of a destructive cell-mediated reaction against unmatched histocompatibility antigens on the tissues in the graft recipient.

Granuloma inguinale a bacterial-induced disease, also called donovanosis, that is thought to be transmitted primarily by anal rather than vaginal intercourse and causes painless genital

ulcers like syphilis but progresses to destroy the internal and external genital tissue.

Graves disease autoimmune hyperthyroidism caused by antibodies that continuously activate TSH receptors, resulting in uncontrolled production of thyroxine and characterized by an enlarged thyroid gland, protrusion of eyeballs, a rapid heartbeat, and nervous excitability.

Guillain-Barré syndrome (GBS) (Landry-Guillain-Barré syndrome, idiopathic polyneuritis, acute inflammatory polyradiculopathy, acute autoimmune neuropathy) an acute, immune-mediated disorder of peripheral nerves, spinal roots, and cranial nerves that commonly presents as a rapidly progressive, areflexive, relatively symmetrical ascending weakness of the limb, truncal, respiratory, pharyngeal, and facial musculature, with variable sensory and autonomic dysfunction; typically reaches its peak activity within 2 to 3 weeks, followed by a plateau period of similar duration, and gradual but complete recovery in most cases; often preceded by a respiratory tract or gastrointestinal tract infection and is associated with albuminocytologic dissociation of the cerebrospinal fluid.

Guttate psoriasis see Psoriasis.

Gynecomastia abnormal breast tissue development on adolescent boys or men as a result of an imbalance in hormones.

Heat exhaustion occurs when sufficient salt and water loss results in hemoconcentration with hypotension occurring secondary to fluid loss (hypovolemia), and the individual feels weak, is nauseated, and can suddenly collapse.

Heat stroke a life-threatening condition associated with high environmental temperatures and humidity causing core body temperature to rise as a result of thermoregulatory failure.

Hematemesis accumulation of blood in the gastrointestinal tract causing irritation, increased peristalsis, and vomiting.

Hematochezia rapid bleeding from the upper GI tract producing bright red stools.

Hemochromatosis disorder of iron metabolism characterized by excessive absorption of ingested iron, saturation of iron-binding protein, and deposition of hemosiderin in tissue, particularly in the liver, pancreas, and skin; cirrhosis of the liver, diabetes (bronze diabetes), bronze pigmentation of the skin, and eventually heart failure may occur; also can result from administration of large amounts of iron orally, by injection, or in forms of blood transfusion therapy.

Hemoglobin H disease see Anemia.

Hemolytic anemia see Anemia.

Hemolytic disease of the newborn (HDN) (erythroblastosis fetalis) see Anemia.

Hemolytic jaundice (prehepatic jaundice, nonobstructive jaundice) jaundice resulting from excessive hemolysis of red blood cells.

Hemolytic-uremic syndrome (HUS) a condition in which platelets aggregate within the kidney's small blood vessels, resulting in reduced blood flow to the kidney and subsequent kidney failure and destruction of the red blood cells; occurs usually after exposure to Shiga-like toxin from a strain of *E. coli*.

Hemophilia A (classic hemophilia) a genetic disorder in which a mutation in factor VIII causes prolonged clotting time, decreased formation of thromboplastin, and diminished conversion of prothrombin.

Hemophilia B (Christmas disease) a genetic disorder similar to hemophilia A in terms of symptoms but with a mutation in the factor IX gene.

Hemophilia C (factor XI deficiency) a genetic disorder characterized by a deficiency in factor XI, resulting in a mild form of hemophilia.

Hemorrhagic stroke (spontaneous intracranial hemorrhage) stroke usually caused by hypertension that results in bleeding in the brain and typically increases intracranial pressure and may lead to death.

Henoch-Schönlein purpura nephritis inflammation of the blood vessels causing bleeding into the skin, mucous membranes, internal organs, and other tissues; pain and inflammation in the joints; abdominal pain; gastrointestinal bleeding; inflammation of the kidneys; subcutaneous edema; encephalopathy; and inflammation of the testis.

Heparin-induced thrombocytopenia (HIT) see Thrombocytopenia.

Hepatic encephalopathy a condition that is usually caused by liver cirrhosis and portal hypertension in which toxins produced by the gut pass into the systemic circulation and damage brain cells, resulting in impaired cognition, tremor, and a decreased level of consciousness.

Hepatocellular carcinoma (hepatocarcinoma; HCC) primary carcinoma of the liver developing in hepatocytes.

Hepatopulmonary syndrome intrapulmonary vasodilation, intrapulmonary shunting, and hypoxia and portopulmonary hypertension (pulmonary vasoconstriction and vascular remodeling) are common respiratory complications of advanced liver disease and portal hypertension.

Hepatorenal syndrome (HRS) acute renal failure occurs because of a decrease in renal blood flow secondary to liver disease.

Hereditary angioedema an inherited, autosomal dominant disease characterized by episodic appearance of nonpitting edema, most often affecting the limbs, but capable of involving other parts of the body, including mucosal surfaces such as those of the intestine (causing abdominal pain) or respiratory tract (causing asphyxia); associated with deficiency of inhibitor of the first component of complement pathway (C1 esterase inhibitor).

Hereditary hemochromatosis (HH) autosomal recessive chronic liver disease caused by excessive intestinal absorption of elemental iron; characterized by elevated serum iron saturation, transferrin, and ferritin levels; improves with phlebotomy; increased risk of developing cirrhosis, liver cancer, and liver failure.

Hereditary sideroblastic anemia see Anemia.

Hereditary spherocytosis see Anemia.

Hiatal hernia an anatomic abnormality in which the esophageal hiatus is larger than normal, causing part of the stomach to protrude through the diaphragm and up into the esophagus or chest.

High altitude cerebral edema (HACE) an increase in severity of symptoms or signs of neurologic dysfunction, such as ataxia or altered consciousness, related to high altitude.

High altitude pulmonary edema (HAPE) a noncardiogenic pulmonary edema associated with pulmonary hypertension and elevated capillary pressure related to high altitude illness.

Hirsutism abnormal growth and distribution of androgen-sensitive hair growth on the face, body, and pubic area in a male pattern that occurs in women.

Hodgkin lymphoma (HL) see Lymphoma.

Hormonal hyperplasia growth of cellular layers chiefly in estrogen-dependent organs, such as the uterus and breast. After ovulation, for example, estrogen stimulates the endometrium to grow and thicken for reception of the fertilized ovum.

Huntington disease (HD) an autosomal dominant disease causing a progressive increase in involuntary, jerky, dyskinetic movements; mental deterioration; and premature death.

Hyaline membrane disease (HMD) a type of respiratory distress syndrome of the newborn in which there is formation of a hyaline-like membrane lining the terminal respiratory passages; extensive atelectasis is attributed to lack of surfactant.

Hydrocephalus ex vacuo hydrocephalus attributable to loss or atrophy of brain tissue; less commonly associated with raised intracranial pressure and dilation of the cerebral ventricles.

Hydrops fetalis edema formation in the fetal subcutaneous tissue because of an enzyme deficiency or any one of several other disorders.

Hyperosmolar hyperglycemic nonketotic syndrome (HHNKS) a complication seen in diabetes mellitus in which very marked hyperglycemia occurs, causing osmotic shifts in water in brain cells, and resulting in coma. It can be fatal or lead to permanent neurologic damage.

Hypersensitive pneumonitis (extrinsic allergic alveolitis) an allergic, inflammatory disease of the lungs caused by inhalation of organic particles or fumes.

Hypertrophic cardiomyopathy a genetic disorder caused by various mutations that thicken the heart muscle, possibly leading to obstruction of blood flow and heart dysfunction; this is a common cause of sudden death in young athletes.

Hypogammaglobulinemia see Immune deficiency.

Hypoplastic anemia see Anemia.

Hypoplastic left heart syndrome (HLHS) a condition in which the left side of the heart, including the aorta, aortic valve, left ventricle, and mitral valve, is underdeveloped and blood returning from the lungs flows through an opening in the atrial septum and the right ventricle pumps the blood into the pulmonary artery and then into the aorta.

Hypospadias a birth defect in which the urethral opening is abnormally placed, opening

anywhere from the tip of the glans penis, to the shaft, or to the junction of the penis and scrotum or perineum in males; usually opens in the vagina in females.

Iatrogenic pneumothorax see Pneumothorax.

Icterus neonatorum (neonatal jaundice) jaundice in newborn infants caused by functional immaturity of the liver; usually subsides within the first few days of life.

Idiopathic pulmonary fibrosis (IPF) an excessive amount of fibrous or connective tissue in the lung.

Idiopathic thrombocytopenic purpura (ITP) (autoimmune or primary thrombocytopenic purpura) see Thrombocytopenia.

IgA nephropathy (Berger disease) the most common form of idiopathic acute glomerulonephritis in developed countries, especially Asia; cause is unknown.

IgA pemphigus the most benign form of pemphigus characterized by tissue-bound and circulating IgA antibodies targeting desmosomal or nondesmosomal cell surface components in the basement membrane of the epidermis.

IgG subclass deficiency see Immune deficiency.

IL-7 receptor deficiency see Immune deficiency.

Immune deficiency a group of disorders in which one or more components of the immune or inflammatory response is impaired, resulting in increased susceptibility to infections. **Primary (congenital) immune deficiencies** result from genetic defects, and secondary immune deficiencies result from nongenetic factors, such as infections and other physiologic or pathophysiologic conditions. Primary immune deficiencies include:

- **B-lymphocyte deficiency** a group of disorders in which B-cell development is defective, resulting in lower levels of circulating immunoglobulins and increased susceptibility to infections in which antibodies are the primary protective mechanism. These include:
  - **Agammaglobulinemia** a condition in which no antibodies are produced.
  - **Autosomal agammaglobulinemia** an autosomal recessive form of agammaglobulinemia resulting from mutations in the B-cell receptor.
  - **Autosomal hyper-IgM syndrome** inability to class-switch resulting from mutations in CD40 on B cells.
  - **Bruton's agammaglobulinemia** a defect in B-cell development results in lower levels of circulating immunoglobulins and increased susceptibility to infections in which antibodies are the primary protective mechanism.
  - **Common variable immune deficiency** the most commonly diagnosed immune deficiency; hypogammaglobulinemia of IgG and other antibody classes; normal numbers of B cells, with or without associated T-cell defects.
  - **Hypogammaglobulinemia** a condition in which immunoglobulin levels are much lower than normal.
  - **IgG subclass deficiency** deficiencies in certain subclasses of antibody.
  - **Selective IgA deficiency** failure to produce IgA, with or without diminished production of other classes of antibody.
  - **X-linked hyper-IgM syndrome** inability to class-switch resulting from a defect in activation-induced cytidine deaminase (AICD).
- **Combined T- and B-lymphocyte deficiency** a group of immune deficiencies in which both T and B lymphocytes are defective. The most severe of these deficiencies is called **severe combined immune deficiency (SCID).** These include:
  - **Adenosine deaminase (ADA) deficiency** a form of SCID caused by an autosomal recessive mutation in the enzyme ADA, leading to death of rapidly dividing cells, particularly lymphocytes.
  - **Ataxia-telangiectasia (AT)** an autosomal recessive disorder resulting from a large variety of sporadic mutations in the *ATM* gene; often associated with ataxia (unsteady gait), telangiectasia (dilation of capillaries), and variable effects on both B and T cells.
  - **Bare lymphocyte syndrome** forms of SCID characterized by an inability of lymphocytes and macrophages to present antigen because of defects in class I (**MHC class I deficiency**) or class II (**MHC class II deficiency**) MHC antigen expression.
  - **IL-7 receptor deficiency** a form of SCID resulting from mutations in the IL-7 receptor, which is necessary for maturation of T cells.
  - **JAK3 deficiency** a form of SCID resulting from mutations in JAK3, which is an enzyme (a tyrosine kinase) associated with their receptor for IL-2.
  - **Purine nucleoside phosphorylase (PNP) deficiency** a form of SCID resulting from a mutation in the enzyme PNP.
  - **RAG-1 and RAG-2 deficiencies** autosomal recessive mutations in RAG-1 or RAG-2 enzyme that are necessary for genetic rearrangement of antibody and T-cell receptor variable regions.
  - **Reticular dysgenesis** the most severe form of SCID in which a common stem cell for all white blood cells is absent; therefore T cells, B cells, and phagocytic cells never develop.
  - **Wiskott-Aldrich syndrome (WAS)** an X-linked recessive trait resulting in chronic eczema with chronic suppurative otitis media, anemia, thrombocytopenic purpura, poor antibody response to polysaccharide antigens, and dysfunctions of cell-mediated immunity.
  - **X-linked SCID** a form of SCID with arrested maturation of T and NK cells and the production of immature B cells as a result of a defect in the IL-2 receptor gamma (γ)-chain (IL-2Rγ), which is shared with many other cytokine receptors.
- **Complement deficiency** a group of conditions in which specific proteins of the complement system are absent or suboptimal, resulting in diminished complement activity. These include:
  - **C1 deficiency** a deficiency of the first component of the classical pathway.
  - **C2 deficiency** a deficiency with an increased risk for recurrent respiratory tract infections with encapsulated bacteria and a systemic lupus erythematosus–like syndrome that may be complicated by kidney disease (glomerulonephritis).
  - **C3 deficiency** the most severe complement defect; an associated deficit of C3b, which is a major opsonin, results in a risk for recurrent life-threatening infections with encapsulated bacteria.
  - **C3 receptor deficiency** deficiencies in the complement receptor for C3 result in recurrent bacterial infections, particularly of the skin.
  - **C4 deficiency** results in an increased risk for recurrent respiratory tract infections with encapsulated bacteria and a systemic lupus erythematosus–like syndrome that may be complicated by kidney disease (glomerulonephritis).
  - **C9 deficiency** the most common terminal pathway defect and generally asymptomatic.
  - **Factor H deficiency** a deficiency of complement factor H resulting in increased destruction of C3 and a secondary C3 deficiency.
  - **Factor I deficiency** a deficiency of complement factor I resulting in increased destruction of C3 and a secondary C3 deficiency.
  - **Mannose-binding lectin (MBL) deficiency** a defect of the lectin pathway of complement activation resulting in an increased risk of infection with microorganisms that have polysaccharide capsules rich in mannose.
  - **Properdin deficiency** an X-linked defect in the alternative pathway of complement activation resulting in recurrent meningococcal infections.
- **Phagocytic deficiency** a group of conditions in which phagocytosis is diminished, resulting in increased bacterial infections. These include:
  - **Chediak-Higashi syndrome** a lethal, progressive, autosomal recessive, systemic disorder associated with oculocutaneous albinism, massive leukocyte inclusions (giant lysosomes), histiocytic infiltration of multiple body organs, development of pancytopenia, hepatosplenomegaly, and recurrent or persistent bacterial infections.
  - **Chronic granulomatous disease (CGD)** both X-linked and autosomal forms of mutations of the NADPH oxidase complex, resulting in diminished production of hydrogen peroxide and other oxygen products necessary for the bactericidal activity of myeloperoxidase.
  - **Cyclic neutropenia** an autosomal dominant mutation in the *ELA2* gene resulting in periods of neutropenia lasting a few days to weeks.

Severe congenital neutropenia inadequate numbers of neutrophils resulting in a variety of recurrent and severe bacterial infections beginning early in life.

Secondary immune deficiencies

Acquired immunodeficiency syndrome (AIDS) an epidemic, transmissible retroviral disease caused by infection with the human immunodeficiency virus (HIV), resulting in destruction of T-helper cells, suppression of both antibody and cellular immune responses, and development of life-threatening infections with opportunistic organisms.

Agranulocytosis complete absence of granulocytes in the blood is usually secondary to arrested hematopoiesis in the bone marrow or massive cell destruction in the circulation.

Qualitative leukocyte disorder a group of conditions with various disruptions of leukocyte function.

Quantitative leukocyte disorder a group of conditions, frequently associated with infections and leukemias, with decreased production of leukocytes in the bone marrow or accelerated destruction of leukocytes in the circulation.

Transient hypogammaglobulinemia of infancy a period at 6 to 8 months when the newborn may not have produced adequate amounts of antibody to replace maternal antibody; in some infants this may lead to a period of increased susceptibility to infections.

T-lymphocyte deficiency a group of disorders in which T-cell development is defective, resulting in lower levels of cellular immunity. Diminished T helper cell function may also decrease the production of antibody. These include:

Chronic mucocutaneous candidiasis a primary defect of T-lymphocyte response to a specific infectious agent, the yeast *C. albicans*.

DiGeorge syndrome a genetic disorder caused by deletion of a piece of chromosome 22 that results in cardiac defects, abnormal facies, thymic aplasia, cleft palate, and hypocalcemia.

Immune thrombocytopenic purpura (ITP) see Thrombocytopenia.

Imperforate anus a congenital defect in which the anal opening is absent because of the presence of a membranous septum or complete absence of the anal canal.

Impetigo a contagious bacterial infection that produces superficial red blisters that rupture and produce thick yellow crusts that commonly occur on the face but can spread to other regions of the body easily.

Infectious mononucleosis (IM) a disease caused by the Epstein-Barr virus or the cytomegalovirus that is transmitted by exchanging saliva or blood or by coughing and sneezing and acts by infecting the B cells and atypical T cells, resulting in fever, sore throat, and fatigue.

Infertility the inability to conceive after 1 year of unprotected intercourse with the same, opposite-sex partner.

Intracerebral hematoma (intraparenchymal hemorrhage) blood accumulation that partially clots inside the brain, usually in the frontal and temporal lobes.

Intraductal papilloma array of papillary cells that grow from the wall of a cyst into the lumen of the duct; growth occurs within a dilated duct often near or beside the nipple causing benign nipple discharge.

Intrarenal (intrinsic) acute kidney injury (AKI) a sudden decline in kidney function with a decrease in glomerular filtration and an accumulation of nitrogenous waste products in the blood (elevation in plasma creatinine and blood urea nitrogen levels); may result from ischemic acute tubular necrosis (ATN), nephrotoxic ATN (i.e., exposure to radiocontrast media or antibiotics), acute glomerulonephritis, vascular disease (malignant hypertension, disseminated intravascular coagulation, and renal vasculitis), allograft rejection, or interstitial disease (drug allergy, infection, tumor growth).

Invasive breast carcinoma a malignant invasive epithelial lesion derived from the terminal duct lobular area.

Invasive carcinoma of the cervix invasion of cervical carcinoma into adjacent tissues, such as ureters and structures of the lateral pelvic wall, the vaginal stroma and epithelium, and the lower uterine segment and myometrium.

Inverse psoriasis see Psoriasis.

Iron deficiency anemia (IDA) see Anemia.

Irritable bowel syndrome (IBS) a chronic noninflammatory disease with a psychophysiologic basis; characterized by abdominal pain, diarrhea or constipation, or both; no detectable pathologic change.

Irritative syndrome (radicular syndrome) a combination of changes usually seen with compromise of a spinal root within the intraspinal canal; these include neck or back pain and, in the affected root distribution, dermatomal pain, paresthesias, or both; decreased deep tendon reflexes; and occasionally myotomal weakness.

Isolated systolic hypertension loss of elasticity of the arteries resulting in an increase in cardiac output or stroke volume, a systolic blood pressure consistently greater than 160 mmHg, and a diastolic pressure less than 90 mmHg.

JAK3 deficiency see Immune deficiency.

Jaundice (icterus) yellowish brown staining of the skin and the conjunctivae caused by high bilirubin levels in blood secondary to excessive erythrocyte breakdown, obstruction in or around the liver, or liver disease.

Juvenile idiopathic arthritis (JIA) chronic pauciarticular arthritis and destruction of joints beginning in childhood and often going into remission at puberty.

Juvenile myoclonic epilepsy a type of epilepsy that occurs in adolescents and young adults, usually on awakening, and is characterized by jerks of the neck, shoulders, and arms and by clonic-tonic seizures.

Kaposi sarcoma (KS) a rare cancer of connective tissue caused by herpesvirus 8 (HHV8) in which many bluish red nodules appear on the skin, especially skin of the lower extremities; occurs in a particularly virulent form in individuals with AIDS.

Kawasaki disease a vascular disease characterized by an inflamed heart and vessels; a coronary artery aneurysm, thickening, and stenosis; a fever that lasts at least 5 days; and at least four of the following: inflammation with reddening of the whites of the eyes; red, swollen hands or feet or peeling skin; rash; swollen lymph glands in the neck; inflamed lips or throat; or red "strawberry" tongue.

Klinefelter syndrome smallness of testes with fibrosis and hyalinization of seminiferous tubules, variable degrees of masculinization, azoospermia, infertility, and increased levels of urinary gonadotropins; associated typically with an XXY chromosome complement although variants include XXYY, XXXY, and XXXXY.

Kwashiorkor a condition in which children do not receive enough protein in their diet, resulting in a swollen and severely bloated abdomen secondary to decreased albumin levels in the blood, skin changes resulting in a reddish discoloration of the hair and skin in dark-skinned children, severe diarrhea, fatty liver, muscle atrophy, and restricted development.

Lactase deficiency a condition in which insufficient lactase is present in the small intestine to digest lactose, resulting in lactose intolerance characterized by diarrhea, bloating, and gas in response to exposure to lactose.

Lactose intolerance a condition caused by lactase deficiency in which lactose is not metabolized, making it impossible for the small intestine to absorb it and causing excessive gas production and diarrhea when exposed to lactose-containing foods.

Lambert-Eaton myasthenic syndrome a generalized disorder of neuromuscular transmission caused by a defect in the release of acetylcholine from the presynaptic nerve terminals; often associated with small cell carcinoma of the lung, particularly in elderly men with a long history of cigarette smoking; weakness tends to affect solely axial muscles, girdle muscles, and less often the limb muscles; autonomic disturbances, dry mouth, and impotence are common; the deep tendon reflexes are unelicitable; caused by loss of voltage-sensitive calcium channels located on the presynaptic motor nerve terminal.

Laryngomalacia a congenital anomaly caused by a developmental delay in the laryngeal cartilage and supporting structures of the larynx that causes the cartilage to be floppy and fold in on itself during inspiration, producing high-pitched, coarse, and low-pitched sounds.

Left heart failure (congestive heart failure) inability of the left ventricle to maintain its circulatory load, with a corresponding rise in pressure in the pulmonary circulation usually with pulmonary congestion and ultimately pulmonary edema.

Legg-Calvé-Perthes disease blood supply to the head of the femur near the hip joint is

interrupted, resulting in osteonecrosis of the corresponding epiphysis.

Lennox-Gastaut syndrome a generalized myoclonic epilepsy that occurs in children between 1 and 5 years of age as a result of various cerebral afflictions such as perinatal hypoxia, hemorrhage, encephalitis, and metabolic disorders of the brain; it is characterized by mental retardation, personality disorders, and generalized tonic seizures.

Leukemia an acute or chronic malignant disease of the bone marrow and blood-forming organs; excessive proliferation of white blood cells occurs and is usually accompanied by dysfunctional blood cells, anemia, impaired blood clotting, and enlargement of the lymph nodes, liver, and spleen.

Acute leukemia characterized by undifferentiated or immature cells, usually a blast cell, and the onset of disease is abrupt and rapid with a short survival time.

Acute lymphoblastic/lymphocytic leukemia (ALL) excessive production and continuous multiplication of malignant and immature white blood cells (lymphoblasts) in the bone marrow that progresses rapidly if left untreated.

Acute myelogenous leukemia (AML) excessive number of immature myeloid cells (myeloblasts) in the blood and bone marrow crowding out the marrow and decreasing the function of other cells.

Chronic leukemia the predominant cell is more differentiated but does not function normally, with a relatively slow progression of the malignancy.

Chronic lymphocytic leukemia (CLL) malignant transformation and progressive accumulation in the marrow of monoclonal B lymphocytes; rarely are CLL malignancies of T-cell origin.

Chronic myelogenous leukemia (CML) production of heterogeneous myeloid cells in the bone marrow, the majority of which express the Philadelphia chromosome; CML is considered a myeloproliferative disorder.

LH deficiency a condition characterized by decreased or absent production of luteinizing hormone (LH), resulting in a decline in sex steroid production in testes/ovaries and associated infertility.

Lichen planus a recurrent rash of small, flat-topped bumps and rough scaly patches appearing on the skin, in the lining of the mouth, and in the vagina in response to inflammation or an allergy to a specific medication.

Localized scleroderma (morphea) rare and idiopathic sclerosis of the skin, usually with childhood onset.

Locked-in syndrome quadriplegia and mutism with intact consciousness and preservation of some eye movements; usually results from a vascular lesion of the anterior pons.

Lupus erythematosus any of a group of autoimmune connective tissue disorders that commonly produce red scaly lesions and are accompanied by fever, malaise, myalgias, fatigue, and weight loss.

Discoid (cutaneous) lupus erythematosus (DLE) lupus erythematosus limited to the skin; can progress to systemic lupus erythematosus (SLE).

Systematic lupus erythematosus (SLE) a chronic, multisystem, inflammatory disease; is one of the most common, complex, and serious of the autoimmune disorders.

Lyme disease (borreliosis) tick-borne spirochete bacterial infection that is characterized by a rash in the area of the bite, headache, neck stiffness, chills, fever, myalgia, arthralgia, malaise, fatigue, and possible development of arthritis in large joints.

Lymphoblastic lymphoma (LL) see Lymphoma.

Lymphogranuloma venereum (LGV) a sexually transmitted bacterial infection that enters the body through breaks in the skin or across the epithelial cell layer of mucous membranes and primarily targets the lymphatics and lymph nodes.

Lymphoma cancer arising from cell proliferation in lymphoid tissue.

B-cell neoplasm a group of lymphomas including myelomas that originate from B cells at various stages of differentiation; previously part of non-Hodgkin lymphoma.

Burkitt lymphoma an aggressive malignancy of the B lymphocytes characterized by a large osteolytic lesion in the facial bones and associated with Epstein-Barr virus infection.

Hodgkin lymphoma (HL) a cancer of lymphoid tissue in which the lymph nodes, spleen, and liver become enlarged with the presence of Reed-Sternberg cells and is often accompanied by anemia, fever, and eventually death if not treated at an early stage; also referred to as Hodgkin disease.

Lymphoblastic lymphoma (LL) a progressive neoplasm arising in the thymus; most are of T-cell origin; a variant of acute lymphoblastic leukemia; common cause of NHL in children.

Lymphoplasmocytic lymphoma also called Waldenström macroglobulinemia.

Mucosa-associated lymphoid tissue (MALT) lymphoma a low-grade B-cell lymphoma linked to infection with *H. pylori.*

Mycosis fungoides most common cutaneous T-cell lymphoma; present as focal or widespread erythematous patches or plaques, follicular papules, comedone-like lesions, and tumors.

NK-cell neoplasm a group of lymphomas that originate from NK cells at various stages of differentiation; previously part of non-Hodgkin lymphoma.

Non-Hodgkin lymphoma (NHL) a group of malignancies of lymphoid tissue classified as B-cell, T-cell, and NK-cell lymphomas that mimic Hodgkin lymphoma but do not produce the cells characteristic of Hodgkin lymphoma; have been reclassified as B-cell, T-cell, or NK-cell neoplasms.

T-cell neoplasm a variety of lymphomas that originate from T cells at various stages of differentiation; previously part of non-Hodgkin lymphoma.

Waldenström macroglobulinemia a rare type of slow-growing plasma cell tumor that secretes a monoclonal IgM molecule; also called lymphoplasmocytic lymphoma.

Lymphoplasmocytic lymphoma see Lymphoma.

Lysosomal storage diseases a group of more than 30 disorders that result from impaired lysosomal function, leading to mucopolysaccharidoses, lipid storage disorders, mucolipidoses, leukodystrophies, and glycoprotein storage disorders.

Macrocytic anemia (megaloblastic anemia) see Anemia.

Major (unipolar) depression severely depressed mood and loss of pleasure that may begin suddenly or slowly; it persists for at least 2 weeks and may recur throughout life.

Malignant hyperthermia an inherited life-threatening disorder that causes muscle rigidity, a hypermetabolic state, tachycardia, and increased body temperature in response to administration of general anesthesics.

Malnutrition lack of nourishment from inadequate amounts of calories, protein, vitamins, or minerals; caused by improper diet, alterations in digestion or absorption, chronic disease, or a combination of these factors.

Mannose-binding lectin (MBL) deficiency see Immune deficiency.

Marasmus a childhood disorder characterized by protein and energy malnutrition, resulting in dry skin, loss of adipose tissue from normal areas of fat deposits such as buttocks and thighs, and behavior that is fretful and irritable.

Maturity-onset diabetes of youth (MODY) see Diabetes mellitis.

McArdle disease a metabolic disorder involving an enzyme defect that causes deficiency of muscle phosphorylase, which helps break down glycogen, and consequently this disorder causes an energy deficit in the muscles, resulting in muscle pain and cramping.

Meconium ileus obstruction with thickened meconium in the intestine of a newborn child as a result of a lack of trypsin and associated with cystic fibrosis of the pancreas.

Medulloblastoma a malignant cerebellar tumor near the fourth ventricle that is most often found in children and consists of neoplastic cells that resemble the undifferentiated cells of the neural tube.

Membranoproliferative glomerulonephritis (MPGN) see Glomerulonephritis.

Membranous glomerulonephritis see Glomerulonephritis.

Membranous nephropathy (membranous glomerulonephritis) see Glomerulonephritis.

Ménière disease (endolymphatic hydrops) dilation of the membranous labyrinth of the inner ear that is thought to be due to impaired absorption of endolymph in the endolymphatic sac; the pathologic finding in Ménière disease.

Ménière syndrome an affliction characterized clinically by vertigo, nausea, vomiting, tinnitus,

and fluctuating and progressive sensory hearing loss associated with endolymphatic hydrops.

Meningioma a slow-growing mass of the meninges that is usually benign but increases intracranial pressure

Meningocele neural tube defect in the skull or spinal column that forms a cyst filled with cerebrospinal fluid through which the meninges of the brain protrude.

Mesangial proliferative glomerulonephritis see Glomerulonephritis.

Mesenteric venous thrombosis a condition in which a blood clot obstructs one of the mesenteric veins and compromises the intestinal blood supply; can result in intestinal gangrene and tissue death.

Mesothelioma a type of cancer that is usually associated with previous exposure to asbestos, which affects the pleura, the lining of the abdominal cavity, the pericardium, and most internal organ coverings.

Metabolic syndrome a condition of unknown cause that presents with symptoms of insulin resistance, obesity, hypertension, dyslipidemia, and systemic inflammation.

Metatarsus adductus a foot deformity in which the front half of the foot bends inward, possibly because of the infant's position in the uterus.

MHC class I deficiency see Immune deficiency.

MHC class II deficiency see Immune deficiency.

Microcephaly defect in which failure of normal brain growth causes delayed skull growth and production of a small head.

Microcytic-hypochromic anemia see Anemia.

Microscopic colitis a relatively common cause of diarrhea; occurs primarily in females and older adults.

Migraine headache headache that usually begins in the temporal region unilaterally after vascular changes of cranial arteries and may cause irritability, nausea, vomiting, constipation or diarrhea, and photophobia.

Mild concussion (mild traumatic brain injury) temporary axonal disturbances without the loss of consciousness in response to a violent blow, jarring, shaking, or other closed-head injury.

Miliaria a skin disease caused by partially obstructed sweat glands that results in small and itchy rashes usually located in skinfolds and on areas of the body that may rub against clothing, such as the back, chest, and stomach.

Minimal change nephropathy (MCN) the foot processes of the renal capillary basement membrane are fused and deformed because of a T-cell disorder that reduces the anion component of the basement membrane and allows proteins to leak into the renal tubule.

Minimally conscious state (MCS) a condition in which a severely brain-damaged patient is capable of deliberate behavior distinguishable from unconscious reflexive actions.

Mitral valve prolapse syndrome the mitral valve cannot close properly because of one or both flaps being too large, possibly resulting in mitral valve regurgitation.

Mixed precocious puberty development of some secondary sex characteristics of the opposite sex (virilization of a girl or feminization of a boy); usually evident at birth and rare in older children.

Molluscum contagiosum a viral infection of the skin occurring in young children that affects the body, arms, and legs; it is spread through direct contact, saliva, or shared articles of clothing and is considered a sexually transmitted disease in adults, affecting the genitals, lower abdomen, buttocks, and inner thighs.

Monoclonal gammopathy of undetermined significance (MGUS) production of monoclonal antibodies by noncancerous plasma cells that accumulate in the blood.

Motility diarrhea diarrhea caused by excessive motility decreases transit time, mucosal surface contact, and fluid absorption secondary to resection of the small intestine (short bowel syndrome), surgical bypass of an area of the intestine, fistula formation between loops of intestine, irritable bowel syndrome–diarrhea predominant, diabetic neuropathy, hyperthyroidism, and laxative abuse.

Moyamoya disease an abnormality of the blood vessels that supply the frontal region of the brain in which vessels constrict or become completely occluded, resulting in diminished blood flow. The body attempts to compensate by growing new vessels at the base of the brain, which appear as a puff of smoke on angiography.

Mucoepidermoid carcinoma a tumor of the main or lobar bronchi lumen that may extend into the peribronchial tissue.

Mucolipidosis (ML) accumulations of both carbohydrates and lipids.

Mucopolysaccharidosis carbohydrate excess disorders.

Mucopurulent cervicitis (MPC) inflammation of the cervix with purulent endocervical exudate that may be asymptomatic or cause abnormal vaginal discharge and vaginal bleeding.

Mucosa-associated lymphoid tissue (MALT) lymphoma see Lymphoma.

Multiple myeloma (MM) most common and most aggressive plasma cell tumor; a clonal plasma cell cancer characterized by the slow proliferation of malignant cells as tumor cell masses in the bone marrow that usually results in destruction of the bone; most secrete large amounts of monoclonal proteins that resemble intact immunoglobulins.

Multiple organ dysfunction syndrome (MODS) progressive disease often involving the ultimate failure of two or more organ systems after a severe illness or injury; disease process is initiated and perpetuated by uncontrolled systemic inflammatory and stress responses and is characterized by a hypermetabolic and hyperdynamic state that persists as organ dysfunction develops.

Multiple papilloma (diffuse papillomatosis) a minimum of five papillomas within a localized segment of breast tissue.

Multiple sclerosis (MS) chronic demyelinating disease of the central nervous system that causes inflammation and scarring of myelin sheaths.

Muscular dystrophy a general term for a number of hereditary, progressive degenerative disorders affecting skeletal muscles, and often other organ systems.

Myasthenia gravis neuromuscular disorder caused by an autoimmune response in which antibodies to acetylcholine receptors impair neuromuscular transmission.

Mycosis fungoides see Lymphoma.

Myelodysplastic syndrome (MDS) a group of hematologic conditions characterized by ineffective production of blood cells, resulting in anemia that requires chronic blood transfusion.

Myoadenylate deaminase deficiency (MDD) a genetic disorder in which an enzyme deficiency prevents the conversion of adenosine monophosphate (AMP) to inosine monophosphate, resulting in increased AMP loss and the inability to synthesize adenosine triphosphate for energy.

Myocardial infarction a heart condition of sudden onset in which muscle tissue dies because of a lack of blood flow, resulting in varying degrees of chest pain or discomfort, weakness, sweating, nausea and vomiting, and possibly loss of consciousness.

Myositis inflammation of a muscle, usually a voluntary muscle, resulting in pain, tenderness, and sometimes spasm in the affected area.

Myositis ossificans a condition in which bone is deposited in muscle tissue, causing pain and swelling.

Myxedema cutaneous edema caused by deposition of connective tissue (e.g., glycosaminoglycans and hyaluronic acid) and associated with hypothyroidism and Graves disease; characterized by dry skin, pretibial myxedema, swelling around the lips and nose, mental deterioration, and a decrease in basal metabolic rate.

Necrotizing enterocolitis (NEC) a condition of extensive ulceration and necrosis of the ileum and colon in premature infants during the neonatal period.

Necrotizing fasciitis a rare, rapidly spreading inflammation starting in the fascia, muscles, and subcutaneous fat with subsequent necrosis of the overlying skin; it is initiated by bacterial infection and treated with antibiotics; often requires surgical débridement.

Neonatal alloimmune thrombocytopenic purpura (NATP) see Thrombocytopenia.

Neonatal purpura fulminans a fatal syndrome found in neonates who are homozygous or double heterozygous for types I and II protein deficiency.

Nephritic syndrome a disorder of the glomerular filtration membrane in which plasma proteins and red blood cells pass into the urine, resulting in mild proteinuria, hematuria, and mild hypertension.

Nephroblastoma (Wilms tumor) a malignant renal tumor of young children that compresses the normal kidney parenchyma, causing an abdominal mass, blood in the urine, and fever and may be associated with anorexia, vomiting, and malaise; often inherited as an autosomal dominant trait.

Nephrotic syndrome a disorder of the glomerular filtration membrane that permits proteins to pass into the urine, resulting in proteinuria,

hypoalbuminemia, hyperlipidemia, and systemic edema.

Neural tube defect (NTD) lack of closure of the neural groove caused by an arrest of the normal development of the brain and spinal cord during the first month of embryonic development.

Neuroblastoma a malignant tumor containing neuroblast cells that originate in the autonomic nervous system or the adrenal medulla; is most common in infants and young children.

Neurogenic shock (vasogenic shock) a type of shock caused by the sudden loss of the sympathetic nervous system signals to the smooth muscle in vessel walls, causing the vessels to relax and a decrease in peripheral vascular resistance and blood pressure.

Neuroleptic malignant syndrome hyperthermia with autonomic and extrapyramidal side effects caused by the administration of neuroleptic drugs.

NK-cell neoplasm see Lymphoma.

Nonalcoholic fatty liver disease (NAFLD) accumulation of fat in hepatocytes, primarily in the form of triglycerides, occurring in the absence of or with little alcohol intake; causes progressive inflammation and scarring that is usually asymptomatic for years.

Nonalcoholic steatohepatitis (NASH) a more serious form of nonalcoholic fatty liver disease resulting from hepatocellular injury, inflammation, and fibrosis; this condition is difficult to distinguish from alcohol-induced liver fibrosis; may progress to cirrhosis, end-stage liver disease, and an increased risk for hepatocellular carcinoma.

Nonbacterial infectious cystitis see Painful bladder syndrome/interstitial cystitis (PBS/IC).

Nonbacterial prostatitis prostatitis causes chronic pain that disappears and returns without warning but shows no signs of bacterial infection in the prostatic fluid even though the semen and other fluids from the prostate contain immune cells that the body produces in response to infection.

Non-Hodgkin lymphoma (NHL) see Lymphoma.

Noninfectious cystitis see Painful bladder syndrome/interstitial cystitis (PBS/IC).

Noninflammatory acne see Acne.

Noninflammatory joint disease a disease in which alterations in the structure or mechanics of the joint result in pain during motion.

Nonoliguric renal failure excretion of more than 500 ml/day of urine concurrent with renal failure; although adequate volume of urine is excreted, renal tubules have impaired reabsorption and concentration and dilution function so that filtration is defective, resulting in accumulation of uremic toxins in the blood.

Nonossifying fibroma (fibrous cortical deficit) a benign fibrous tissue tumor forms in the metaphysis of any of the long bones but usually occurs in the thigh and shin bones in children and adolescents.

Nonpuerperal hyperprolactinemia the presence of excessive amounts of prolactin (the pituitary hormone that stimulates milk production) in the blood not related to pregnancy or childbirth; most common cause of galactorrhea.

Nonsyndromic craniosynostosis (see Craniosynostosis) the premature closure of one or more of the cranial sutures during the first 18 to 20 months of an infant's life, but an isolated defect unrelated to syndrome.

Normocytic-normochromic anemia (NNA) see Anemia.

Obesity hypoventilation syndrome (pickwickian syndrome) a condition of severely overweight individuals related to the inability to breathe rapidly or deeply enough to maintain adequate blood oxygen levels; characterized by obstructive sleep apnea, somnolence, hypoventilation, erythrocytosis, and heart failure.

Obsessive-compulsive disorder (OCD) an anxiety disorder characterized by obsessive thoughts and repetitive compulsive actions, such as cleaning, checking, or counting.

Obstructive jaundice jaundice related to extrahepatic or intrahepatic obstruction.

Obstructive pulmonary disease airway obstruction that is worse with expiration so that more force or more time is required to expire a given volume of air and emptying of the lungs is slowed; characterized by shortness of breath (dyspnea) and wheezing.

Obstructive sleep apnea syndrome (OSAS) a disorder of sleep characterized by airway obstruction and episodes of apnea accompanied by snoring.

Obstructive uropathy the blockage of urine flow, often by ureteral or kidney stones, resulting in the reflux of urine and subsequent injury to kidneys.

Onychomycosis a fungal infection of the fingernails or toenails that causes thickening, roughness, and splitting of the nails.

Oophoritis inflammation of the ovaries.

Open pneumothorax (communicating pneumothorax) see Pneumothorax.

Optic glioma tumor originating from glial cells in the brain that affects the optic nerve; commonly seen in children with neurofibromatosis.

Organic brain syndrome a constellation of physical brain disorders with psychologic or behavioral signs and symptoms and grouped according to symptoms rather than etiology.

Orthopnea shortness of breath (dyspnea) that occurs when an individual lies flat and is common in individuals with heart failure.

Orthostatic (postural) hypotension a sudden drop in blood pressure when a person assumes a standing position, resulting in dizziness, lightheadedness, blurred vision, and temporary loss of consciousness.

Osmotic diarrhea nonabsorbable substance in the intestine draws water into the lumen by osmosis, resulting in large-volume diarrhea; caused by drinking solutions with excessive sugars, salt, or vitamin C; maldigestion syndromes.

Osteoarthritis (OA) inflammatory degenerative joint disease in which synthesis and degradation of the articular cartilage in the movable joints are altered, resulting in wearing and destruction of cartilage.

Osteochondrosis (Osgood-Schlatter disease) a condition in children that results from the tendons pulling on the epiphysis of long bones, causing pain just below the knee, irritation and swelling, and possibly abnormal bone growth.

Osteogenesis imperfecta (brittle bone disease) a genetic disease in which collagen production is deficient, making the bones abnormally fragile and causing recurring fractures with only minimal trauma, deformity of long bones, a bluish coloration of the sclerae, and often the development of otosclerosis.

Osteoid osteoma a benign tumor in one of the bones of the lower extremities that is painful and is characterized by vascularized connective tissue and osteoid material that is surrounded by a large zone of thickened bone.

Osteomalacia a disease in which vitamin D or calcium deficiency or excessive renal phosphate loss causes a softening of the bones with accompanying pain and weakness.

Osteomyelitis a bacterial infection of the bone and bone marrow that occurs through open fractures, penetrating wounds, surgical operations, or by infiltration of the bloodstream; causes pain, high fever, and formation of an abscess at the site of infection.

Osteoporosis a disease in which the bones become porous and weakened, making them easily fracture and slow to heal.

Overactive bladder syndrome (OAB) a chronic syndrome of overactivity of the detrusor muscle; characterized by urgency with involuntary detrusor contractions during the bladder filling phase.

Oxygen toxicity an iatrogenic inflammatory condition caused by prolonged exposure to high concentrations of supplemental oxygen resulting from damage to alveolocapillary membranes, disruption of surfactant production, and interstitial and alveolar edema; caused by oxygen free radicals.

Paget disease (osteitis deformans) a bone disorder in which excessive bone remodeling causes enlarged, deformed bones that can weaken the bone integrity and result in bone pain, arthritis, deformities, or fractures.

Painful bladder syndrome/interstitial cystitis (PBS/IC) (see Cystitis) a condition occurring in women ages 20 to 40 years who have symptoms of cystitis, such as frequency, urgency, dysuria, and nocturia, for more than 6 weeks duration; usually related to bacterial infection.

- **Nonbacterial infectious cystitis** cystitis with negative urine cultures and no other known etiology; most common in immunocompromised individuals and related to viral, mycobacterial, chlamydial, or fungal infection.
- **Noninfectious cystitis** cystitis without evidence of infection; usually autoimmune or related to exposure to radiation or chemotherapy treatment for pelvic or urogenital cancers.

Panacinar emphysema see Emphysema.

Pancreatic insufficiency a condition in which the pancreas does not secrete enough hormones and digestive enzymes for normal digestion to occur, resulting in malabsorption, malnutrition, vitamin deficiencies, and weight loss.

Pancreatitis inflammation of the pancreas, usually resulting in abdominal pain.

Panhypopituitarism a condition in which the secretion of all anterior pituitary hormones is inadequate or absent; caused by a variety of disorders that result in destruction or loss of function of all or most of the anterior pituitary gland.

Panic disorder a psychologic disorder that is characterized by recurrent attacks of anxiety or terror and usually results in the development of one or more phobias.

Papulosquamous disorder collective reference to inflammatory disorders characterized by papules, scales, plaques, and erythema, including psoriasis, pityriasis rosea, and lichen planus.

Paraesophageal hiatal hernia herniation of the greater curvature of the stomach through a secondary opening in the diaphragm.

Paraneoplastic pemphigus see Pemphigus.

Paraphimosis a condition in which the foreskin becomes trapped behind the glans penis and cannot return to its normal flaccid position covering the glans penis.

Parkinson disease degeneration of the basal ganglia dopaminergic nigrostriatal pathway that causes hypokinesia, tremor, and muscular rigidity.

Parkinsonism (Parkinson syndrome, parkinsonian syndrome) a neurologic condition characterized by tremors, rigidity, hypokinesia, and postural instability as a result of degeneration of the corpus striatum or substantia nigra caused by Parkinson disease and other conditions related to toxins or metabolic conditions.

Paroxysmal nocturnal dyspnea (PND) attacks of breathing discomfort, shortness of breath, and coughing that occur at night with varying intensity so that individuals must sit up or stand to relieve dyspnea; may occur in individuals with heart failure or lung disease.

Partial obstruction of the bladder outlet or urethra partial obstruction related to deposition of collagen within the smooth muscle bundles of the detrusor muscle; causes an increase in the force of detrusor contraction.

Partial precocious puberty the partial development of appropriate secondary sex characteristics alone or in combination.

Pediculosis pubis a contagious condition, also known as crabs or crab lice, that is an infestation of the pubic hair in which the louse feeds on human blood and multiplies rapidly.

Pelvic inflammatory disease (PID) inflammation of the female genital tract caused by microorganisms, typically those that are sexually transmitted such as chlamydia and gonococci; characterized by severe abdominal pain, high fever, vaginal discharge, and possibly infertility.

Pelvic organ prolapse (POP) bladder outlet obstruction in women caused most commonly by a cystocele (the downward protrusion of the bladder into the vagina) that descends below the level of the urethral outlet.

Pemphigus a group of autoimmune skin diseases marked by groups of itching blisters and raw sores on the skin and mucous membranes.

Paraneoplastic pemphigus the most severe form of pemphigus; is associated with lymphoproliferative neoplasms and affects internal organs, including lungs, thyroid, kidney, smooth muscle, and gastrointestinal tract.

Pemphigus foliaceus a milder form of pemphigus involving loss of cell-to-cell adhesion (acantholysis) at the subcorneal level with blistering, erosions, scaling, crusting, and erythema usually of the face and chest.

Pemphigus vulgaris the most common form of pemphigus with acantholysis at the suprabasal level and initiated by IgG autoantibodies against the desmoglein adhesion molecules, resulting in acantholysis in the epidermis with fluid accumulation and blister formation; oral lesions precede the onset of skin blistering.

Pericarditis the pericardium is infected by a virus, bacteria, parasite, or fungus and becomes inflamed, resulting in pain and fluid and blood components entering into the pericardial space.

Perihepatitis (Fitz-Hugh–Curtis syndrome) a complication of pelvic inflammatory disease secondary to gonococci bacteria traveling up the peritoneum to the upper abdomen and causing inflammation.

Periodic paralysis one of a group of diseases in which muscular weakness or flaccid paralysis occurs without loss of consciousness, speech, or sensation.

Peripheral artery disease (PAD) any of a group of diseases caused by the obstruction of large peripheral arteries secondary to atherosclerosis, inflammatory processes, embolism, or thrombus formation that causes ischemia.

Pernicious anemia see Anemia.

Pes planus (flatfoot) a condition in which the arch of the foot never develops or it collapses and contacts the ground.

Peyronie disease (bent nail syndrome) a condition in which fibrous plaques grow in the soft tissue of the penis because of injury of the internal cavity of the penis that is accompanied by bleeding and scar tissue formation at the tunica albuginea of the corpora cavernosa.

Phagocytic deficiency see Immune deficiency.

Phenylketonuria (PKU) a genetic disorder in which the body lacks the enzyme necessary to metabolize the amino acid phenylalanine to tyrosine, resulting in accumulation of phenylalanine and subsequent brain damage and progressive mental retardation.

Pheochromocytoma a tumor of the adrenal medulla that causes the chromaffin cells to secrete increased amounts of epinephrine or norepinephrine.

Phimosis the foreskin of the penis of an uncircumcised male cannot be fully retracted.

Pick disease progressive atrophy of the cerebral convolutions in a limited area (lobe) of the brain, with clinical manifestations and course similar to those of Alzheimer disease.

Pityriasis rosea a skin disorder, thought to be caused by a virus, in which patches of ovular pink rash appear primarily on the trunk and extremities.

Plaque psoriasis see Psoriasis.

Pneumoconiosis a chronic disease of the lungs typically seen in miners, sandblasters, and metal grinders that is caused by repeated inhalation of dust particles, including iron oxides, silicates, and carbonates, that collect in the lungs and become sites for the formation of fibrous nodules that eventually replace lung tissue.

Pneumonia an infection of one or both lungs caused by a bacterium, virus, fungus, or other organism that enters the body through respiratory passages and causes high fever, chills, chest pain, difficulty breathing, cough with sputum, and possibly bluish skin from insufficiently oxygenated blood.

Pneumothorax the collapse of a lung and subsequent escape of air into the pleural cavity between the lung and the chest wall that is caused by trauma, environmental factors, or spontaneous occurrence and results in a sudden pain in the chest.

Iatrogenic pneumothorax the presence of air or gas in the pleural space caused by a rupture in the visceral pleura (which surrounds the lungs) or the parietal pleura and chest wall; is most commonly caused by transthoracic needle aspiration.

Open pneumothorax (communicating pneumothorax) spontaneous and traumatic pneumothorax in which air pressure in the pleural space equals barometric pressure because air that is drawn into the pleural space during inspiration (through the damaged chest wall and parietal pleura or through the lungs and damaged visceral pleura) is forced out during expiration.

Primary (spontaneous) pneumothorax occurs unexpectedly in healthy individuals (usually men) between ages 20 and 40 years; is most often caused by the spontaneous rupture of blebs on the visceral pleura.

Secondary (traumatic) pneumothorax spontaneous or secondary pneumothorax beginning with sudden pleural pain, tachypnea, and possibly mild dyspnea.

Tension pneumothorax the site of pleural rupture acts as a one-way valve, permitting air to enter on inspiration, but preventing its escape by closing during expiration and leading to air pressure in the pneumothorax exceeding barometric pressure.

Polycystic ovary syndrome (PCOS) a hormonal condition in which multiple ovarian cysts form because of elevated levels of androgens, resulting in hirsutism, obesity, menstrual abnormalities, infertility, and enlarged ovaries.

Polycythemia vera a chronic, progressive disease that is characterized by overgrowth of the bone marrow, excessive red blood cell production, and an enlarged spleen and causes headache, inability to concentrate, and pain in the fingers and toes.

Pompe disease see Acid maltase disease.

Port-wine (nevus flammeus) stain a birthmark caused by superficial and deep dilated

capillaries in the skin that produce a reddish to purplish discoloration of the skin, usually on the face, but can occur anywhere on the body.

Postconcussive syndrome physical and personality changes that may occur after concussion of the brain, including amnesia, headache, dizziness, tinnitus, irritability, fatigability, sweating, heart palpitations, insomnia, and difficulty concentrating.

Posthemorrhagic anemia see Anemia.

Postobstructive pulmonary edema (POPE) (negative pressure pulmonary edema) a rare life-threatening complication that can occur after relief of upper airway obstruction (e.g., postextubation laryngospasm after anesthesia induction, epiglottitis, laryngeal tumor, or obstructive tonsils).

Postrenal acute kidney injury rare complication of urinary tract obstruction that affects the kidneys bilaterally (e.g., bilateral ureteral obstruction, bladder outlet obstruction–prostatic hypertrophy, tumors or neurogenic bladder, and urethral obstruction); obstruction causes an increase in intraluminal pressure upstream from the site of obstruction.

Post-thrombotic syndrome (PTS) a syndrome that follows a vascular thrombosis, such as persistent edema.

Posttraumatic stress disorder (PTSD) a psychologic disorder that may develop in individuals who have experienced or witnessed traumatic events; is characterized by recurrent flashbacks of the traumatic event, nightmares, irritability, anxiety, fatigue, forgetfulness, and social withdrawal.

Potter syndrome a syndrome of renal agenesis with hypoplastic lungs and associated neonatal respiratory distress, hemodynamic instability, acidosis, cyanosis, edema, and characteristic (Potter) facies; death usually occurs from respiratory insufficiency, which develops before uremia.

Poverty of content a disorder, also called poverty of speech content, that is characterized by disorganized speech that conveys little information and may be vague or contain repetitive or obscure phrases.

Prader-Willi syndrome a rare genetic disorder caused by gene deletions on paternal chromosome 15 that result in short stature, hypotonia, small hands and feet, obesity, mild to moderate mental retardation, and hypogonadism.

Precocious puberty a condition in which a boy or girl undergoes the changes associated with puberty at an unexpectedly early age; often caused by a pathologic process that increases the secretion of estrogens or androgens.

Premenstrual dysphoric disorder (PMDD) recurrence in the luteal phase of the menstrual cycle of distressing physical, psychologic, or behavioral changes that impair interpersonal relationships or interfere with usual activities.

Premenstrual syndrome (PMS) a group of symptoms that occur in many women from 2 to 14 days before menstruation begins, including abdominal bloating, breast tenderness, headache, fatigue, irritability, depression, and emotional distress.

Prerenal acute kidney injury rapid development of renal hypoperfusion with elevation of serum creatinine and urea levels.

Presbyopia a form of farsightedness usually accompanying advanced age in which the lens loses elasticity and becomes unable to accommodate and focus light for near vision.

Priapism a painful condition in which the erect penis maintains an erection in the absence of physical and psychologic stimulation.

Primary accidental hypothermia unintentional drop in core body temperature below 35° C (95° F) of a previously healthy person attributable to the changes that occur with cold temperatures.

Primary adrenal insufficiency (Addison disease) adrenal hypofunction resulting in bronzelike pigmentation of the skin, severe prostration, progressive anemia, low blood pressure, diarrhea, and digestive disturbance.

Primary amenorrhea continued absence of menarche and menstrual function by 14 years of age without the development of secondary sex characteristics or by age 16 years if these changes have occurred.

Primary biliary cirrhosis see Cirrhosis.

Primary (congenital) immune deficiency see Immune deficiency.

Primary dysmenorrhea painful menstruation because of a functional disturbance rather than because of inflammation, growths, or anatomic factors.

Primary gout acute episodes of urate crystal–induced synovitis resulting from abnormality of purine metabolism; lower-than-normal urinary excretion of urate leads to hyperuricemia and acute episodes of joint inflammation.

Primary hyperaldosteronism (Conn disease, primary aldosteronism) an adrenocortical disorder caused by excessive secretion of aldosterone and characterized by headaches, nocturia, polyuria, fatigue, hypertension, potassium depletion, hypokalemic alkalosis, hypervolemia, and decreased plasma renin activity; may be associated with small benign adrenocortical adenomas.

Primary hyperparathyroidism usually the result of a benign parathyroid tumor that secretes parathyroid hormone and increases circulating calcium levels; this condition is accompanied by hypercalcemia, nausea, vomiting, lethargy, depression, muscular weakness, and an altered mental state.

Primary hypertension (essential hypertension, idiopathic hypertension) elevated blood pressure of unknown etiology accompanied by increased total peripheral vascular resistance by vasoconstriction, increased cardiac output, or both.

Primary multiple organ dysfunction syndrome (MODS) multiple organ injury directly associated with a specific insult, most often ischemia or impaired perfusion from an episode of shock or trauma, thermal injury, soft tissue necrosis, or invasive infection with decreased local perfusion in the injured organs.

Primary (spontaneous) pneumothorax see Pneumothorax.

Primary syphilis a stage of syphilis infection that occurs after an incubation period of 10 to 90 days and is characterized by a primary sore or chancre that develops at the point of initial exposure and lasts 4 to 6 weeks.

Prinzmetal angina a form of angina pectoris characterized by pain that is not precipitated by cardiac work; it is of longer duration and usually more severe, and is associated with unusual electrocardiographic results including elevated ST segments.

Progressive bulbar palsy (see Bulbar palsy) a slowly progressive neurodegenerative disorder of the motor neurons of the cerebral cortex, spinal cord, and brainstem, resulting in progressive symptoms of bulbar palsy that may advance to loss of ability to manipulate food in the mouth, inability to swallow, choking, and emotional changes; may lead to aspiration of food and fluid and death from pneumonia.

Progressive spinal muscular atrophy a progressive degenerative disorder of the motor neurons of the spinal cord causing muscular weakness and wasting, typically beginning in the distal portions of the limbs and spreading proximally.

Prolactinoma the most common type of anterior pituitary tumor; produces visual disturbances and prolactin excess that results in infertility and changes in menstruation in females and impotence, loss of libido, and infertility in males.

Properdin deficiency see Immune deficiency.

Prostatitis inflammation of the prostate gland caused by urinary tract infection.

Protein C deficiency a disorder characterized by a lack of anticoagulant activity and an increased tendency to form blood clots because of decreased degradation of factor Va and factor VIIIa secondary to thrombosis, deep vein thrombosis, pulmonary embolism, thrombophlebitis, neonatal purpura fulminans, and disseminated intravascular coagulation.

Protein S deficiency a disorder characterized by a lack of anticoagulant activity and an increased tendency to form blood clots because of decreased degradation of factor Va and factor VIIIa.

Pseudothrombocytopenia see Thrombocytopenia.

Psoriasis a noncontagious autoimmune skin disorder in which the skin becomes scaly and inflamed when cells in the outer layer of skin reproduce faster than normal and accumulate as plaques on the skin surface.

- **Erythrodermic (exfoliative) psoriasis** widespread red, scaling lesions that cover a large body surface area; often accompanied by itching or pain associated with constitutional symptoms (fever, chills, fatigue) and skin infections.
- **Guttate psoriasis** sudden appearance of small papules on the trunk and extremities, occasionally after a streptococcal respiratory tract infection in children.
- **Inverse psoriasis** rare development of large, smooth, dry, and deep red lesions in skinfolds (i.e., axilla or groin).

Plaque psoriasis most common form of psoriasis; begins with well-demarcated, thick, silvery, scaly erythematosus inflammatory lesions with epidermal hyperproliferation and the presence of activated T lymphocytes that may become mild, moderate, or severe, depending on the size, distribution, and inflammation of the lesions.

Pustular psoriasis blisters of noninfectious pus that develop over areas of plaque psoriasis.

Pulmonary artery hypertension (PAH) increased blood pressure in the pulmonary artery attributable to vasoconstriction that may eventually lead to fibrosis, increased workload, hypertrophy of the right ventricle, and right heart failure; etiology may be idiopathic, familial, or associated with other diseases.

Pulmonary embolism (PE) dislodgement of a blood clot from its site of origin and embolization to the arterial blood supply of one of the lungs, resulting in shortness of breath and difficulty breathing, rapid breathing that is painful, cough, and (in severe cases) hypotension, shock, loss of consciousness, and death.

Pulmonary stenosis a condition in which the opening into the pulmonary artery from the right ventricle narrows.

Pure red cell aplasia (PRCA) an acquired or congenital condition in which the bone marrow lacks red blood cell precursors even though megakaryocytes and white blood cell precursors are usually present at normal levels.

Purine nucleoside phosphorylase (PNP) deficiency see Immune deficiency.

Pustular psoriasis see Psoriasis.

Pyloric stenosis a congenital abnormality in which the pylorus is narrow, resulting in poor feeding, weight loss, and progressively worsening vomiting.

Pyramidal/spastic cerebral palsy palsy resulting from damage or defects in the brain's corticospinal pathways (upper motor neuron) in either one or both hemispheres.

Qualitative leukocyte disorder see Immune deficiency.

Quantitative leukocyte disorder see Immune deficiency.

RAG-1/RAG-2 deficiencies see Immune deficiency.

Rapidly progressive (crescentic) glomerulonephritis (RPGN) see Glomerulonephritis.

Raynaud disease a condition in which the blood vessels spasm because of inadequate blood supply, resulting in discoloration of the fingers and/or toes after exposure to changes in temperature or emotional events.

Rectocele a condition caused by childbirth or hysterectomy in which the region between the rectum and vagina bulges toward the vagina, resulting in a sense of pressure or protrusion within the vagina, the feeling of incomplete emptying of the rectum, difficulty passing stool, discomfort or pain during evacuation or intercourse, constipation, vaginal bleeding, fecal incontinence, prolapse of the bulge through the opening of the vagina, or rectal prolapse through the anus.

Refeeding syndrome metabolic disturbances that occur upon initiating parenteral or enteral nutritional therapy to individuals who are severely malnourished; starvation results in movement of phosphate, magnesium, and potassium ions out of the cells and into the plasma and refeeding increases insulin levels and stimulates movement of glucose and these ions back into the cells, resulting in dangerously low levels in the plasma (hypophosphatemia, hypomagnesemia, hypokalemia, hyponatremia, hypocalcemia, and vitamin deficiency) and other potentially fatal metabolic complications.

Relative polycythemia a relative increase in the number of red blood cells caused by loss of the fluid portion of the blood.

Renal agenesis only one functional kidney is present at birth.

Renal dysplasia abnormal tissue development in one or both kidneys.

Respiratory distress syndrome (RDS) of the newborn a condition, also known as hyaline membrane disease (HMD), that is a type of respiratory distress in newborns, most often in prematurely born infants, those born by cesarean section, or those having a diabetic mother; the immature lungs do not produce enough surfactant to retain air so the air spaces empty completely and collapse after exhalation.

Reticular dysgenesis see Immune deficiency.

Retinoblastoma an autosomal dominant or sporadic disorder in which a malignant tumor forms in the retina of one or both eyes; typically found in infants.

Reversible sideroblastic anemia see Anemia.

Rhabdomyolysis a potentially fatal condition in which skeletal muscle breaks down as a result of injury such as physical damage to the muscle, high fever, metabolic disorders, excessive exertion, convulsions, or anoxia of the muscle for several hours; large amounts of myoglobin are usually excreted.

Rheumatic fever an inflammatory disease that is associated with recent streptococcal infection and causes inflammation of the joints, fever, jerky movements, nodules under the skin, and skin rash and often is followed by serious heart damage or disease secondary to antibodies that react both with streptococcal antigens and with those of the heart valve.

Rheumatic heart disease (RHD) sequela to rheumatic fever in which heart valves are repeatedly inflamed, developing fibrosis and thickening that can result in valve deformities, stenosis, or regurgitation.

Rheumatoid arthritis an autoimmune disease that causes chronic inflammation of the joints and the tissue around the joints and other organs.

Rickets a bone disease that is caused by a deficiency of vitamin D or calcium and manifests in children as softening of bones, abnormal growth of bones, and enlargement of cartilage at the ends of long bones.

Ringed sideroblast an erythroblast in which one third or more of the nucleus is encircled by 10 or more siderotic granules that may be caused by antituberculous drugs and alcohol abuse.

Roseola a viral disease in infants and young children that causes fever and a spotty rash that appears shortly after the fever has subsided.

Rotavirus a viral infection seen in young children that causes diarrhea by attacking the lining of the small intestine, resulting in the inability to absorb fluid and electrolytes.

Rubella an infectious viral disease of children and young adults that is spread by a droplet spray from the respiratory tract of an infected individual; the disease causes a rash that lasts about 3 days with tender and swollen lymph nodes behind the ears.

Rubeola an infectious viral disease of young children, also known as measles, that is spread by a droplet spray from the nose, mouth, and throat of individuals in the infective stage and causes a rash, white spots in the mouth, a rash on the face that spreads to the rest of the body, and fever.

Russell-Silver syndrome (Russell-Silver dwarfism) a growth disorder manifesting as retardation, proportionate short stature, leg length discrepancy, and a small, triangular-shaped face.

Saccular aneurysm (berry aneurysm) a localized, progressively growing sac that affects only a portion of the circumference of the arterial wall and may be the result of congenital anomalies or degeneration.

Saccular bronchiectasis (see Bronchiectasis) bronchiectasis resulting in dilated bronchi that become balloon-like.

Salmon patches (nevus simplex) patches, also known as stork bites, of small, pink, flat spots that are small dilated blood vessels visible through the skin and are usually found on the forehead, eyelids, and upper lip; between the eyebrows; and on the back of the neck.

Salpingitis inflammation of one of the two fallopian tubes caused by infection spreading from the vagina or uterus.

Sarcoma tumor of the connective tissue cells.

Scabies skin infestation with the itch mite, *Sarcoptes scabiei,* acquired through close contact with an infected person or contaminated clothing that produces intense itching.

Schizophrenia a psychotic disorder characterized by delusions, hallucinations, loosening of associations, disturbances in mood and sense of self and relationship to the external world, and bizarre, purposeless behavior.

Sclerosing adenosis a condition in which the number of acini per terminal duct is more than twice the number of normal terminal ducts and is associated with a significantly increased risk of subsequent breast carcinoma.

Scoliosis a condition in which the spine is curved sideways to varying degrees; occurs because of either physiologic curvature or functional curvature in which contraction of the paraspinal muscles of the back creates a vertebral curve.

Seborrheic dermatitis scaly, flaky, itchy, and red skin on the scalp, face, and trunk because of a yeast infection.

Seborrheic keratosis a benign proliferation of cutaneous basal cells that produces smooth or

warty elevated lesions; seen primarily in older people and presents as multiple lesions on the chest, back, and face.

Secondary (acquired) immune deficiency see Immune deficiency.

Secondary amenorrhea menstruation begins at puberty but then is subsequently suppressed for three or more cycles or for 6 months in women who previously menstruated.

Secondary dysmenorrhea altered menstruation because of inflammation, infection, tumor, or anatomic factors.

Secondary generalization the process by which a simple partial seizure involving one hemisphere becomes a generalized seizure involving the second hemisphere.

Secondary hyperparathyroidism a condition of elevated levels of parathyroid hormone resulting from disease such as renal failure in which parathyroid hormone concentration is elevated in response to vitamin D deficiency.

Secondary hypertension a condition of elevated blood pressure that is associated with other conditions, primarily with renal disease by a renin-dependent mechanism or a fluid volume–dependent mechanism.

Secondary hypothermia depressed body temperature as a consequence of a serious systemic disorder, for example, endocrine disorders.

Secondary MODS the result of an excessive inflammatory reaction, after a latent period following the initial injury, in organs distant from the site of the original injury. It is postulated that the resulting organ trauma is caused by the host response to a second insult rather than being a direct result of the primary injury.

Secondary (traumatic) pneumothorax see Pneumothorax.

Secondary septic arthritis a bacterial infection in the joints, causing them to become inflamed and the bacteria to proliferate.

Secondary syphilis the most contagious stage of syphilis infection; characterized by a skin rash that appears on the trunk and extremities 1 to 6 months after the primary infection and possibly mucous patches on the genitals or inside the mouth.

Selective IgA deficiency see Immune deficiency.

Septic shock a condition caused by systemic infection that results in decreased tissue perfusion and oxygenation and can lead to multiple organ dysfunction syndrome and death.

Serum sickness a form of hypersensitivity caused by injection of soluble antigen such as antiserum, which activates a type III hypersensitivity response (formation of soluble circulating antigen-antibody [IgG or IgM] complexes) that activates the complement system.

Severe combined immune deficiency (SCID) see Immune deficiency.

Severe congenital neutropenia see Immune deficiency.

Shock a condition in which the circulatory system is unable to provide adequate circulation to the body tissues because of inadequate pumping by the heart, a reduction in blood volume, or a reduction in blood pressure; it results in slowing of vital functions and possibly death.

Short bowel syndrome a group of malabsorption conditions resulting from massive resection of the small bowel, the degree and kind of malabsorption depending on the site and extent of the resection; it is characterized by diarrhea, steatorrhea, and malnutrition.

Sickle cell anemia see Anemia.

Sickle cell disease (SCD) see Anemia.

Sickle cell–Hb C disease see Anemia.

Sickle cell–thalassemia disease see Anemia.

Sickle cell trait see Anemia.

Sideroblastic anemia (SA) see Anemia.

Silicosis inflammation of the lung resulting from the inhalation of free silica (silicon dioxide) and silica-containing compounds, which occurs in mining and related industries.

Simple febrile seizure benign and most common form of childhood seizure.

Simple fibroadenoma benign solid tumors composed of both fibrous and glandular tissue.

Sliding hiatal hernia the most common type of hernia, occurring when the proximal portion of the stomach moves into the thoracic cavity through the esophageal hiatus, an opening in the diaphragm for the esophagus and vagus nerves.

Small cell lung carcinoma (SCLS) the most common type of neuroendocrine lung tumors and mostly arise from the central part of the lung.

Smallpox (variola) an infectious viral disease that is caused by a poxvirus and result in high fever, aches, and widespread eruption of large sores that leave scars.

Smoldering myeloma a condition in which abnormal plasma cells produce a monoclonal protein, but no symptoms or complications of myeloma are present and may not be present for several years.

Solitary plasmacytoma a solitary tumor of malignant plasma cells that may result in a single lytic bone lesion or may be in the tissues (extramedullary plasmacytoma).

Spina bifida occulta the mildest form of congenital disorder of incomplete closure of the embryonic neural tube; the outer part of some vertebrae may not be completely closed, but the defect is not apparent to the unaided eye and usually causes no serious neurologic dysfunctions.

Spinal stenosis narrowing of the spinal canal as a result of congenital anomaly or spinal degeneration, resulting in pain, paresthesias, and neurogenic claudication.

Spondylolisthesis forward displacement of one of the lower lumbar vertebrae over the vertebra below it or over the sacrum.

Squamous cell carcinoma (SCC) a tumor of the epidermis and the second most common human cancer.

Stable angina a condition in which ischemic attacks occur at predictable frequencies and duration after activities that increase myocardial oxygen demands such as exercise and stress.

Staphylococcal scalded-skin syndrome (SSSS) a disease in infants that is caused by a staphylococcal infection with release of an exfoliative toxin that results in peeling of large areas of skin.

Stevens-Johnson syndrome an inflammatory eruption of circular lesions that can cover the majority of the skin and mucous membranes and usually occurs after a respiratory tract infection or as an allergic reaction to drugs or other substances.

Strawberry hemangioma a red birthmark caused by densely packed blood vessels that usually appears on the face, scalp, back, and chest and disappears during childhood.

Stress ulcer acute peptic ulcer that occurs in association with various other pathologic conditions, including burns, cor pulmonale, intracranial lesions, and surgical operations.

Structural scoliosis a side-to-side curvature of the spine.

Subacute thyroiditis (subacute granulomatous thyroiditis, de Quervian thyroiditis) a painful inflammation of the thyroid that develops suddenly in a patient who has had a viral infection, such as mumps or an upper respiratory tract illness. Pain radiates throughout the neck and patients feel ill and feverish.

Subglottic stenosis narrowing of the airway below the larynx caused by a congenital anomaly or acquired narrowing secondary to injury, possibly resulting in respiratory distress, cyanotic episodes, or recurrent lung infections.

Sudden infant death syndrome (SIDS) a syndrome, also known as crib death, that is characterized by the sudden, unexpected, and unexplained death of an apparently healthy infant less than 1 year of age.

Superior vena cava syndrome (SVCS) restriction of the blood flow through the superior vena cava secondary to compression by malignancies or lymphadenopathy.

Sydenham chorea (St. Vitus dance) a postinfectious chorea appearing several months after a streptococcal infection with subsequent rheumatic fever. The chorea typically involves the distal limbs and is associated with hypotonia and emotional lability.

Symphysis fibrocartilaginous joint; a type of joint in which the apposed bony surfaces are firmly united by a plate of fibrocartilage.

Synchondrosis a cartilaginous joint creating a union between two immovable bones, such as the synchondroses of the cranium, the pubic symphysis, the sternum, and the manubrium.

Syndesmosis a fibrous union in which two bones are connected by interosseous ligaments, such as the anterior and the posterior ligaments in the radioulnar and tibiofibular articulations; is usually converted into bone before adult life.

Syndrome of inappropriate antidiuretic hormone (ADH) secretion (SIADH) a condition in which the release of ADH from the posterior pituitary is elevated relative to serum sodium levels, resulting in increased water reabsorption by the kidneys and fluid overload.

Syndromic craniosynostosis (see Craniosynostosis) synostosis that occurs as part of a genetic syndrome; usually associated with various dysmorphisms involving the face, skeleton, and nervous system and usually accompanied by developmental delay.

Syphilis a chronic infectious disease that is transmitted by direct contact, usually in sexual intercourse, or passed from mother to child in utero, and progresses through three stages characterized by chancres, ulcerous skin eruptions, and systemic infection that leads to damage to the cardiovascular and nervous systems.

Systemic inflammatory response syndrome (SIRS) a generalized inflammatory response that may lead to depressed cardiac function and decreased organ perfusion.

Systemic lupus erythematosus (SLE) (see Lupus erythematosus) a chronic, multisystem, inflammatory disease and one of the most common, complex, and serious of the autoimmune disorders.

Systolic heart failure a condition in which the heart muscle contracts so weakly that insufficient oxygenated blood is pumped throughout the body.

Tay-Sachs disease (GM2 gangliosidosis) a fatal autosomal recessive lysosomal storage disorder in which the lysosomal enzyme hexosaminidase A (HexA) is deficient, leading to accumulation of gangliosides in the brain and nerve tissue, mental retardation, convulsions, blindness, and premature death.

T-cell neoplasm see Lymphoma.

Tension pneumothorax see Pneumothorax.

Tertiary syphilis the most severe stage of syphilis, which can begin as early as 1 year after the initial infection but can take up to 10 years to manifest and is characterized by gummas—soft, tumor-like growths found in the skin and mucous membranes and often in the skeleton—joint deformity, neurosyphilis, and cardiovascular syphilis.

Tethered cord syndrome a group of neurologic disorders related to malformation of the spinal cord in which the cord becomes abnormally attached or tethered as a result of scar tissue that develops as the cord transcends the vertebral canal with growth; tethering may decrease blood flow.

Tetralogy of Fallot a congenital condition that is characterized by four malformations including ventricular septal defect, misplacement of the origin of the aorta, narrowing of the pulmonary artery, and enlargement of the right ventricle.

Thalassemia see Anemia.

Thromboangiitis obliterans (Buerger disease) inflammation of the medium-sized arteries and veins because of thrombotic occlusion, resulting in ischemia and gangrene.

Thrombocythemia a chronic disorder of sustained megakaryocyte proliferation that increases the number of circulating platelets and results in megakaryocytic hyperplasia, splenomegaly, and complications by hemorrhagic and thrombotic episodes.

Thrombocytopenia a reduced number of circulating platelets.

- **Acute idiopathic thrombotic thrombocytopenic purpura** a form of TTP characterized by thrombotic microangiopathy in which platelets aggregate and cause occlusion of arterioles and capillaries within the microcirculation, leading to increased platelet consumption and organ ischemia.
- **Autoimmune neonatal thrombocytopenia** destruction of platelets in a fetus/neonate by antiplatelet antibodies produced in the mother against her own platelet antigens (autoimmune) that are shared with the child, and the antibodies are transported across the placenta and destroy the child's platelets.
- **Chronic relapsing thrombotic thrombocytopenic purpura** a rare familial form of TTP characterized by recurring episodes of thrombocytopenia; usually seen in children.
- **Heparin-induced thrombocytopenia (HIT)** a form of drug-induced thrombocytopenia caused by IgG antibodies against the heparin–platelet factor 4 complex leading to platelet activation and thrombocytopenia.
- **Idiopathic thrombocytopenic purpura (ITP) (autoimmune or primary thrombocytopenic purpura)** the most common cause of thrombocytopenia, secondary to increased immune-mediated platelet destruction; can be acute or chronic.
- **Immune thrombocytopenic purpura (ITP)** a condition in which the number of platelets in the blood is reduced by the production of antibodies against platelets, resulting in ecchymoses and hemorrhages from mucous membranes, anemia, and extreme weakness.
- **Neonatal alloimmune thrombocytopenic purpura (NATP)** a condition in which fetal platelets have an antigen from the father that is absent in the mother, and the mother forms antibodies that cross the placenta and destroy the fetal platelets.
- **Pseudothrombocytopenia** an artificially low platelet count in anticoagulated blood caused by cooling of the blood and autoagglutination of platelets.
- **Thrombotic thrombocytopenic purpura (TTP)** altered blood coagulation caused by an enzymatic deficiency that is characterized by a reduced number of platelets in the blood, the formation of blood clots in tissue arterioles and capillaries, and neurologic damage.

Thrombophilia genetic or acquired abnormality of the coagulation system with an increased risk for thrombosis.

Thrombotic thrombocytopenic purpura (TTP) see Thrombocytopenia.

Thrush a yeast infection of the mouth and throat that presents as creamy white curd-like patches on the tongue, inside the mouth, and on the back of the throat and that is commonly associated with yeast infection of the esophagus.

Thyrotoxicosis excessive concentrations of thyroid hormones in the body that are marked by increased metabolic rate, heat intolerance, goiter, reproductive disorders, excessive sweating, and other alterations in systemic function.

Tinea capitis fungal infections of the skin classified according to their location on the body.

Tinea corporis (ringworm) a fungal infection of the scalp; much more common in children than adults.

Tinea infection one of a group of fungal skin infections that include athlete's foot, folliculitis, jock itch, ringworm, and pityriasis versicolor.

Tinea pedis chronic, superficial fungal infection of the skin of the foot common in adults.

Tinea unguium a fungal infection of the nails.

Tinnitus hearing ringing, buzzing, or other sounds without an external cause.

T-lymphocyte deficiency see Immune deficiency.

Tophaceous gout a form of purine metabolism disorder characterized by formation of chalky deposits of sodium biurate under the skin and in the joints.

Toxic epidermal necrolysis (TEN) a rare adverse reaction to certain drugs in which a large portion of the skin becomes intensely red, may develop blisters, and peels off.

Tracheomalacia (tracheobronchomalacia) a congenital or acquired condition characterized by weakness of the tracheal support cartilage, resulting in tracheal collapse when increased airflow is needed.

Trachoma (granular conjunctivitis or Egyptian ophthalmia) a contagious, chronic inflammation of the mucous membranes of the eyes, caused by *Chlamydia trachomatis*.

Transcortical dysphasia (transcortical sensory dysphasia, mixed transcortical dysphasia, isolated speech center) a type of aphasia with poor comprehension, but fluent grammatically correct speech. Patients can communicate well and are capable of good repetition.

Transient hypogammaglobulinemia of infancy see Immune deficiency.

Transient ischemic attach (TIA) brief episode in which the brain receives insufficient blood supply; symptoms depend on the site of the blockage.

Transposition of the great arteries (TGAs) the aorta arises from the right ventricle and the pulmonary artery arises from the left ventricle.

Traumatic (dissecting) aneurysm aneurysm caused by weakening of arterial walls, by a penetrating missile, or after neurosurgery or neuroimaging following an injury.

Trichomoniasis a sexually transmitted bacterial infection of the urethra in males and vagina in females that can cause urinary tract infection and a painful, malodorous vaginitis in women and urethral and bladder infection in males.

Tricuspid atresia congenital absence of the tricuspid orifice, circulation being made possible by the presence of an atrial septal defect.

True aneurysm localized dilation of an artery with an expanded lumen lined by stretched remnants of the arterial wall.

Truncus arteriosus a congenital defect in which a large great vessel arises from a ventricular septal defect and does not divide into the aorta and pulmonary artery, resulting in one vessel carrying blood both to the body and to the lungs.

TSH deficiency a condition characterized by decreased or absent production of thyroid-stimulating hormone (TSH), resulting in a decline in thyroid hormone level and subsequent symptoms such as fatigue, cold intolerance, weakness, depression, muscle aches, weight gain, and constipation.

Tuberculosis (TB) an infectious disease of humans caused by *Mycobacterium tuberculosis* that results in the formation of tubercles on the lungs and other tissues of the body.

Tuberous sclerosis complex (TSC) an inherited disease caused by mutation of the hamartin and tuberin genes and resulting in malformation of the brain, retina, and viscera and development of epileptic seizures, mental retardation, and skin nodules on the face.

Turner syndrome gonadal dysgenesis with short stature, undifferentiated (streak) gonads, and variable abnormalities such as webbing of the neck, low posterior hair line, increased carrying angle of elbow, cubitus valgus, and cardiac defects. The genotype is XO (45, X) or X/XX or X/XXX mosaic. The phenotype is female.

Type 1 diabetes mellitus see Diabetes.

Type 2 diabetes mellitus see Diabetes.

Ulcerative colitis chronically inflamed and ulcerated mucosal and submucosal lining of the large intestine, resulting in abdominal pain, diarrhea, and rectal bleeding.

Unclassified epileptic seizure seizure disorders that do not fit neatly into a classified grouping. These seizures characteristically have a wide variety of abnormal clinical activity. Examples of this activity include rhythmic eye movements, chewing, and swimming movements. These activities are commonly seen in neonatal seizures.

Undifferentiated large cell anaplastic cancer a cancer of epithelial origin that has lost all evidence of differentiation and may have arisen from a stem cell.

Unilateral neglect syndrome hemiapraxia with failure to pay attention to bodily grooming and stimuli on one side but not the other; usually caused by a lesion in the central nervous system.

Unstable angina a condition in which unprovoked ischemic attacks occur at unpredictable frequencies and may increase in severity.

Uremia syndrome of renal failure resulting in elevated blood urea and creatinine levels.

Uremic syndrome a complex of symptoms resulting from the accumulation of urea and other nitrogenous compounds and toxins in the blood, leading to alterations in levels of fluid and electrolytes, metabolic acidosis, anemia, hyperphosphatemia, and hypocalcemia; symptoms include hypertension, anorexia, nausea, vomiting, diarrhea or constipation, malnutrition and weight loss, pruritus, edema, anemia, and neurologic, cardiovascular disease, and skeletal changes.

Ureterohydronephrosis dilation of both the ureter and the pelvicaliceal system.

Ureteropelvic junction (UPJ) obstruction an impediment to the drainage of urine from the kidney, usually attributable to partial or intermittent blockage of the renal collecting system at the junction of the renal pelvis and ureter.

Urethral atresia congenital absence or closure of a normal body opening or tubular structure; congenital imperforation of the urethra.

Urothelial (transitional cell) carcinoma the most common bladder malignancy, appearing on the inner lining of the bladder.

Usual ductal hyperplasia (UDH) description of normal hyperplasia of cells that line the ducts in the normal breast; additional layers of benign cells are present, but with normal cellular structure and arrangement.

Uterine prolapse descent or herniation of the uterus into or beyond the vagina because of weakness of the pelvic musculature, ligaments, and fascia or obstetric trauma and lacerations sustained during labor and delivery.

Vacuolar myelopathy HIV-induced loss of myelin and spongy degeneration of the spinal cord that may cause spastic paraparesis, sensory ataxia in lower limbs, and unsteady gait.

Vaginismus a form of sexual dysfunction that is caused by a psychologic disorder or vaginal inflammation in which the muscles at the entrance to vagina contract and prevent sexual intercourse.

Vaginitis infection of the vagina usually caused by a fungus that may cause itching or burning and a discharge.

Vaginosis vaginal irritation without white blood cells or other indication of infection.

Varicocele a painful condition in which the veins in the scrotum that develop in the spermatic cord enlarge, and if the valves that regulate blood flow from these veins become dysfunctional, blood does not leave the testis, thereby causing swelling in the veins above and behind the testis.

Varicose bronchiectasis the bronchi become large and balloon-like.

Venous angioma abnormal veins, usually near the ventricular wall, that form as a congenital anomaly.

Venous stasis ulcer a condition affecting the lower leg in which leaky valves, obstructions, or regurgitation in veins impairs blood flow back to the heart, resulting in pooling of blood in the lower leg and subsequent tissue damage.

Ventricular septal defect (VSD) a congenital malformation in which the wall between the left and right ventricles has a hole that allows blood to travel between the left and right ventricles, potentially leading to congestive heart failure.

Vesicoureteral reflux (VUR) reflux of urine from the bladder into the ureter.

Vestibular nystagmus involuntary rapid movement of the eyeball that is due to disturbance of the vestibular system; eye movements are rhythmic, with slow and fast components.

Vitiligo an autoimmune-related loss of melanocytes resulting in the depigmentation of patches of skin.

von Willebrand disease an inherited disease in which the von Willebrand factor proteins that are made in the blood vessel walls and function to control platelet activity are abnormal or absent, resulting in a tendency to hemorrhage.

Waldenström macroglobulinemia see Lymphoma.

Wallerian degeneration the degeneration of a nerve fiber that has been separated from its nutritive center by injury or disease; characterized by segmentation of the myelin and resulting in atrophy and destruction of the axon.

Warm autoimmune hemolytic anemia see Anemia.

Wilms tumor see Nephroblastoma.

Wilson disease a genetic disease in which the ability to metabolize copper is impaired, resulting in an accumulation of copper deposits in organs such as the brain, liver, and kidneys and subsequent organ dysfunction and failure.

Wiskott-Aldrich syndrome (WAS) see Immune deficiency.

Xanthelasma a planar xanthoma involving the eyelid(s).

X-linked hyper-IgM syndrome see Immune deficiency.

X-linked SCID see Immune deficiency.

Zollinger-Ellison syndrome the association of atypical, intractable, sometimes fulminating peptic ulcers with extreme gastric hyperacidity and benign or malignant gastrinomas in the pancreas.

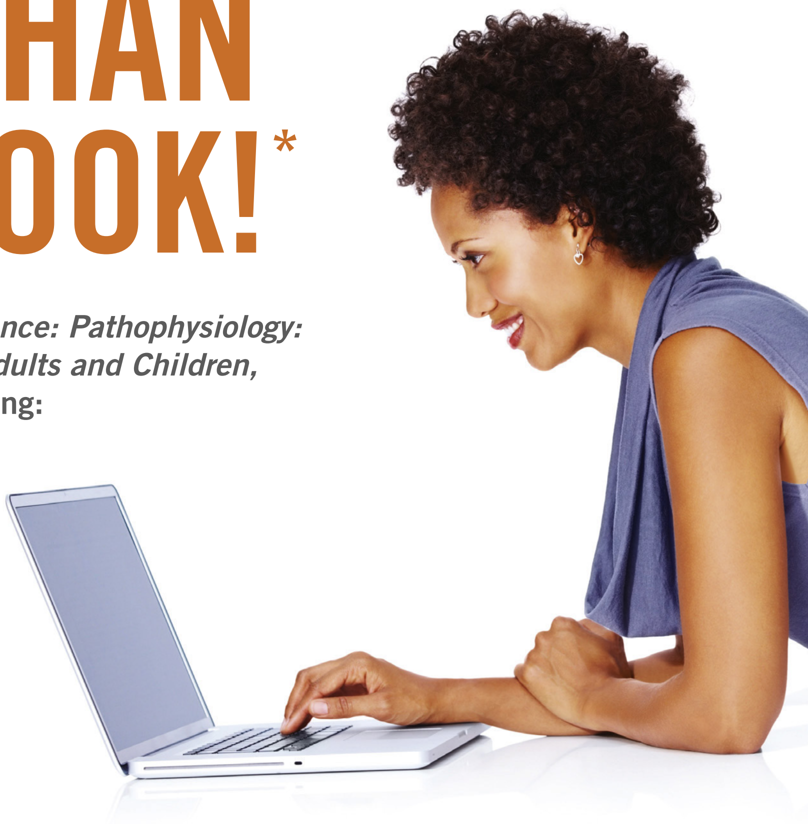
BRIEF CONTENTS

WHAT'S NEW?



COMMON LABORATORY VALUES*

CONSTITUENT	NORMAL MEAN VALUE AND SOME RANGES	NORMAL RANGE IN SI UNITS
Electrolytes	Total, 1% of plasma weight	
Na^+	135-145 mEq/L	135-145 mmol/L
K^+	3.5-5.0 mEq/L	3.5-5.0 mmol/L
Ca^{++} (serum)	8.4-10.6 mg/dl	2.10-2.65 mmol/L
Mg^{++}	1.3-2.1 mg/dl	0.65-1.05 mmol/L
Cl^-	96-106 mEq/L	96-106 mmol/L
HCO_3^- (venous)	23-29 mEq/L	23-29 mmol/L
Phosphate (mostly HPO_4^-)	3.0-4.5 mg/L	1.0-1.5 mmol/L
SO_4^-	1 mEq/L	0.25-0.75 mmol/L
Proteins	6-8 g/dl	60-80 g/L
Albumin	3.3-5.5 g/dl	33-55 g/L
Gamma globulin	0.7-1.7 g/dl	7-17 g/L
Globulins	2-4 g/dl	20-40 g/L
Fibrinogen	200-400 mg/dl	2-4 g/L
Troponin I	0.05-0.50 ng/ml	0.05-0.50 ng/ml
Blood Gases		
pH (arterial)	7.35-7.45	7.35-7.45
CO_2 content (arterial)	35-45 mm Hg	35-45 mm Hg
O_2 content (arterial)	80-100 mm Hg	80-100 mm Hg
Bicarbonate (arterial)	21-27 mEq/L	21-27 mmol/L
Nutrients		
Glucose (fasting)	75-110 mg/dl	3.85-6.05 nmol/L
Total proteins	6-8 g/dl	—
Total lipids	400-800 mg/dl	4.0-8.0 g/L
Cholesterol (total)	<200 mg/dl	<5.20 mmol/L
Triglycerides (after 12 hr fast)	<150 mg/dl	0.45-1.81 mmol/L (males) 0.40-1.52 mmol/L (females)
Phospholipids	150-380 mg/dl	1.50-3.80 mol/L
Free fatty acids	9.0-15.0 mM/L	9.0-15.0 mM/L
Waste Products		
Urea (BUN)	24-49 mg/dl	4.0-8.2 nmol/L
Uric acid (serum)	2.2-8.0 mg/dl	130-476 μmol/L
Creatinine	0.6-1.2 mg/dl	53-106 μmol/L
Creatinine clearance	107-139 ml/min	1.78-2.32 mmol/L
Bilirubin (conjugated)	0.1-0.4 mg/dl	1.7-6.8 μmol/L
Bilirubin (total)	0.3-1.1 mg/dl	5.1-19.0 μmol/L
Individual Hormones		
Prolactin	<20 ng/ml	<20 μg/L
Thyroid tests		
Thyroxine (T_4)	4-11 μg/mL	58-154 nmol/L
T_4 expressed as iodine	3.2-7.2 ng/dl	253-569 nmol/L
T_3	75-220 ng/dl	975 nmol/L
Free thyroxine (T_4)	0.9-2.1 ng/dl	12-27 pmol/L
T_3 resin uptake	25%-38%	0.25-0.38
TSH	0.4-4.8 μIU/mL	0.4-4.8 μIU/L
Hematology Values		
Erythrocyte (red blood cell count)	4.2-6.2 million/mm^3	$4.2–6.2 \times 10^{12}$/L
Leukocyte (white blood cell count)	4500-11,000/mm^3	$4.5\text{-}11.2 \times 10^9$/L
Lymphocyte	25%-33% of leukocyte differential	$1500–3000 \times 10^6$/L

COMMON LABORATORY VALUES—cont'd		
CONSTITUENT	NORMAL MEAN VALUE AND SOME RANGES	NORMAL RANGE IN SI UNITS
Monocyte and macrophage	3%-7% of leukocyte differential	$300–500 \times 10^6$/L
Eosinophil	1%-3% of leukocyte differential	$50–250 \times 10^6$/L
Neutrophil (segmented)	54%-62% of leukocyte differential	$3000–5800 \times 10^6$/L
Basophil	0-1% of leukocyte differential	$15–50 \times 10^6$/L
Platelet	150,000-400,000/mm^3	$150–400 \times 10^9$/L
Hematocrit	37%-54%	0.40–0.54 g/L
Hemoglobin	12-18.0 g/dl	7.4–11.2 mmol/L
Mean corpuscular volume	80–96 mcm^3	80–96 fL
Hemoglobin A_{1c}	3–5% of total	0.03–0.05 of total
Serum Enzymes		
Lactic dehydrogenase	110-220 units/L	110-220 units/L
Isoenzymes:		
LDH-1 (heart)	17% to 27%	
LDH-2 (reticuloendothelial system)	27% to 37%	
LDH-3 (lungs)	18% to 25%	
LDH-4 (kidney, placenta, pancreas)	3% to 8%	
LDH-5 (liver, striated muscle)	0% to 5%	
Phosphatase P acid (units/LI)	Cherry-Crandall	0.1-0.6 units/L
	King-Armstrong	0.1-0.6 units/L
	Bodansky	0.1-0.6 units/L
Alkaline Phosphatase (units/L)	King-Armstrong	35-150 units/L
	Bodansky	35-150 units/L
	Bessey-Lowry-Brock	35-150 units/L
Aspartate aminotransferase (AST; previously serum glutamate oxaloacetate transaminase [SGOT])		
Female	6-34 units/L	6-34 units/L
Male	8-40 units/L	8-40 units/L
Alanine aminotransferase (AST; previously serum glutamate oxaloacetate transaminase [SGOT])		
Female	9-32 units/L	9-32 units/L
Male	10-40 units/L	10-40 units/L
Creatine kinase		
Female	30-135 units/L	30-135 units/L
Male	55-170 units/L	55-170 units/L
Amylase	25-125 units/L	25-125 units/L
Lipase	10-140 units/L	10-140 units/L
Other		
Bile acids	0.3-3.0 mg/dl	0.8-7.6 mmol/L
Bilirubin, direct (conjugated)	0.1- 0.4 mg/dl	1.7-6.8 μmol/L
Bilirubin, indirect (unconjugated)	0.1-1.0 mg/dl	1.7-17.1 μmol/L
Creatine (s)	0.2-0.9mg/dl	15-70 μmol/L
Creatinine	0.6-1.2 mg/dl	50-110 μmol/L
Iron, total (s)	60-150 μg/dl	11-27 μmol/L
Iron-binding capacity (s)	300-360 μg/dl	54-64 μmol/L
Phosphorus, inorganic (s)	3.0-4.5 mg/dl	0.97-1.45 mmol/L
Prothrombin time	10-13 seconds	
Partial thromboplastin time	22-37 seconds	
Erythrocyte sedimentation rate (ESR or sed rate)		
Westergren method		
Men under 50 years	<15 mm/hr	
Men over 50 years	<20 mm/hr	
Women under 50 years	<20 mm/hr	
Men under 50 years	<30 mm/hr	

*Note: Reference ranges may vary because of differences in laboratory methods and modes of instrument standardization. Above reference values are from *Dorland's illustrated medical dictionary,* ed 32, Philadelphia, Saunders, 2012; *SI;* International System of Units.
